Explanatory Note

Illustrated articles are marked with an asterisk (*), book notices by a dagger (†), inquiries by a double dagger (‡). The cross-references condense the material and assist the reader, but are not to be regarded as complete or conclusive. So, if there were a reference from "Boiler" to "Blowoff," and if the searcher failed to find the required article under the latter word, he should look through the "Boiler" entries, or others that the topic might suggest, as he would have done had there been no cross-reference. A reference from "Oil" to "Lubricating" would apply equally to "Lubrication," "Lubricator," etc. Letters are indexed under title or subject, general articles under writer's name as well. Not all articles relating to a given topic necessarily appear under the same entries.

Following is a list of the pages included in the several numbers of the volume, by date:

Western Newspaper Union Plant in Chicago

By Thomas Wilson

SYNOPSIS—Moving an isolated plant having 525 hp. in boilers and 400-kw. generating capacity while maintaining the service. The operating cost is less than central-station service. An analysis of the plant.

In the summer of 1910 the Western Newspaper Union, which does a general printing and manufacturing business on a large scale, moved into a new building at the corner of Adams and Clinton St., Chicago. In plan, the building measured approximately 125x125 ft. and was eight stories high above the street level. Practically the entire floor space was occupied by the company, and as power was required night and day for the presses, steam for manufacturing and heating, and current for lighting, a private plant was installed.

For three years the plant gave a good account of itself, but late in 1913 the building site was purchased to form part of a tract on which to erect the new Pennsylvania station. As the building was to be torn down the mechanical equipment was moved to a building at Desplaines and Adam St. The latter is five stories high, but as it measures 150x165 ft., the floor space and cubic contents are nearly the same as for the building first occupied.

Past Records Favor Isolated Plant

As is common at such times, strenuous efforts were made by the central station to get its service into the new building. With the printing company it was a question of

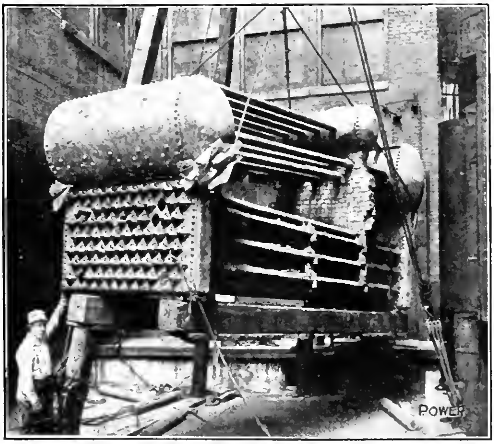

Fig. 1. Moving One of the Water-Tube Boilers

disposing of the generating equipment and accepting the rates offered or moving the plant and continuing to generate its current: this question was thoroughly discussed. Records for three years were available from which to determine the average loads and the cost of operation. Using the rate quoted by the central station, it was an easy matter to obtain an accurate comparison. The figures are not available, but as the station equipment is now being moved, of course, the results favored the isolated plant. Factors influencing the decision were twenty-four-hour service seven days in the week, the use of all exhaust steam for heating except during peak loads and in the summer months, and a demand for steam at 60 lb. pressure in the manufacturing processes. It was seldom

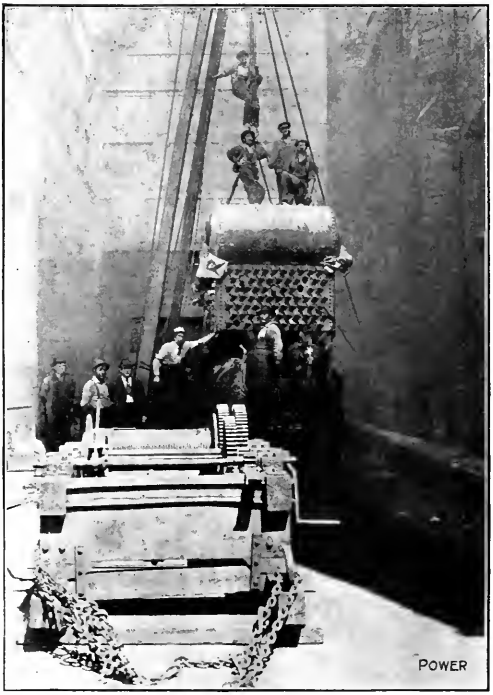

Fig. 2. Hoisting a Boiler onto a Wagon

that live steam was needed to supplement the exhaust, but on the coldest mornings of winter it was used to a limited extent to help heat up the building.

Briefly, the plant equipment consists of three 175-hp. water-tube boilers with extension furnaces and coal-handling equipment, the usual pumps, and in the engine room three direct-current generating units, one rated at 200 kw., a second at 125 kw. and the third at 75 kw. There are four tandem-gear electric elevators, two for passenger service, with a carrying capacity of 2500 lb. at a speed of 250 ft. per min., and two 5000-lb. freight elevators designed for a speed of 150 ft. per min. For freight there is also a 2000-lb. sidewalk lift. A two-pipe vacuum heating system with 16,000 sq.ft. of radiation was put in the building.

Moving the Plant

The above was the power-plant machinery which had to be moved, and to accomplish it without interrupting the service it was necessary to work on Saturday nights and Sundays, when the load was lighter than usual. The equipment was moved a unit at a time and put into operation in the new building. At the present writing more than half of the printing and power-plant machinery has been transferred and is in operation. Two boilers, the largest and smallest generating units and the switchboard have also been moved. It is intended to complete the work very shortly. A temporary switchboard, one boiler and the 125-kw. unit keep the old plant in operation. As a safeguard, breakdown emergency service has been installed. Due to careful planning and working to schedule, the plant has not lost any time to the company.

For moving, the smaller apparatus and generating units were dismantled and then conveyed by wagon to the new site. Wagons also transported the boilers, but as each weighed 34,000 lb., the task was more difficult. After a boiler had been disconnected, the settings knocked down and the furnace removed, it was placed on blocks and skidded under an opening in the driving court provided for the passage of machinery. By means of a derrick over the opening having the usual block and tackle and operated by a winch, the boiler was hoisted onto the wagon, and in much the same way, only with the operations reversed, it was lowered into the new plant. Figs. 1 to 3 will tell the story.

Boiler Room of the New Plant

Fig. 4 shows the layout of the new plant, which differs somewhat from the old, although the installation contains the same machinery. In the Dec. 20, 1910, issue of Power the older plant was described, but as the arrangement differs and additional data are available, a short analysis of the design may be of interest.

In the present plant two of the boilers will be arranged in a battery and the other set singly. Each has 1740 sq.ft. of heating surface and is equipped with a stoker having 33 sq.ft. of grate surface. The ratio is 53 to 1. The operating pressure is 150 lb. gage, although the boilers were designed for 180 lb. At the boiler farthest from the stack, the breeching is 3 ft. wide by 6 ft. high and is widened to 5 ft. at the second boiler, giving an area of 30 sq.ft. The brick stack is 5 ft. in diameter and is 150 ft. above the grate line. Its sectional area is 19.635 sq.ft. To the connected grate surface this area bears a ratio of 1 to 5, a good average figure for Western coal, and for every horsepower of boiler rating there is 0.037 sq.ft., or 5.3 sq.in. of stack area. The breeching dimensions are liberal, as the ratio of breeching area to connected grate is 3 to 10 and of breeching to stack area 3 to 2.

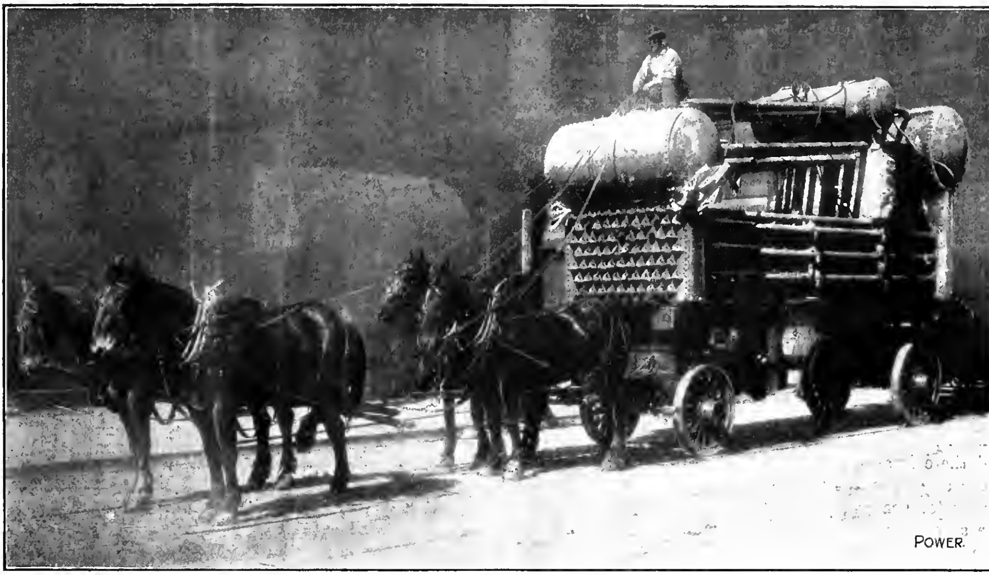

Fig. 3. On the Way to the New Plant

As in the old plant, a damper regulator will be arranged to control the dampers and at the same time the speed of the stoker engines, so that the supply of coal to the grates will be regulated according to the load conditions. When first set up the boilers developed an efficiency of 70 per cent. with coal averaging 11,150 B.t.u.

It is the intention to have complete coal-handling apparatus. Coal is dumped into a bunker, 20x75 and 20 ft. high, under the driving court. It will be carried by wheelbarrow to the boot of an elevator leg delivering to a one-ton traveling and weighing hopper over the furnaces. At present the coal is wheeled from the bunker to the furnaces. A revolving soot blower facilitates cleaning and the ashes will be removed by a bucket elevator rising to the street level and spouting to wagons.

The source of water-supply is the city mains. In winter the returns from the heating system with sufficient make-up is passed to a closed heater having a capacity of 16,000 lb. of water per hour. It is handled by either one of two 7x4½x10-in. duplex pumps, when exhaust steam is needed for heating, and by a 4x6-in. triplex motor-driven pump in the summer months; the latter is naturally more economical of steam. The three pumps are to be so interconnected that any one of them can be used for boiler feed or house purposes. Connection from the pumps will be made to a manifold at the side of one of the boilers, from which point the feed will be controlled. There will also be a city water connection so that the boilers may be filled conveniently after being washed out.

Engine Room

Here the three generating units are arranged as shown in the plan view. The large 200-kw. machine is an angle compound, 17 and 28 by 14 in., running at 260 r.p.m. The other two units, 125 and 75 kw., are driven by simple horizontal engines with cylinders 16x16 in. and 14x12 in. in the order of their size. The speeds are 240 and 275 r.p.m., respectively. Direct current at 230 volts is generated, and duplicate compensating sets, each of 15-kw capacity, will supply lighting current at 115 volts. Besides the elevator motors there is a connected motor load of 450 hp. made up of 175 motors ranging in size from $\frac{1}{8}$ to 40 hp. In the old plant—the load conditions will be practically the same in the new building—the compound unit carried the load during the day, with some help from the 75-kw. machine during the peaks. The latter carried the load at night and the 120-kw. unit was held as a reserve.

Piping

The arrangement of the piping is shown in Fig. 4. From each boiler 6-in. pipes lead into the top of an 8- and 10-in. header which delivers to a secondary 10-in. header in the engine room supplying the three units through 7-, 6- and 5-in. pipes in the order of their size. A 3-in. pipe to the auxiliaries taps the boiler-room header and there is also a couple of connections to supply live steam at reduced pressure to the heating system and the feed-water heater. The exhaust pipes from the engines rise at each unit and eventually join overhead in a 12-in. pipe leading to the heater, the heating system and to the atmospheric exhaust. The location of the valves and the subdivision of the piping will be apparent in the plan view.

It may be of interest to determine the sectional area of the steam pipes per unit of boiler and engine rating and the velocities in the engine supply and exhaust piping. A 6-in. pipe from each boiler allows 0.165 sq.in. per boiler-horsepower. If the boiler were delivering steam at its full rating

$$175 \times 30 = 5250 \textit{ lb. per hr.}$$

or 87.5 per min., would be delivered. At 150-lb. gage pressure this weight of steam would occupy

$$2.758 \times 87.5 = 241.33 \textit{ cu.ft.}$$

and the velocity in feet per minute through the pipe would be

$$241.33 \div 0.2006 = 1203$$

For the engines the following sectional areas of piping for the supply and exhaust have been allowed per kilowatt of rating: 200-kw. unit, supply 0.1937 sq.in., exhaust 0.3943 sq.in.; 125-kw. unit, supply 0.2311 sq.in., exhaust 0.3099 sq.in.; 75-kw. unit, supply 0.2667 sq.in., exhaust 0.3852 sq.in.

To arrive at the approximate velocity of the steam in the piping, assume an average operating rate of 40 lb. per kilowatt-hour for the compound engine and 50 lb. for the two smaller machines. At full load the compound engine would use 8000 lb. of steam per hour, or 133 lb. per min.; the 125-kw. machine 6250 lb. per hr., or 104.2 lb. per min., and the smallest unit 3750 lb. per hr., or 62.5 lb. per min. At 150 lb. gage the volumes of steam passing per minute in the same order would amount to 368, 287 and 172 cu.ft. The velocity of the steam supply in each would then be 1366, 1431 and 1241 ft. per min.,

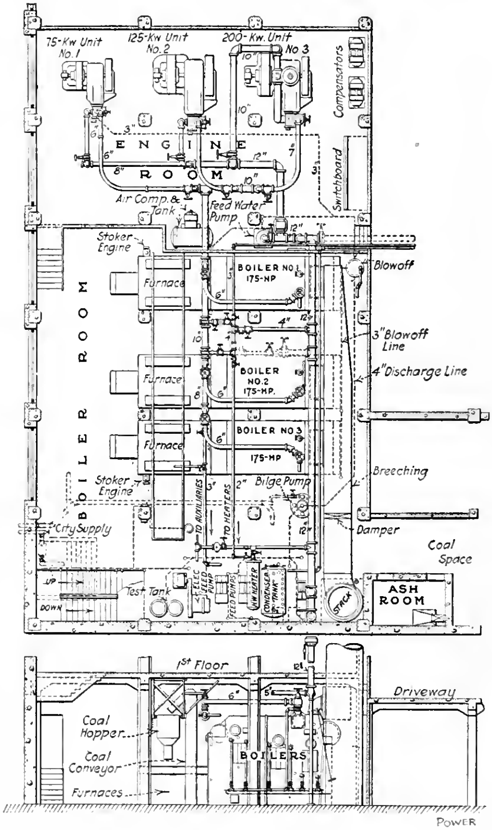

Fig. 4. Plan of Piping and General Layout of the New Plant

assuming, as is usual, that the flow is continuous throughout the stroke. These velocities average 1346 ft. per min. as compared with 6000 ft., the average for current practice. It is evident that the sizes of the supply pipes are liberal, but at the time the plant was installed it was the practice to use large piping and relatively low steam velocities. It must be remembered that with a small receiver the steam flow would be intermittent and the velocity during admission would be practically four times as great as previously indicated. Sudden and heavy overloads and the size of the openings into the cylinder also influence the size of the piping.

With the exhaust at atmospheric pressure, which would be the case in the summer months,

$$133 \times 26.79 \times 0.87 = 3100 \textit{ cu.ft.}$$

of steam per minute would be discharged from the 200-kw. unit. The 26.79 is the cubic feet in a pound of steam at atmospheric pressure and the 0.87 the quality of the steam after expanding adiabatically from 150 lb. gage to atmospheric pressure. As the area of the 10-in. pipe in square feet is 0.5476, the velocity of the steam would be

$$3100 \div 0.5476 = 5661 \textit{ ft. per min.}$$

Figuring in the same way, the 125-kw. unit would discharge 2428 cu.ft. of steam at a velocity of 9026 ft. per min. and the 75-kw. unit 1456 cu.ft. at a velocity of 7261 ft. per min. The average of the three exhaust steam velocities is 7361 ft. per min. This is a little above the usual velocity allowed in the exhaust piping of an engine, but a slight increase in back pressure or running below rating would reduce the volume and consequently the velocity of the steam.

Velocities in steam-engine piping are largely a matter of individual opinion. Since the advent of the steam turbine the tendency has been upward. In these days a velocity of 8000 ft. for the supply is not considered excessive. The exhaust velocity is usually limited to 4000 ft. to prevent friction in the piping and to hold down the back pressure.

Besides the equipment just enumerated there is an air compressor driven by a 20-hp. motor. The machine supplies 100 cu.ft. of air per min. at 100 lb. pressure for operating a pneumatic system, certain machinery in the printing and manufacturing plants and for cleaning the various machines.

PRINCIPAL EQUIPMENT OF WESTERN NEWSPAPER UNION PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
3	Boilers	Water-tube	175 hp.	Generating steam	Mechanically fired, natural draft, 150-lb. gage	Atlas Water Tube Boiler Co
3	Stokers	Top feed	5½x6 ft.	Boiler furnace	Mechanically operated	Model Stoker Co.
1	Coal elevator	Bucket	15 tons per hr.	Lift coal above furnaces	Motor driven	Jeffrey Mfg. Co.
1	Coal hopper	Traveling and weighing	1 ton	Weigh coal and feed to furnaces		Jeffrey Mfg. Co.
1	Ash elevator	Bucket	10x6-in. buckets	Hoist ashes to street level	Motor driven	Chain Belt Co.
2	Pumps	Duplex	7x4½x10-in.	Boiler feed	150 lb. steam	Piatt Iron Works
1	Pump	Triplex power	4x6-in.	Boiler feed or house service	Driven by 7½-hp motor	Deane Steam Pump Co
1	Heater	Open	16,000 lb. per hr.	Heat boiler feed	Exhaust steam, water 208 deg.	The Griscom Russell Co.
1	Engine	Angle compound	17x28x14-in.	Main unit	150 lb. steam, 260 r p.m.	American Engine & Electric Co.
1	Generator	Direct-current	200 kw.	Main unit	230 volts, 260 r p.m.	American Engine & Electric Co.
1	Engine	Simple horizontal	16x16-in.	Main unit	150 lb. steam, 240 r p m.	American Engine & Electric Co.
1	Generator	Direct-current	125-kw.	Main unit	230 volts, 240 r p.m	American Engine & Electric Co.
1	Engine	Simple horizontal	14x12-in.	Main unit	150 lb. steam, 275 r p.m	American Engine & Electric Co.
1	Generator	Direct-current	75 kw.	Main unit	230 volts, 275 r p.m	American Engine & Electric Co.
2	Elevators	Tandem gear	2500 lb.	Passenger service	250 ft. per min., 40-hp. motor	Western Electric Co
2	Elevators	Tandem gear	5000 lb.	Freight	150 ft. per min., 40-hp. motor	Western Electric Co.
1	Heating system	Two-pipe vacuum	16,000 sq.ft. rad.	Heat building	Exhaust steam	Warren Webster & Co
1	Soot blower	Revolving type		Blow soot off boiler tubes		Vulcan Soot Cleaner Co.
1	Air compressor	Single stage horizontal	6x9¼x10-in.	Compressed air for general use	100 cu.ft. per min. at 100 lb. pressure	National Brake & Electric Co.
1	Motor	Direct-current	20 hp.	Drive air compressor	220 volts, 860 r p.m.	National Brake & Electric Co.

Water for drinking is doubly filtered and cooled. It passes through sand and paper-disk filters in series and is cooled in galvanized-pipe coils laid in an ice box. Bubbling fountains are distributed throughout the building.

For the new layout of the plant as well as the old, and for the moving, Charles G. Atkins, consulting engineer, is responsible.

Will Quizz, Jr.

SYNOPSIS—How Will got his first ideas of engineering, and later learns that faithful plodding does not necessarily bring large success. His conference with Chief Teller on this occasion was not of a technical character, but perhaps it was as vital as any.

"You know, Chief, a boy always has an ideal, and my ideal was to become an engineer like Heintz, the late chief engineer at the gas works.

"When I was a youngster I used to peer longingly through the engine-room window. Heintz would sometimes allow me in the engine room where I would sit in rapture watching the moving machinery—and Heintz. He was a veteran engineer, and my ambition was to be able to wield the long-spouted oil can like he did. You know my pet saying, 'Heintz would do it this way'—but did he do the best way? .

"Since Heintz's enforced retirement, practically on charity, some of the dreams of my childhood have been shattered and I have serious doubts about it. Many good things are said about Heintz, but to me they have brought a flood of doubt. Do I want to follow in his footsteps? Heintz was a fine old character, and his whole career had been in the same engine room. His friends always had seen him in one of three places—at home, in the engine room, or on the path between the two. He worked every Sunday and every holiday; he never had a vacation—never received an increase of pay.

"I notice that his two sons are not following engineering. I am very much bothered as to whether I am on the right track for my life's work. What do you think, Chief?"

"I am glad, Will, that you have so much confidence in me, but it puts a grave responsibility on me too. Everyone has periods of doubt, and evidently you do not want to become an engineer of the Heintz class. It is unfortunate that so little encouragement is offered by some corporations and that there are men so situated or constituted that they will never rise above the lowest grade jobs in any line.

"It is entirely possible, however, for engineers to work reasonable hours, and for them to improve mentally, financially and socially. To avoid becoming disappointed after it is too late to make a change, exert yourself to acquire an engineering education. You will find that the greatest pleasure comes from improving your mind. Cut out those things which will surely leave you stranded and disappointed. You can fire boilers and run an engine and know next to nothing. You can't get on very far in that way. The only hope for a young man to escape the mediocre life is to educate and advance himself day by day.

"There are two elements of greater importance than the trade or occupation—one is the boy (or man) and the other the opportunity or set of conditions surrounding him. When it comes to averaging the load factor of the whole lot of us it's going to be surprising to see how near the maximum some unassuming fellows have been operating with the equipment they had, and under handicaps or unavoidable circumstances of which others may have known nothing.

"I feel sure that you have the right stuff in you, son, to become an engineer worth while, but remember that there can be no excellence without great labor. You have my best wishes and are welcome to any help I can give."

⁂ ⁂

Test of 200-Hp. Gas-Producer Plant

By F. V. Larkin*

SYNOPSIS—Figures showing what may be expected of an anthracite suction producer of this size supplying a four-cylinder, four-stroke-cycle engine under full-load conditions.

During the autumn of 1913 the department of experimental engineering at Lehigh University was called upon to make an acceptance test of a suction producer supplying a 200-hp. gas engine, the object being to ascertain whether the manufacturer's guarantee of capacity, speed regulation and economy was being fulfilled.

TABLE 1. RESULTS OF GAS PRODUCER TEST

Duration of test	24 hr
Kind of coal used	Anthracite pea
Height of the producer	9 ft.
Inside diameter	5 ft., 8 in.
Area of grate	25.2 sq ft.
Air space in grate	29 per cent.
Area of water heating surface in vaporizer	.70 sq.ft.
Rated capacity of producer in lb. of coal per hr	250 lb.
Average Pressures and Temperatures	
Steam pressure in vaporizer	14 lb
Gas pressure in main where measured, in. of water	0 985
Draft in ashpit, in. of water	0 102
	Deg. F
Temperature of water entering vaporizer	166
Temperature of gas in main near producer	584
Temperature of gas where measured	59 7
Temperature of air in producer room	67 7
Temperature of water entering scrubber	53
Temperature of water leaving scrubber	112 9
Weight of dry gas per cu.ft. reduced to 62 deg. and 30 in	0 066 lb.
Hourly Quantities	
Dry coal consumed per hour	206 8 lb
Dry coal consumed per hour per sq.ft. of grate	8 2 lb.
Gas delivered per hour	14,628 cu ft.
Gas per hour at 62 deg. and 30 in	15,520 cu ft.
Weight of dry gas per hour	1,032 lb.
Steam supplied to producer per hour	543 lb.
Water fed to scrubber per hour	2,164 lb
Ultimate Analysis of Dry Coal	Per Cent
Carbon (C)	79 21
Hydrogen (H)	2 01
Oxygen (O)	0 00
Nitrogen (N)	0 80
Sulphur (S)	1 32
Ash	17 37
Moisture in sample of coal as received	2 74
Analysis of Ash and Refuse	Per Cent.
Carbon	39 99
Earthy matter	60 01
Analysis of Gas by Volume	Per Cent.

Heat converted into work	2545	25 4
Heat rejected in cooling water	2700	26 9
Heat rejected in exhaust gases	2582	25 8
Heat lost due to moisture formed by the burning of hydrogen	228	2 2
Heat lost by incomplete combustion	205	2 0
Heat unaccounted for, including radiation	1774	17.7
Total heat consumed per i.hp -hr	10,034	100.0

The plant was put in readiness for the test by the manufacturer's representative, who installed the test flywheels and prony brakes and operated the plant during the test. The university furnished and installed the remainder of the test apparatus, including meters, pitot tubes, gas-analyzing apparatus for fuel and exhaust gases, and the gas calorimeter.

An unusual feature was the means provided to secure continuous determinations of the calorific value of the gas. Continuous samples were drawn from the main by a water aspirator which delivered water and gas to a small tank where the desired pressure was maintained by regulating the water-outlet valve. The calorimeter was of the simple Junker type, with Centigrade thermometers, the wet meter reading to thousandths of a cubic foot, and the water-measuring receptacles graduated in cubic centimeters.

Four preliminary runs of approximately ten hours each at no load, one-fourth, one-half and three-fourths load, respectively, were made to insure satisfactory operation of the plant and test apparatus and to bring the producer up to the condition of every-day operation. Following these runs the final test was made at full rated load and without stops for a period of twenty-four hours. Observations were taken at fifteen-minute intervals during all the tests.

Remarks

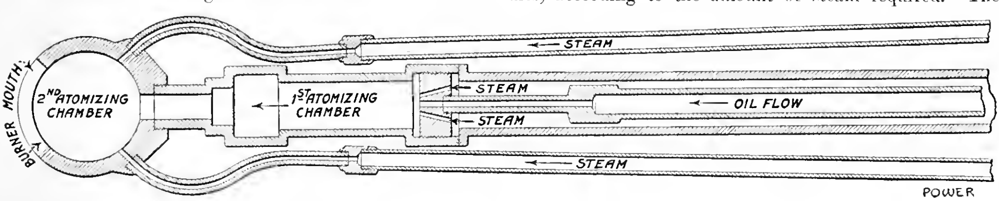
The gas volumes were calculated from the analyses of the coal and gases, because the four pitot tubes installed were so greatly affected by the engine pulsations that their indications were wholly unreliable.

The high mechanical efficiency is probably due, in part at least, to the fact that two of the four indicators used were steam-engine indicators.

It would seem that the manufacturer might arrange to utilize part of the heat lost in the exhaust gases by taking the air necessary for combustion from a preheater surrounding the exhaust gases. In this particular case the owner of the plant can doubtless utilize a sufficient amount of this heat to furnish the hot water necessary for shower baths and other purposes.

Champion Oil Burner

This oil burner is designed to atomize the fuel oil twice during its passage through the burner and also to control the size and shape of the flame. The illustration is a sectional view of the burner.



Section through Champion Oil Burner

As shown, there are two atomizing chambers. The steam comes into the first from above and below the oil-supply pipe, and the mixture then passes to the burner head. Just before it leaves this head it comes in contact with the two jets of live steam from the two side pipes which enter the burner head in the second atomizing chamber, where the mixture is again atomized as it goes to the mouth of the burner.

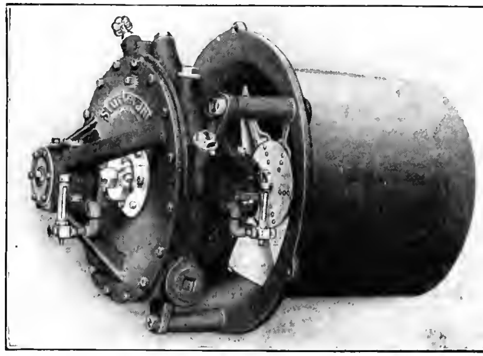
In addition to atomizing the oil the second time, the steam from the two side pipes gives the operator control of the blaze. By closing the valves on these two pipes the blaze will shoot straight back into the furnace, but by opening them the shape of the blaze is controlled. The burner works in connection with a pump and pressure tank, is made to fit any furnace, and is easily placed.

This burner is manufactured by the Champion Oil Burner Co., Kingman, Kan.

Sturtevant Turbo Undergrate Blower

A new design of undergrate blower for use where more furnace draft is needed is placed in the boiler brickwork.

In this set (see illustration), which is made by the B. F. Sturtevant Co., Hyde Park, Boston, Mass., the turbine is practically identical with the large standard turbines built by the company. The bearings are provided with oil-ring lubrication, and a floating, metallic stuffing-box prevents steam from getting into the bearings and enables a back pressure of 15 lb. to be carried.



Sturtevant Turbo Undergrate Blower

The new machine is controlled by from one to six nozzles, according to the amount of steam required. The fireman can shut off any number of nozzles to regulate the steam consumption at low loads.

Wrought Iron—Taken for the purpose of general calculations, the average weight of one cubic foot of wrought iron is 480 lb. per cu.ft., or 40 lb. per sq.ft. one inch thick.

Steel—The average weight of one cubic foot of steel is taken as 489.6 lb. per cu.ft., or 40.8 lb. per sq.ft. one inch thick.

More Gas than Oil—Pennsylvania's supply of gas will outlast the state's supply of oil, in the opinion of Roswell H. Johnson, professor of oil and gas production in the School of Mines in the University of Pittsburgh. Pennsylvania stands sixth among the states as a consumer of oil and second as a consumer of gas. Since 1903 the oil supply has been declining, Prof. Johnson declared, while the supply of gas has been increasing. If there were greater markets, he says, more gas could be produced, as the state has large reserves of gas lying in the deeper sands.

Governor-Stop Control and Belt Tightener

This device is designed for the purpose of allowing the governor stop to remain in position to prevent the shutting down of the engine in case of an overload and to remove the stop and allow the governor to fall to its lowest

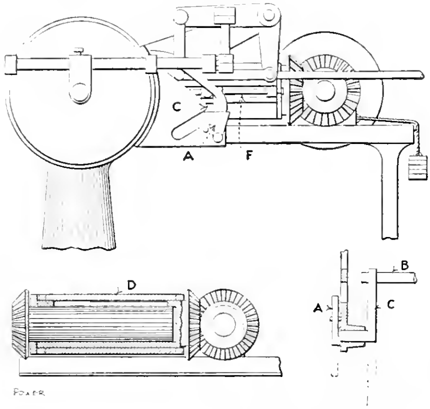


Fig. 1. Details of the Governor-Stop Control

position to stop the engine in case the governor belt breaks or runs off the pulley.

Referring to Fig. 1, *A* represents the governor stop in a position to reverse the governor with the engine stopped. The dotted lines show the governor stop in its lowest po-

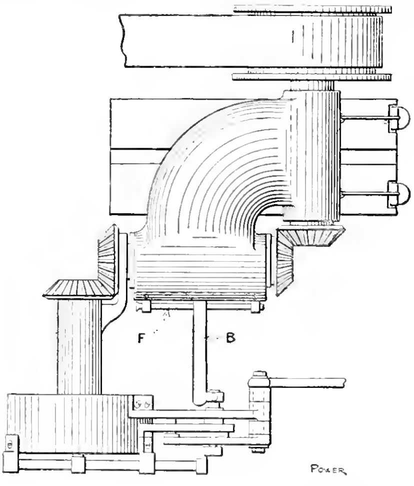

Fig. 2. Plan View of the Stop Control

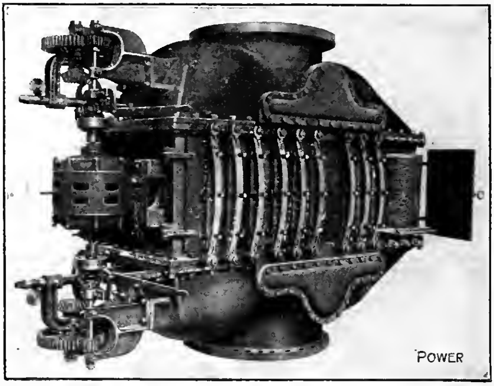
sition. The stop receives motion from the governor-stop controlling rod *B*. When the engine is running and the governor is performing its normal operation, the governor stop will rise in its "up position" with the governor-control pin *B* in contact with the arm *C* of the stop. If the engine should become suddenly overloaded the governor will drop to the governor stop and descend no farther, thus allowing the engine to continue running; in case the governor belt should break or slip off the pulley, the carriage *D* would be shifted on the bed by the weights *E*. This sliding movement of the carriage causes the controlling rod *A* to strike the arm *C* and to move the governor stop out of its elevated position, turning it to the position shown by the dotted lines. Consequently, when the governor drops, it moves to its lowest position and stops the engine. The weights also exert a pull on the governor belt, thus maintaining a proper tension. The stretching of the belt may alter the position of the stop control rod *A*, and this is compensated for by adjusting the screw rod *F* (Fig. 2) which passes through the pin *A*.

Motor-Operated Twin Strainer

Multiple strainers have performed such good service in connection with water-supply lines, condensers, etc., that they are now regarded as desirable in all uptodate installations.

The shifting of the valves on the small twin strainers by hand is simple, whereas on the larger units up to 48



Motor-Operated Twin Strainer

in., the time consumed in changing over from one side to the other is an item and involves considerable manual labor. To overcome these objections, the Elliott Co., Pittsburgh, Penn., has recently adopted a motor drive applicable to all its twin strainers of 20 in. and above.

An electric motor is mounted on one end of the strainer and drives trains of gears communicating with the two valve stems, friction clutches controlling each valve stem independently of the other, and also independently of the motor. Each stem has a device for indicating the position of each valve. The illustration shows one of the baskets partially removed for cleaning purposes.

After the baskets are cleaned and replaced and the doors closed, and it becomes necessary to open up the baskets on the other side of the strainer for cleaning, the motor is started, and at full speed one of the friction clutches is caused to engage the motor shaft, which moves the valve off its seat. This clutch is then released and the other clutch thrown into engagement with the other shaft, which moves the other valve from its seat. Then both friction clutches are thrown into engagement with the motor shaft and the valves are moved together to the opposite side of the strainer.

When the valves are about an inch from their seating position, one clutch is thrown out of service and the full power of the motor is then employed in seating one valve. After it is seated, its clutch is released and the other clutch is thrown into service, which seats the second valve. The motor is then stopped, the doors opened and the baskets cleaned.

When it becomes necessary to shift the valves in the other direction, the rotation of the motor is reversed and the same operation is repeated.

On a 36-in. strainer the time required to start up the motors and shift the valves from one side to the other is 61 seconds, and to take off the doors and remove the baskets, clean and replace them, on this size strainer, requires less than ten minutes. This added to the time for shifting makes the total time needed to clean a 36-in. twin strainer less than eleven minutes, whereas with the hand-operated screws the time would be about three times as long. The time element in changing strainer baskets is important in order to prevent loss of vacuum and of water-supply, especially when the water strained contains large quantities of leaves and other foreign substances during high-water periods.

Equipment and Methods in Largest Refrigeration System--V

By Charles H. Bromley

SYNOPSIS—A novel gage records the height of brine in the tank, an ordinarily difficult practice due to precipitation of the calcium. A gage of the same general design records the height of water in the condensing water crib, and this together with the manometer tube connected in the suction main enables the operator to avoid low water due to plugged screens. Turbo-generators furnish energy for light and power for the plants, warehouses and Clinton Market. An exceptionally well trained crew operates the plant, maintains it, and rebuilds it as it wears out. The record system is most complete. The article concludes with a description of the lubricating system and ammonia condensers.

Novel Recording Brine Gage

The amount of brine in the suction tank is an indication of the tightness of the system, for if there is a serious leak it will not be long before the brine level will drop perceptibly. To register or record, by pressure by ordinary means, the height of brine in the tank is practically impossible if accuracy is desired, because in time the calcium settles out and, due to its weight, gives readings which are too great. To eliminate error due to calcium, a diaphragm chamber is used in connection with the recording gage, the outfit being shown in Fig. 21. As the

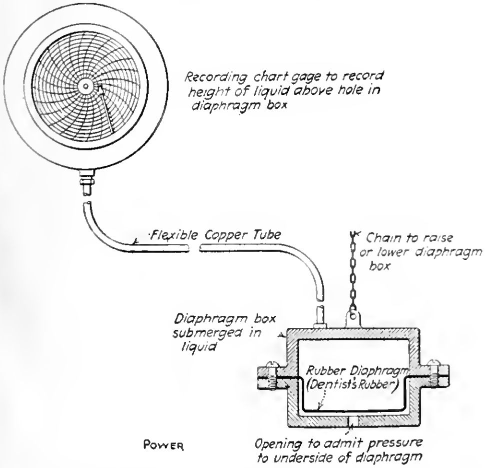

Fig. 21. Section of Type of Gage for Measuring Height of Brine and Condenser Cooling Water

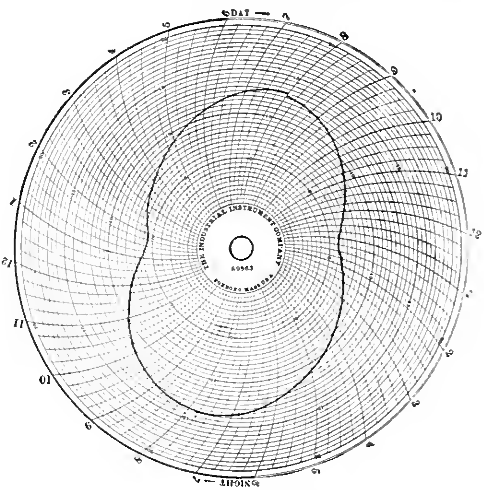

Fig. 22. Chart Showing Rise and Fall of Tide in Crib for Condenser Cooling Water

height of liquid above the hole in the bottom of the diaphragm box increases it pushes up the diaphragm, made of dentist's rubber, thus increasing the air pressure on the recording gage.

Similar Gage Used to Measure Tide

Water for the ammonia and steam condensers is taken from a crib in which the height is governed by the tide. The height in the crib was formerly kept track of by a tide table written on a blackboard in the engine room, but now a record of the tide and the height of water in the crib is recorded by the same kind of outfit as used for measuring the brine. A chart from the tide gage showing the action of the tide on June 18 of this year is shown in Fig. 22. Notice that the maximum high tides for the day differ by a foot and the low tides by 6 in. There are other interesting features if one has the time to study them. Below the gage that records the height of water in the crib is the manometer tube of a venturi meter, Fig. 23. These two gages tell a man all he needs to know about the water condition in the crib and offer him no excuse for losing the water because of dirty screens, as a plugged screen is immediately indicated. A piece of hard black rubber was put in the tube and the instrument calibrated with the rubber floating on the mercury. This makes it easy to quickly get readings.

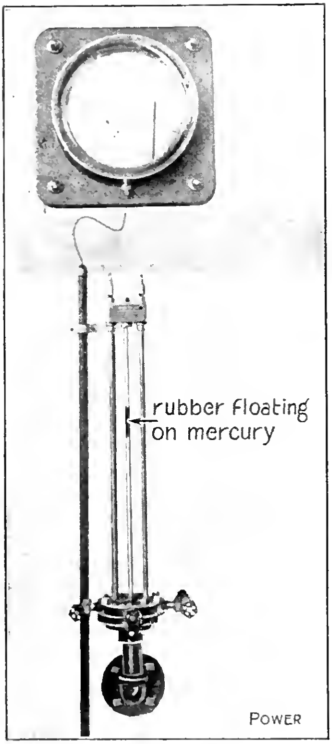

Fig. 23. Manometer Tube of Venturi Meter for Cooling Water Suction Line Placed below Dial Gage That Records Height of Water in Cooling Water Crib

Electric-Generating Equipment

The two main generating sets are turbine driven and are each of 500-kw. capacity, of 450 volts and 3600 r.p.m. Both turbines operate under nearly 29 in. vacuum in winter, 146 lb. pressure and 125 deg. superheat; total temperature, 486 deg. F. Although the superheat at the boilers is 125 deg. F., there is a 15-deg. drop between the superheaters and the turbines. Indicating and recording thermometers are provided in the steam inlet and exhaust pipes.

Two 10-kw. induction motor-driven and one 10-kw. engine-driven, direct-current generators light the station. Light and power as well as refrigeration are furnished to some of the warehouses, and Clinton Market gets its light, power and refrigeration from this station. The switchboard is quite completely fitted, having, besides other instruments, integrating wattmeters, alternating-current load-averaging meters, power-factor meter, graphic voltmeter, syncroscope and a frequency meter. The turbine at the right, Fig. 25, has the distinction of having made a nonstop run for 18 months. The turbines average about 18 lb. steam per kilowatt-hour, and the cost of current is approximately 3/4 cent per kilowatt-hour at the board.

A central surface condensing system is used. Many of the tubes in these condensers have been in service for twelve years and are still in good condition. The tubes are made of a composition consisting of 88 per cent. copper, 10 per cent. tin and 2 per cent. lead, a most unusual composition, for there is seldom more than 1 or 2 per cent. tin and nearly always considerable zinc in condenser tubes, except in some of those brought out recently, namely, aluminum bronze, cupro-nickel and Monel metal. The water in Boston Harbor is quite pure compared to that of the East, Hackensack, Chicago, and other rivers on which there are large condensing plants.

The feed water and the circulating water are measured with venturi meters.

Labor

All labor is departmentized, there being a separate crew for each division of work; the engineers work eight hours and all other employees nine hours a day. The engineers are not allowed to make any mechanical adjustments or repairs except in emergencies: the machinists do all such work. The same is true of all pipe fitting, pipe covering, electrical work, etc.; a separate crew looks after the street system. The company pays for telephones in the homes of all foremen of the crews.

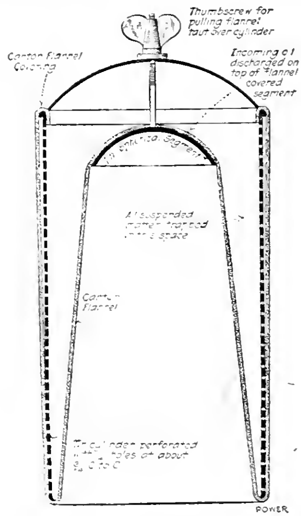

Fig. 24. One of the Perforated Flannel-Covered Cylinders for the Oil Filters

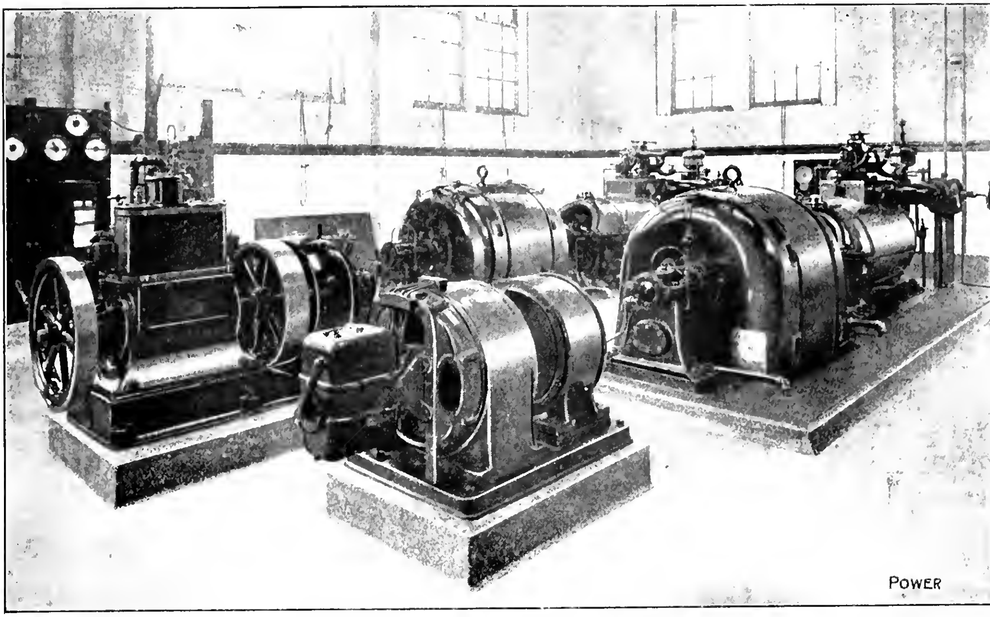

FIG. 25. TURBO-GENERATOR PLANT AT SARGENT'S WHARF
The turbine on the right made a nonstop run of 18 months.

As all except heavy-machine and repair work is done by the different gangs, it enables the company to maintain workmen who in time become trained in team work and thoroughly familiar with the plant. These men do excellent work, too, as is evidenced by even a casual look around the engine room. The lagging, for example, is exceptionally good. Much of the lagging that one finds in plants is made of thin Russian iron, which, after it has been taken off and put on a few times, would exhaust the patience of anyone to get on again. At the Sargent's Wharf plant the iron for the lagging is in heavy sheets and the reinforcing strips used are likewise heavy.

RECORDS

Seven different record forms, including a "summary," are made out daily in the engine room. In addition, there are turned into the chief's office more than a score of charts from recording instruments for various purposes. All record sheets are of uniform size. Reports,

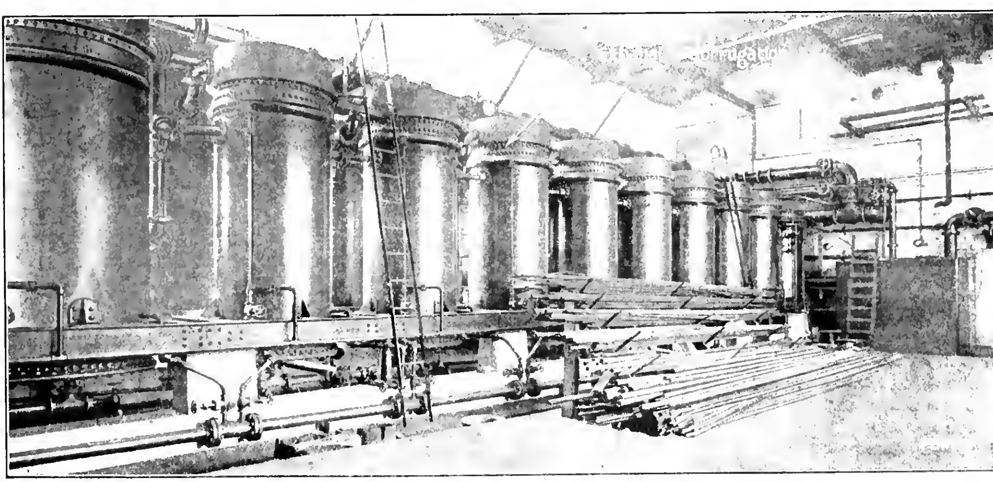

FIG. 26. SHELL-TYPE AMMONIA CONDENSERS
The condensers were built for 300 lb. pressure. Note the expansion corrugation that each has to allow for expansion and contraction

Fig. 27, giving maximum items and costs per units of refrigeration, electricity, water evaporated, etc., are forwarded to the general manager. Report sheets from the engine and boiler rooms are bound in regular book form, size 9½x8 in., shown, and filed in the chief's office; a single volume contains one month's daily reports.

Lubricating Main Bearings

A bearing may be adjusted for running clearance—i.e., clearance enough to allow for smooth running with the brasses and journal at normal temperatures—or it may be given enough clearance so that should it become hot from any cause the expansion of the brasses and journal will not be sufficient to cause the bearing to "freeze" or grip so tightly as to make it unfit for use without much scraping. As pounding frequently accompanies expansion-clearance adjustments, it is the usual practice to adjust for running clearance. No trouble is had so long as the lubricating oil is of proper quality and is supplied in sufficient quantities and no foreign matter gets into the bearing, but sometimes the system oil "wears out" and trouble begins.

MEMORANDA

Station underloaded on account of cool weather.

Signed, F. L. Fairbanks, Chief Engineer

Fig. 27. Some of the Report Forms Used at Sargent's Wharf

All important reports are made on sheets of uniform size and monthly reports are bound as shown by the log book at the top of this illustration.

In many plants where oil is put through filters, returned to the system and used over and over again, serious troubles sometimes arise due to hot bearings. No good reason is evident; the oil is clean and supplied in the usual or even greater quantities, yet nearly all the bearings are hot at the same time. Trouble of this nature frequently happens on a hot summer's day. The reason usually lies in the fact that the system oil has so weakened in viscosity and specific gravity that when an extra warm day comes, with its increase in load, if the plant supplies refrigeration it cannot furnish sufficient lubrication; therefore all bearings with small running clearances and those supporting heavy journals which squeeze out the thin oil overheat.

System Oils Tested Daily

To prevent this trouble in the Quincy Market Co.'s plants the night engineer tests a sample of each system oil each day for the viscosity and specific gravity, the report going to the chief engineer, who will direct that fresh oil be added to increase these properties when the reports show this to be necessary.

Oil Filters

The filters through which the oil finally passes on its way to the engines were made in the plant. Briefly, their construction is this: A tank of oblong section has six canton flannel-covered perforated cylinders set into it, all the cylinders being supported by a sheet-tin partition. Fig. 24 shows how the cylinder is covered with flannel. The oil flows to the cylinder through 5/8-in. brass pipe, a swinging elbow and a nipple instead of a valve being used to stop the oil flow to each of the six cylinders in a filter.

Ammonia Condensers

The present ammonia condensers are of the shell type. Formerly open-coil condensers were used and located in the place now occupied by those of the shell type shown in Fig. 26. To insure a steady flow of water over them, the cooling water was pumped into a large tank at the right of the room and elevated 20 ft. above the condensers, the water gravitating to the latter. When the present condensers were installed this tank was not needed, and as the discharge head was decreased 20 ft., it helped to increase the pump's capacity.

Another advantage following the introduction of the shell-type condenser was that no water was splashed over the floor, on the I-beams, etc. This is more favorable than one may at first believe, but a look at the balcony of the Richmond St. plant, where the structural work was very seriously corroded in only seven years, convinces one that the shell-type condenser is best for the conditions in these two plants.

The condensers are 4 ft. in diameter and contain 367

Note: The big steel forgings for the 1000-ton compressor were made by the Bethlehem Steel Co.; the steel castings, by the Chester Steel Casting Co.; the very large castings for the bed plate and A-frames by the Farrell Foundry and Machine Co.; the bronze castings by the Philadelphia Phosphor Bronze Smelting Co.; the steam and ammonia cylinders by the J. C. Colvin Co. and the condensers and coolers by The Bigelow Co., makers of the Hornsby-Bigelow boiler. All piping and valves are of the Quincy Market Cold Storage and Warehouse Co.'s make one and one-half inch Shelby cold-drawn steel tubes, each 8 ft. long; the condensers were built for 300-lb. pressure.

Notice the expansion corrugation in the condenser shell. When the Quincy Market Co. first drew up its specifications, this expansion corrugation was made of heavier metal than the rest of the shell and riveted to it, but experience shows that it is cheaper and better to make the whole shell of the thickness of the corrugation.

An unmistakable error appeared in article III, p. 883. The word "more" in the next-to-the-last line should be "less."

Electromagnets for Alternating-Current Circuits

By Norman G. Meade

SYNOPSIS—Electromagnets in general and sample calculations for the design of a pair of small magnets to operate on a 25-cycle circuit.

Alternating-current electromagnets differ from those used on direct-current circuits, and the calculations for the windings are essentially the same as for the primary winding of a static transformer. The cores are laminated and built up from soft iron or steel punchings, as in Fig. 1, which gives front and side views of a pair of tractive magnets for general use such as actuating mechanisms, lifting purposes, etc.

To secure economical design the electromagnet should conform to established proportions. It is essential that the magnetic circuit be complete and, where space will not permit the use of two coils, the construction shown in Fig. 2 may be used, the one coil serving to excite the consequent pole.

For long-range magnets—that is, where the pull exceeds an inch or more in length—the plunger style of construction, shown in Fig. 3, should be used. On single-

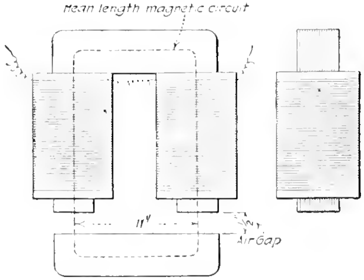

Fig. 1. Pair of Tractive Magnets

phase circuits, or when connected to one phase of a polyphase circuit, plunger magnets will make considerable noise, owing to the oscillations of the plunger. This can be relieved by placing a small compression spring between the plunger and the stop, as shown.

For alarm bells operating from an alternating supply circuit, the polarized electromagnet, shown in Fig. 4, is used. It has the distinctive advantage over direct-current signaling magnets in that no make-and-break contacts are necessary. The coils are wound in a manner similar to the direct-current magnets, but the armature is pivoted at the center and is free to move in both directions. A permanent magnet is attached to the electromagnet yoke; having the form of an elongated U, the lower end being just beneath the armature. When there is no current passing through the coils the cores will correspond in polarity to the permanent magnets as well as the armature, as indicated. When an alternating current flows through the coils, it will tend to strengthen one core and weaken the other at every alternation. The armature will then be drawn up to the strongest core,

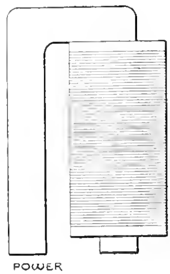

Fig. 2. Single-Coil Electromagnet

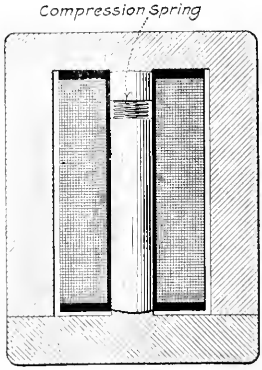

Fig. 3. Plunger Type

causing it to give the striker two vibrations during each cycle.

When the magnet coils are wound on metal spools, the latter should be split from end to end, as in Fig. 5, to prevent excessive loss due to eddy currents. Large coils are generally wound on forms and held in position on the cores by small brackets.

Magnet Calculations

The first essential in the design of an electromagnet is to determine the pull. Assume that it is desired to construct a pair of magnets, as in Fig. 1, which must have a combined pull of 50 lb. through a ½-in. air gap. The pull in the air gap decreases as the square of the distance, so that the magnets will have to be designed for a combined pull of 200 lb. for a total of one inch or ½ in. on each side. Assume a 25-cycle circuit and a core density of 30,000 lines of force to the square inch. The formulas for determining pull and the transpositions for determining the other factors are as follows:

$$P = \frac{B^2 \times A}{72,134,000}$$

$$A = \frac{72,134,000 \times P}{B^2}$$

$$B = \sqrt{\frac{P \times 72,134,000}{A}}$$

where,
P = Pull in pounds;
B = Magnetic density per square inch;
A = Area of core in square inches.

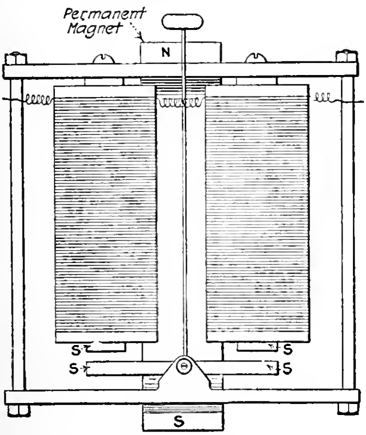

Fig. 4. Polarized Electromagnet

The pull is divided between the two magnets and therefore will be 100 lb. in each.

The area of the core will be:

$$A = \frac{72,134,000 \times 100}{30,000^2} = 8 \textit{ sq.in. (approximately)}$$

To allow for some losses, it will be best to make the core 9 sq.in., or 3 in. square.

The number of turns required will depend on the magnetic flux N which threads through the turns, the maximum value being expressed as follows:

$$N = B_{max} \times A$$

where B_{max} is the maximum value which the magnetic

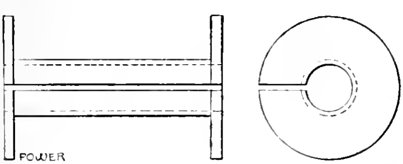

Fig. 5. Split Spool to Prevent Eddy Currents

density reaches during a cycle, and A is the cross-sectional area of the iron, in this case 9 sq.in. Hence,

$$N = 30,000 \times 9 = 270,000 \textit{ lines.}$$

Taking the induced electromotive force as equal and opposite to the line voltage,

$$E = \frac{4.44 \times N \times T \times n}{10^8}$$

where
N = Maximum value of the magnetic flux through the core;
T = Number of turns in the coil;
n = Frequency in cycles per second;
E = Impressed e.m.f.

Applying to the present example.

$$440 = \frac{4.44 \times 270,000 \times T \times 25}{10^8}$$

whence,

$$T = \frac{440 \times 10^8}{4.44 \times 270,000 \times 25} = 1468$$

Assume the core to be 9 in. long and the width of half the keeper and half the armature to equal 3 in. Also

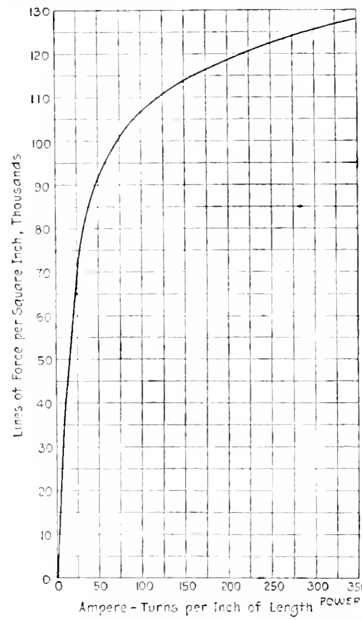

Fig. 6. Ampere-Turns vs. Lines of Force

let the distance from center to center of the cores be 11 in. Then the length of one-half the magnetic circuit, or the length per pole = 9 + 3 + 5½ + 5½ = 23 in.

From a permeability curve the permeability of soft iron at a density of 30,000 lines per square inch is found to be 1100 and that of air is always taken as one: therefore, it will require 1100 times as many ampere-turns per inch of length of the magnetic circuit for the air gap. From Fig. 6 it will be found that approximately 5.5 turns per inch of length of the magnetic circuit are required. Then the turns per coil for the iron will be 23 × 5.5 = 126½, and for each air gap of ½ in., 5.5 × 1100 × 0.5 = 3025, and 3025 + 126 = 3151 ampere-turns per spool.

As there are 1468 turns per spool, the current will be approximately two amperes. Allowing 2000 circ.mils per ampere, it will be found from a wire table that No. 14 B. & S. gage corresponds the nearest to the required size. The table shows that No. 14 wire has 13 turns to the inch;

and, allowing $8\frac{1}{2}$ in. as the length of the spool, the result is 13 × 8.5 or approximately 110.5 turns. Then 1468 ÷ 110.5 = 13+, the number of layers.

SINGLE COTTON-COVERED MAGNET WIRE DATA

B. & S. Gage	Turns per Inch	Layers per Inch
4	4.5	4.78
5	5.09	5.82
6	5.66	6.41
7	6.02	7.3
8	7.05	8
9	7.66	8.42
10	8.54	9.6
11	9.7	11
12	11.2	12.8
13	12	14
14	13	15.4
15	15.37	17.9
16	16.74	19.4
17	17.74	21.33
18	19.5	23
19	22.77	24.9
20	25.7	29.7
21	28.3	32.5
22	31	36
23	34.4	40.36
24	36.9	44.6
25	38	47
26	42	50.5
27	48	55.5
28	53.28	61.1
29	59	68
30	63.26	76.8

From the table it will also be found that there are 15.4 layers to the inch for No. 14 wire, so it will be necessary to allow 1½ in. for the depth of the winding, including the insulation between layers.

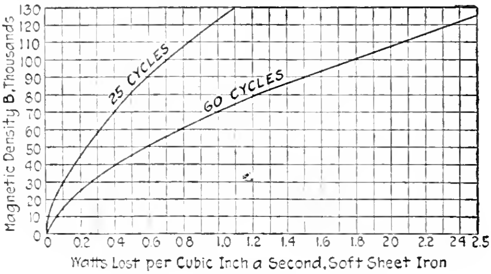

FIG. 7. HYSTERESIS CURVES

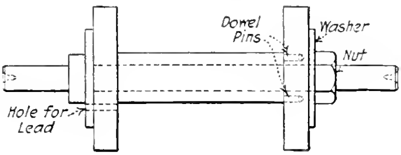

FIG. 8. FORM FOR WINDING COILS

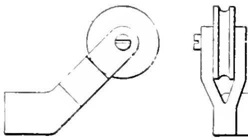

FIG. 9. GUIDE FOR WIRE

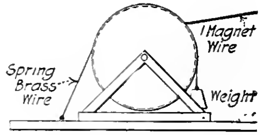

FIG. 10. METHOD OF PROVIDING PROPER TENSION

As the spool is square in cross-section, this will give each side a width of 3 in. or a perimeter of 12 in., and the mean perimeter of the coil is 18 in.

1468 × 18 ÷ 12 = 2202 *ft.*

is the length of wire per coil. The resistance of No. 14 wire is approximately 2.5 ohms per 1000 ft.; hence, there is approximately 12 ohms resistance for the two coils connected in series. Then the I^2R loss is 4 × 12 = 48 watts. The total core volume is 23 × 2 × 9 = 414 cu.in. From the hysteresis curves, Fig. 7, it will be seen that for 25 cycles the loss per cubic inch is 0.1 watt, so that the hysteresis loss will be 41.4, and the eddy current loss may be estimated as 10 watts. Then the total loss in watts will be 48 + 41.4 + 10 = 99.4 watts. The outside surface of the coils is 4 × 6 × 8.5 = 200 sq.in. per coil. As at least one square inch of coil surface must be allowed for each watt lost, it will be seen that the figures are well within the safe limit.

For winding spool magnets, small hand-driven machines can be purchased at low cost, but a lathe is more satisfactory. Fig. 8 shows a simple form for winding coils which have no spools. It consists of a wooden spindle and end turned from one piece and mounted on a steel arbor. It is secured by a flange attached to the arbor with a pin or setscrew. One end of the spool is removable and is held in place by a nut and dowel pins.

A guide for the wire is shown in Fig. 9, which is intended to be clamped in the tool post of the lathe. It consists simply of a grooved brass wheel free to revolve on a pin supported by a forged-iron holder. By moving the lathe rest backward and forward the wire can be wound evenly and quickly. It should be wound under tension, which may be provided as shown in Fig. 10.

Practically all wire reels have a groove on one side which will receive a wire to which a weight is attached, as shown. The tension can be made as great or as little as desired by varying the weight. If there is no groove in the reel, a flat band of sheet iron or steel can be substituted.

To secure the last turn of wire on the coil in position, a piece of webbing in the form of a loop is laid under the last five or six convolutions and the wire end is passed through it, after which it is drawn up tight. The coil is then slipped off the spool or form and given a wrapping of tape or webbing, after which it should be given a thorough coat of insulating paint. It is generally preferable to solder a piece of flexible conductor to the wire ends inside the coil.

Nipples—A nipple is a fitting made from tubular goods, and usually threaded on both ends. It is under 12 in. in length. Pipe over that length is referred to as cut pipe.

A close nipple has no shoulder and is about twice the length of a standard pipe thread.

A shoulder nipple has any length. It derives its name from the shoulder of pipe left between the two threads. A shoulder nipple is intermediate in length between a close and a short nipple.

A short nipple is slightly longer than the lengths of the two threads, being a trifle longer than a close nipple. Some unthreaded shoulder exists between the two threads.

A space nipple contains a shoulder between the two threads, and may be of any length allowing a shoulder.

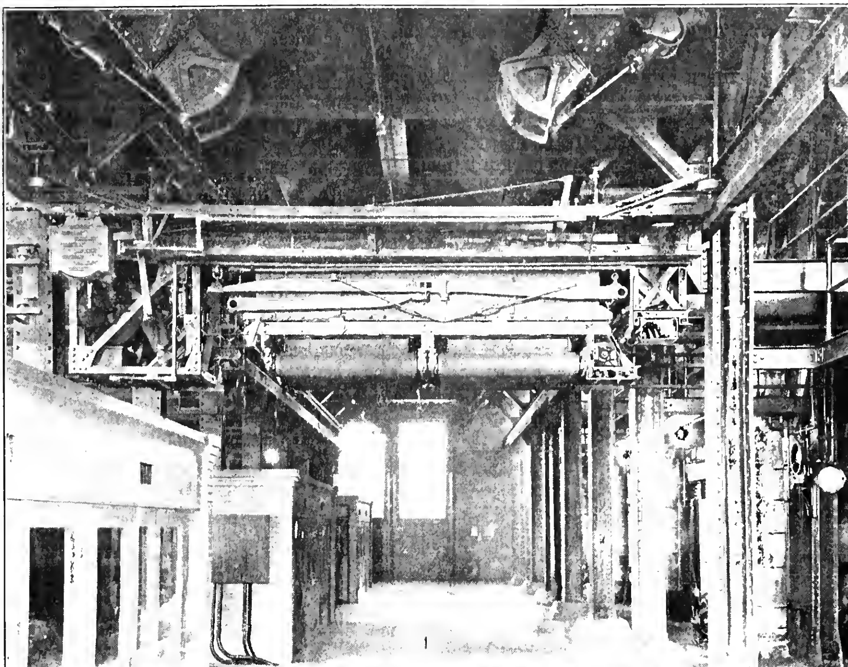
A sub-nipple is a substitute nipple, or, in other words, a short pipe with different styles of thread on its ends.

A swage nipple is a reducing nipple, having one end smaller than the other.

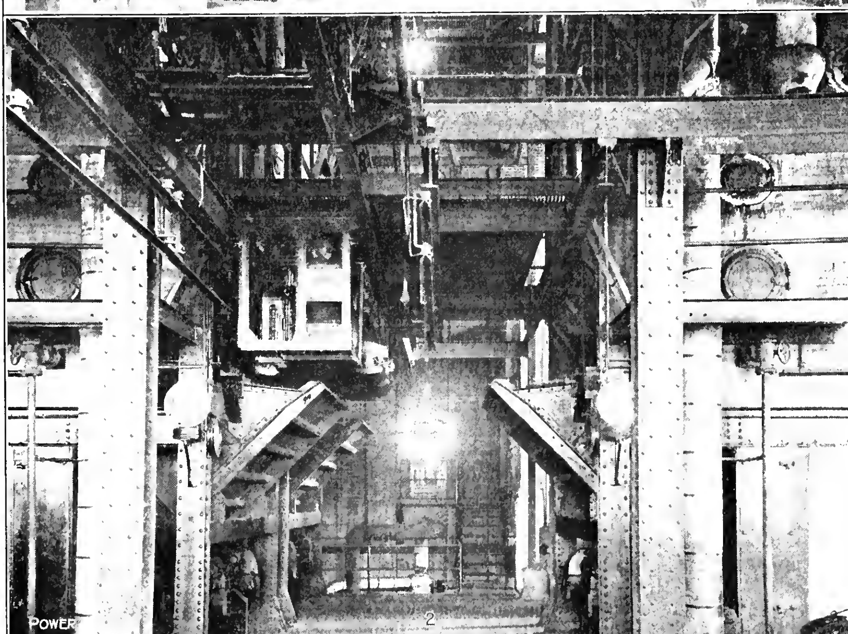
A long screw nipple is made up of a short length of pipe; one end has a standard thread, the other is threaded far enough to allow a coupling and lock-nut to be turned by hand without overlapping the pipe end. It is an advantage when making a connection, or for connecting pipes in place.

Coal-Weighing Larries

The Cleveland municipal electric-light plant uses two Brownhoist coal-weighing larries to transport the coal from the bin to the stokers and weigh each load (Fig. 1). The plant is equipped with a large coal bin arranged with four rows of hoppers, each fitted with a Brownhoist air-operated gate, and each separately controlled by an air valve located along the crane runway within reach of the larry operator when the larry is stopped beneath the gate. The air cylinder is swiveled so that it will adjust itself to the different positions of the piston while the gate is in the act of opening and closing.



1



2

Each larry operates with a transfer crane which travels along a runway beneath two rows of the gates. The larries reach the other two rows of gates by individual tracks. The transfer crane is operated from the larry. The operator brings the transfer crane into alignment with the tracks running to the stokers or to the farthest coal gates and the larry runs off the crane onto these tracks after a locking device is set to keep the crane in alignment with the tracks. Fig. 2 shows the larry delivering coal to the stokers. Each electrically operated larry is of two-ton capacity. Two gates are provided through which the coal flows onto a belt which throws it into the hoppers.

The larries and cranes are equipped with brakes, and all open ends on the tracks are provided with safety stops to prevent the larries running off. Each larry is equipped with scales, with the scale beam in the operator's cab. The operator keeps a record of all coal delivered to the stokers.

The Wages of Engineers

By Earl Pagett

Much has been written about the compensation received by engineers. As data on the salary drawn by engineers are noticeably lacking, the writer set out to collect the facts from the men themselves by a letter sent to engineers in widely separated sections of the United States. Of the seventy-five letters sent out, many came back and a number were not answered. It is regrettable that a greater number of places could not be heard from.

The following table shows the data as collected:

Place	Size of Plant, Hp	No. of Men Chief	No. of Men Ass't	Hr. per Week		Salary per Week Chief	Salary per Week Ass't
Cambridge, Mass.	25,000	1	4		56	$45 00	$26 50
	600	1	3		56	40 00	25 00
	400	1	3		56	35 00	25 00

Exeter, Neb.	225	1	1	54	54	90	70
	250	1	1	54	54	100	70

The standard rate for the mining districts of the Southwest does not vary greatly over a wide range of plant size. Chief engineers get from $150 to $200 a month, sometimes including house, light and water. Watch engineers receive from $125 to $150 a month; eight hours is considered a watch and thirty and thirty-one days a month. No reports on special plants were received.

Memphis, Tenn.: No report on special plants. The correspondent states that chief engineers average about $125 and assistants about $75 a month.

Foxboro, Mass.: The wages in this vicinity will average as follows:

	Per Week
First-class engineers	$23 to $30
Second-class engineers	18 to 23
Third-class engineers	15 to 21
Firemen	14 to 17
Hours worked will average	55 to 60

Framingham, Mass.: In plants of from 1000 to 5000 kw. three or four men are employed, working in eight-hour shifts, the chief sometimes standing a watch. Chief engineers receive from $25 to $35 per week and assistants from $18 to $25 per week.

In manufacturing plants of from 1000 to 2000 hp., usually one chief and three operating men are employed in eight-hour shifts. The chiefs get about $30 per week and the assistants from $18 to $24.

In smaller manufacturing plants of from 100 to 500 hp., one engineer and a day and a night fireman are employed. The engineer works 60 hours per week, spends from two to five hours at the plant on Sundays, and receives from $18 to $26 per week. Plants smaller than this pay from $15 to $18 per week of about 60 hours.

Large brewery plants in this vicinity pay about $35 per week for the chief engineer and $21 to $25 for the assistants; engineers work in eight-hour shifts.

South Chicago, Ill.: Information on one plant only. The men work six 12-hour shifts and change every week. First assistants get $4 per day, second assistants $3.50 and third, $3; oilers and stokers, $2.50 per day; chief engineer's salary not given.

Norman, Okla.: Plant of 250 hp., one day and one night engineer; 84 hours per week with $100 and $80 per month respectively. Pumping plant, one engineer at $1200 per year. Plant with three boilers and one 125-kw. generating set; one chief and two assistants on eight-hour shifts; chief receives $1000 a year, assistants $70 to $75 a month. Plant of 150 hp.; one chief, who is also superintendent of machinery, at $1200 per year.

New Orleans, La.: Chief engineers of ice and cold-storage plants, $100 to $200 per month, subject to call at any hour; assistants, $75 to $85 a month, 84 hours a week. No report on other plants.

Wichita, Kan.: Only one plant reported; 8750-kw.; one chief engineer and three assistants, each working 56 hours per week. The chief gets $125 a month and the assistants $75.

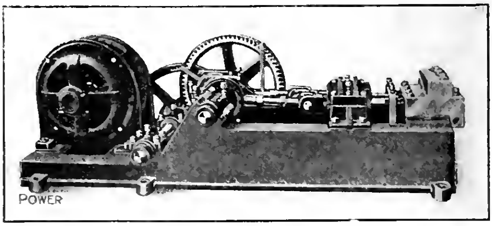
Coffeyville, Kan.: Plant of 900 kw., one chief engineer and two assistants on eight-hour shifts. The chief gets $100, assistants $75 per month. Plant of 400 kw.; one chief engineer, three assistants on nine-hour shifts. The chief gets $150 and the assistants $75 per month. Plant of 700 hp.; one chief working 70 to 77 hours per week at $95 a month. Plant of 150 hp.; one day and one night engineer on 12-hour shifts; day man gets $3 and the night man $2.50 per day. The day man washes the boilers on Sundays. Plant of 300 hp.; one day engineer, working 84 hours a week at $100 a month. The watchman cares for the plant at night.

There seems to be a wide variation in the wages paid in similar plants. Take the plant of 600 hp. in the vicinity of Cambridge, Mass.; it pays the chief engineer $160 a month, working 56 hours a week, while in the vicinity of Clay Center, Ohio, a plant of 500 kw. pays the chief engineer $75 a month for 84 hours a week.

It would seem that if it is worth $160 a month to run a plant in one place, it should be worth at least that much to run a similar plant almost any place.

Watson-Stillman Triplex Hydraulic Pump

The Watson-Stillman Co., 50 Church St., New York City, has added to its line a new type of motor-driven



Triplex Hydraulic Pump, Motor Driven

geared, triplex, single-acting pump. While primarily designed to meet the severe demands of tunnel service, it will be equally suitable for other conditions.

To secure compactness, rigidity and alignment of the working parts when under severe service, the motor is mounted on an extension of the heavy cast-iron base. The driving shaft and bearings are large and are provided with lubricating cups. The gears are of the heavy cut-tooth type. The drive from the shaft is by eccentrics set at 120 deg. cast in one piece and keyed with one key to the driving shaft. The eccentric straps are heavy.

The plungers are of tool steel and are guided in a cross-head guide, which is keyed and bolted to the base.

The pump body is a steel forging fitted with bronze valves and bonnets. All passageways are made large to reduce the friction of the water to a minimum. The pump, shown herewith, is operated by a 10-hp. motor running at 600 r.p.m., and delivers 100 cu.in. of water per minute at 3500 lb. pressure, with a crankshaft speed of 100 r.p.m. Other sizes of the pump are built to suit operating conditions.

Installation and Care of Fire-Protection Apparatus

By J. O. Benefiel

Usually, such apparatus is installed under the supervision of an insurance company, but it often happens that additional buildings are erected requiring automatic sprinklers, and the engineer should be able to plan and supervise the extensions satisfactorily, thus saving his employers considerable expense.

One thing he should avoid is getting too many sprinklers on one branch line. The distance from the wall to the first sprinkler should not be more than half the distance between sprinklers in the same direction. Under a pitch roof one line of sprinklers should be in the peak. Splash plates should not be less than three nor more than ten inches from joists or ceilings. All stairways, closets and odd corners should be looked after.

LOCATION AND SPACING OF SPRINKLERS (FROM THE RULES AND REGULATIONS OF THE ASSOCIATED FACTORY MUTUAL INSURANCE CO.)

One Row of Automatics Placed Midway between Beams in Each Bay		Water Pressure at Highest Sprinkler Exceeding 20 Lb.		Less Than 20 Lb.	
		Medium Hazard	Special Hazard	Medium Hazard	Special Hazard
In 12-ft. bays	Sprinklers:	8 ft. apart	7 ft. apart	7 ft. apart	6 ft. apart
In 11-ft. bays	Sprinklers:	9	8	8	7
In 10-ft. bays	Sprinklers:	10	9	9	8
In 9-ft. bays	Sprinklers:	11	10	10	9
In 8-ft. bays	Sprinklers:	12	11	11	10
In 7-ft. bays	Sprinklers:	12	11	11	10
In 6-ft. bays	Sprinklers:	12	11	11	10

The terms "medium" and "special hazard," in the table, relate to the contents or occupancy of each room. Especially hazardous places are picker rooms, sawing departments of wood-working plants and varnish rooms.

The following tabulation gives the maximum number of sprinklers to be supplied by the sizes of pipe given:

Size of Pipe, In.	No. of Sprinklers	Size of Pipe, In.	No. of Sprinklers
¾	1	3	36
1	2	3½	55
1¼	3	4	80
1½	5	4½	110
2	10	5	140
2½	20	6	200

Supporting the branch pipes by hangers in rooms where there is much heat or steam is a serious problem. Another annoyance is leakage around the valve stems.

The swing checks on the inlet from city mains and the discharge from the fire pump sometimes stick open when the spindle on which the check swings is iron and corrodes. All moving valve parts should be made of brass.

In rooms where certain processes are carried on, the sprinklers should be taken off and cleaned whenever they become coated with deposits.

During the regular overhauling in a certain plant the disks of the 2-in. drain valves are taken out, cleaned, and a ring of gasket rubber is put on the disk to prevent a leakage which would cause a loss of the water seal on top of the dry valve.

To those not acquainted with the valves it is explained that the upper (sprinkler) side of these valves has about five times the area exposed to the air pressure to hold it shut to one on the lower side subjected to water pressure. About 35 lb. of air is usually carried to balance 100 lb. water pressure. When a sprinkler head acts, the air pressure is reduced and the water-supply valve opens. The system then fills with water. After being in action it is necessary to again put the system in order. All the

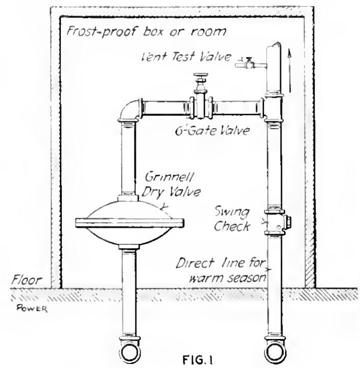


FIG. 1

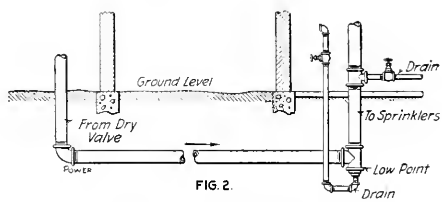

FIG. 2.

Underground Section of Line

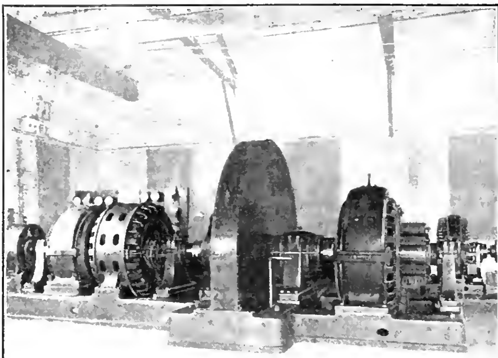
drains are opened to let the water out to the test valve above the tee shown, Fig. 1.

All the drains are then closed and from forty to fifty pounds of air pressure is put on the system. One man goes around opening the drains, one at a time, until they show no water. The air pressure is then brought up to about thirty-five pounds and the valve in the yard is opened to let the water pressure against the under side of the dry valve. The drains should be opened about twice a week for two or three weeks to make sure the system is free of water.

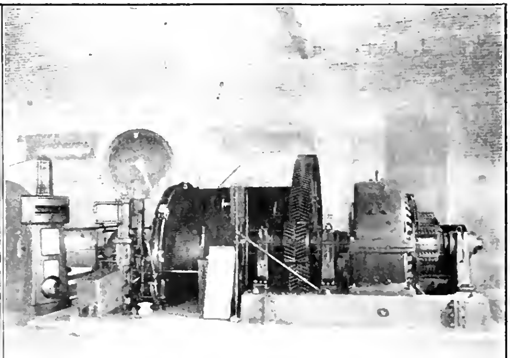
If the building is warm during the day and cold at nights and on Sunday, an allowance must be made for a loss of pressure due to the air contracting in the pipes.

Fig. 2 shows a drop underground to another building. The draining of the underground section was a problem, there being no sewer. It was done by bringing the drain to the surface, as shown, and blowing the water out by air. It has worked successfully for years and has but one drawback—so much talking must be done to convince each new inspector that it works.

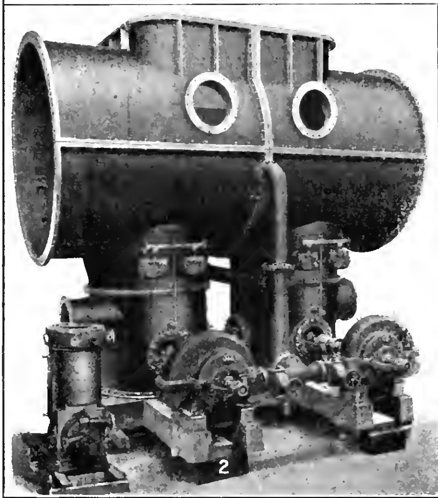
Interesting Power-Plant Apparatus



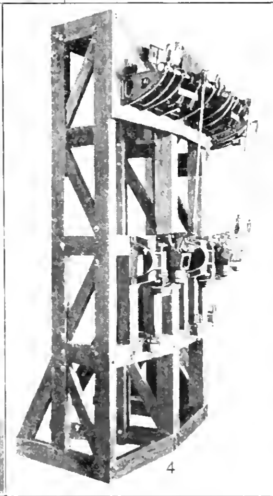
1



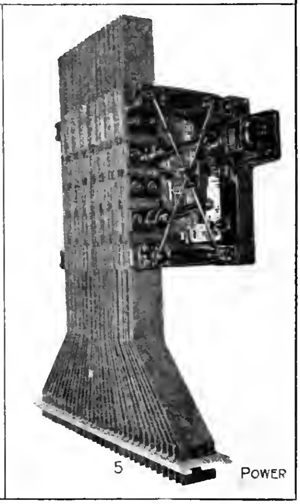
3



2



4



5

Fig. 1 shows a Wellman-Seaver-Morgan Co. duplex motor-generator flywheel set consisting of a 350-hp. motor driving one 400-kw. and one 200-kw. direct-current, 550-volt generator running at 720 r.p.m. At one end of the shaft there is attached a direct-current exciting unit. The flywheel weighs 25,000 lb.

This machine, which is used by the Cleveland Cliffs Iron Co., acts as a balancing set and furnishes direct-current to a main ore hoist and to a man-and-timber hoist. Fig. 3 is a geared hoist with a single drum for hoisting men and timber in a single 1300-ft. compartment shaft, the counterbalance being obtained by the use of counterweights. The machine is geared to produce a hoisting speed of 1000 ft. per min.

The drum is 96 in. diameter by 84 in. face, and is grooved for a $1\frac{1}{4}$-in. rope. A 96-in. diameter band brake is on one end of the drum. The double-acting brake is applied by gravity and is released by means of a combined air and cataract cylinder. The gears are of the herringbone or helical type. The electrical equipment consists of a 500-volt, 200-hp. direct-current motor running at 250 r.p.m. and receiving its current from the duplex motor-generator set, Fig. 1.

Fig. 2 is a large jet condenser with a small jet condenser in the foreground. The large unit is in use at the Westport plant of the Consolidated Gas, Electric Light & Power Co., Baltimore, Md., with a 15,000-kw. turbo-generator. This condenser takes care of 200,000 lb. of steam per hour to a $28\frac{1}{2}$-in. vacuum with 70 deg. F. injection water.

The small condenser shown is used with turbines up to 300 kw. capacity. This particular unit takes care of a low-pressure turbine of 100 kw. capacity.

In both condensers the same general idea is worked out; viz., the air- and water-removal pumps being on the one shaft, either turbine or motor driven, the removal pump being submerged in the tank base of the condenser. Both units have substantially the same water distribution and are of the parallel-flow design.

Fig. 4 is a 12,000-amp., 600-volt circuit-breaker, the largest capacity alternating-current circuit-breaker in the world. It is in the Wood Worsted Mills, Lawrence, Mass., the largest worsted mills known.

Fig. 5 illustrates a 40,000-amp., motor-operated switch for electric furnace. The output of the furnace is either 20,000 amp. with a potential of 40 volts, or 40,000 amp. with a potential of 20 volts. The weight of the switch is $7193\frac{1}{2}$ lb. In the construction of this switch 5268 lb. of copper was used, over $2\frac{1}{2}$ tons; 871 lb. of composition metal; 681 lb. of cast iron; 342 lb. of steel and $31\frac{1}{2}$ lb. of mica. This switch was manufactured by the General Electric Co., Schenectady, N. Y., as was the 600-volt circuit-breaker.

Editorials

The Year's Review

In 1913 the word "large" best defined the tendencies of development, and the impetus gained in this period has carried over into the year just past. Notwithstanding the general depression in business, installations were made in which some of the equipment holds first place in size or capacity. Long ago the advantages of concentration were appreciated and the constantly growing demands have urged the manufacturer to greater efforts. Each year something bigger than ever before makes its appearance and apparently only raises the horizon for the particular field concerned.

In looking over the files for the year the first large device to attract attention is a Mesta triple staggered-tooth spur gear, 22 ft. 8 in. in diameter, having a 38-in. face and 154 teeth spaced on 5½-in. circular pitch. It was built to drive a sheet mill of the Inland Steel Co., and at a speed of 2000 ft. per min. the gear transmits 1600 hp.

For the Woodward Iron Co. two horizontal cross-compound Mesta blowing engines, 48 and 84 by 60 in., were installed. A notable feature was the building of one engine in 38 days and the completion of both in 59 days. The Nichols Copper Co., Long Island City, has the largest Keeler water-tube boiler ever built. The boiler is rated at 1280 hp. and has a little more than half the capacity of the Stirling boilers now being installed at the new Connors Creek station of the Detroit Edison. It will be remembered that these boilers are rated at 2350 boiler-horsepower, and by forcing are capable of carrying continuously the enormous load of 13,300 kw. Normally, they are designed to care for 10,000 kw.

In cooling towers there have been three large installations: one a twin Wheeler-Barnard forced-draft tower for the American Hardware Co., New Britain, Conn., capable of cooling 132,000 gal. of water per hour from 100 to 80 deg. F.; a battery of towers of the same type to cool 600,000 gal. of water per hour for the Texas Power Co., Waco, and a Mitchell-Tappen atmospheric tower capable of cooling 120,000 gal. per hour through the range previously given. The tower last mentioned was installed for the main power house of the South West Missouri Railroad Co., at Webb City, Mo.

A notable pump installation was made for the Plaquemine & Jefferson Drainage District of Louisiana, consisting of four 76-in. and one 48-in. centrifugal pumps built by the Southwark Foundry & Machine Co. The larger pumps each have a capacity of 168,000 gal. per min. (over 10,000,000 gal. per hr.), at 1-ft. head and 40,000 gal. per min. against a head of 13 ft., and are used to pump water back over the levee into the Mississippi River. The 100-million gal. De Laval centrifugal pump recently installed at Pittsburgh has a 48-in. outlet, but it must raise the water against a total head of 56 ft. Another interesting installation is the first large American-built Humphrey gas pump which is to be used for irrigation purposes near Del Rio, Texas. The cylinder is 66 in. in diameter and is supplied with gas by a 300-hp. Akerlund down-draft producer capable of gasifying either soft coal or mesquite wood.

The Alabama Power Co. has recently installed the first of four 17,500-hp. generating units at its hydro-electric station on the Coosa River. The turbine is the largest of the single-runner type in operation. To the Brooklyn Edison must be credited the largest single-cylinder steam turbine. It is rated at 22,000 kw. and with a moderate temperature rise it is expected to carry 25,000 kw.

Recently the first car containing parts of the mammoth direct-current generators for the Ford plant in Detroit left the works of the Crocker-Wheeler Co. Each of the four machines is to have a normal capacity of 3750 kw. and will weigh 105 tons. The field frame is 24 ft. high and 26 ft. wide across the supporting feet. The armature is 16 ft. in diameter and weighs 87,000 lb. As this dimension exceeded the limits for track clearance the assembling of the armature parts and the winding must be done in Detroit.

Another event worth noting in the electrical field is the completion of the longest transmission line by the Southern Sierras Power Co. It extends 400 miles from the generating station to the most distant customer, but the main straight-away transmission is not as long as that of the Big Creek system.

Credit for the largest Diesel engine built in this country to date belongs to the Lyons Atlas Co., Indianapolis. It has four 24x30-in. cylinders, which will develop normally 600 hp. and a maximum of 690 hp. driving a two-stage turbine pump of 15 million gal. capacity against a head of 200 ft. The unit will be used by the Hawaiian Commercial & Sugar Co. for irrigation purposes.

Valves for steam headers which weigh 3600 and 3900 lb., respectively, are not common. In fact, the Nelson valves of the above weights recently furnished the New York Edison Co. are claimed to be the largest steel gate valves for superheated steam yet installed. When open they measure 9 ft. 1 in. from the bottom of the body to the top of the stem. The valves are to be mounted in 18-in. steam leads, carrying steam under 200 lb. pressure and 150 deg. superheat.

Steam Turbines

Of the various large turbines building for Chicago, New York, Philadelphia and elsewhere, perhaps the most interesting is the 35,000-kw. unit for the Philadelphia Electric Co., as it is the largest in the world by 5000 kw. The prime mover is a thirteen-stage horizontal Curtis turbine 63 ft. 2 in. long over all, 21 ft. 7 in. wide and 15 ft. 10 in. high. The weight of the unit is 600 tons. It will receive steam at 215 lb. pressure and 150 deg. superheat and exhaust against an absolute pressure of 1.5 in. of mercury. At the most economical load, 25,000 kw., it is expected to develop a kilowatt-hour on 11.9 lb. of steam. At the full rated load of 35,000 kw. the water rate increases to 12.6 lb. per unit. With a better vacuum the steam consumption will be lowered slightly. The condenser for this immense unit is naturally the largest in the field. It is of the center-flow surface type containing 50,000 sq.ft. of surface in 1-in. tubes. This reduces to 1.43 sq.ft. per kilowatt of turbine rating, which may be compared to an average of 3 sq.ft. a few years ago. That injection water is supplied through a 48-in. pipe will give some indication of the quantity required. The auxiliaries are all turbine-driven centrifugal units, and the air pumps are the Le Blanc type. The generator delivers three-phase 60-cycle currents at 13,200 volts. The speed is 1200 r.p.m. The station is to contain also a 30,000-kw. unit of the same type which will deliver 25-cycle current with the same expenditure of steam at the most economical load, 22,500 kw. The speed will be 1500 r.p.m.

When the above water rate is compared to the guarantee for the 25,000-kw. Parsons turbine at Fisk Station, of 11.25 lb. per kw.-hr. against a back pressure of 1 in. of mercury, it will be seen that there is little if any difference in economy between the two machines. It may be of interest to state that this English unit is now in satisfactory operation. The troubles usually encountered when starting a machine of a type new to the station, and other troubles due to damaged insulation, have been overcome.

As previously stated in these columns, this unit is of the two-cylinder tandem type; the Brooklyn Gold St. turbine has but a single cylinder, while the 30,000-kw. Interborough turbines have two cylinders arranged cross-compound and operating at different speeds. Several advantages are claimed for the compound units such as a smaller temperature range in each cylinder, the possibility of separating the moisture midway in the expansion of the steam, smaller cylinder structure and the reduction of stress set up by wide temperature ranges. In the single-cylinder turbine this is offset by a machine which takes about three-fifths the floor space occupied by the tandem compound and a still lower fraction of the space taken by the cross-compound. The water rates do not vary appreciably. The action of the Brooklyn turbine in practice will no doubt help to determine the limits of a single cylinder.

In this same turbine the stationary blading for the high- and intermediate-pressure sections is not fastened to the casing but is mounted on cylinders set into it. This practice is being followed in other large turbines as it has been found desirable from the standpoint of convenience and strength. An increase in the speed of these large units is also a point of interest. The earlier of the large turbines were designed for 750 r.p.m.; the Brooklyn unit makes 1500 turns per minute, and some 20,000-kv.-a. turbines now being built for the Public Service Corporation of New Jersey are to run at 1800 r.p.m.

A serious difficulty tending to limit the capacity of these great machines is the problem of utilizing effectively the immense volumes of steam in the lower stages. The struggle to obtain greater peripheral velocity for the final stages and greater section through them so as to maintain the most efficient ratio between steam and blade velocity has resulted in a number of suggestions such as a considerable increase in the diameter of the final elements, a combination of velocity, pressure-impulse and reaction stages and other arrangements tending toward the same end, as discussed quite recently in these pages.

Engine Progress

For several years the tendency has been toward higher speeds and consequently engines of less weight which require less excavation and concrete and give more room for purposes other than power generation. By the use of higher pressures and some superheat, water rates have been lowered, although the longevity and low upkeep of the Corliss have been sacrificed to some extent. The reduction in initial cylinder condensation by the adoption of the una-flow principle has boosted the economy of condensing engines. With pressures ranging from 300 to 500 lb. there are great possibilities for the above type. Already results obtained from one cylinder equal those from the average compound, and the ultimate goal is an economy approaching that of the Diesel engine.

In this connection it may be of interest to state that the year has seen the first una-flow engine built in America under the patents of Professor Stumpf and the personal supervision of his representative. A 15x16-in. engine designed to carry 100 kw. and running at 250 r.p.m. under a steam pressure of 145 lb., a superheat of 88 deg. and a vacuum of 25½ in. developed an indicated horsepower-hour on 12.5 lb. of steam. The lowest noncondensing rate with steam superheated 130 deg. was 16.8 lb. and with saturated steam, 20.4 lb. It is evident that the una-flow is primarily intended to operate condensing. Another design of una-flow engine has been perfected by the Skinner Engine Co. with practically the same noncondensing steam rates, and the Nordberg Co. has produced a una-flow engine with poppet valves to supersede, for high pressures and superheats, its previous design employing Corliss valves. The same company has also improved its poppet-valve engine by locating the valve seats in the heads and operating the valves mechanically instead of depending on a spring for the return movement.

The first Buckeye-mobile in commercial service is a feature of the year. This particular unit is rated at 115 hp. and is directly coupled to a 75-kw. alternator at the works of the International Cork Co., Greenpoint, L. I. It occupies a floor space 17 ft. 10 in. long by 7 ft. 6 in. wide. From the base to the top of the flywheels the unit stands 9 ft. high. In its shop test the engine, which is compounded, developed a steam rate of 13.3 lb. per i.hp.-hr. on 1.33 lb. of coal. The boiler pressure was 210 lb. and the superheat 171 deg.

Boilers

The practice of forcing boilers for the peak load to double and, in some cases, triple their rating is becoming more firmly established. Where formerly it was customary to provide a boiler-horsepower for every kilowatt of generating capacity, a ratio of 1 to 4 is now common in the larger stations. Lower water rates, of course, help in this direction. In the new generating plant of the United Electric Light & Power Co., of New York, commonly known as the 201st St. Station, which was officially put in commission on Jan. 31, one boiler-horsepower is expected to care for 4.7 kw. At Waterside No. 2, the ratio of boiler-horsepower actually used to installed generator capacity is 1 to 4.2 and in emergencies at Delray one boiler-horsepower will supply 5.65 kw. This necessitates a more extended use of forced draft, although in Boston a natural-draft plant with some cheap means, such as steam jets, of materially increasing the draft during peak loads, is considered the ideal installation.

The amount above normal rating at which a boiler can be safely operated depends largely upon the scale-forming and suspended matter in the feed-water. In quite a number of the larger stations where boilers are forced to several times their ratings, the use of distilled water is being considered. The cost would not be great, as the make-up in a "tight" plant is only a small percentage of the feed. Some doubts as to the corrosive effect of distilled water are prevalent, but its use for years in marine plants has failed to reveal any serious trouble.

A startling suggestion brought forward this year by W. L. R. Emmet, of the General Electric Co., is the use of mercury as a working fluid for heat engines. The project has taken more definite form than a mere proposal, as experimental work has been conducted for some time and the installation of a 100-hp. unit at Schenectady was completed some nine months ago. A mercury boiler supplies vapor to a turbine. The latter exhausts to a condensing boiler which generates steam for another turbine on the same shaft. The mercury is, of course, returned to its respective boiler. The advantage of using mercury lies in its ability to utilize much higher temperatures without excessive pressures. At atmospheric pressure mercury boils at 677 deg. F. and condenses in a 28-in. vacuum at 455 deg. The density of its vapor is another advantage permitting in a turbine the use of much shorter blading in the low-pressure stages. Comparing the system to the ordinary steam plant, Mr. Emmet estimates a gain of 66 per cent. in delivered power at an additional fuel expenditure of 15 per cent. About $10 worth of this new medium will be needed per kilowatt of mercury turbine.

In Europe, high-voltage, alternating-current electric boilers have been in use for a number of years. These boilers take the primary current and may be used to generate steam for heating or commercial purposes, to keep the water hot in boilers of a steam reserve plant or to maintain reserve water units in operation, which may be switched into service on the line at a moment's notice. The first plant on this side of the Atlantic was installed this year in eastern Canada. It consists of two single units of 750 kw. each, operating on 2400-volt, three-phase current to generate steam of 125 lb. pressure for heating a cotton mill during night hours. It is estimated that one kilowatt-hour will produce about three pounds of saturated steam at pressures up to 125 lb.

A new sectional water-tube boiler in which one large circulating pipe conveys all of the water from each drum to the bottom of the header sections has been perfected by A. Venning, Preston, Ont. T. T. Parker, New York, has patented a cross-drum water-tube boiler with several novel features, and quite recently the possibilities of the high-pressure Winslow boiler have been brought to the attention of the engineering fraternity.

In locomotive practice in the past year the Crawford stoker has shown wonderful possibilities for heavy freight and transfer as well as fast passenger service. Rates of combustion as high as 200 lb. of coal per square foot of grate per hour have been obtained.

Marine Tendencies

Relative to development in the marine field the Talbot and the Niclausse boilers have been improved with a view to bettering the circulation and as a natural consequence the efficiency. The new Ward wrought-steel, water-tube boiler for marine purposes is also a product of the year.

On Feb. 26 the "Britannic" was launched. In spite of the war, the White Star Line expects to put this 50,000-ton liner in service in 1915. She is 900 ft. long, which may be compared to 882 ft. 9 in. for her predecessor, the "Olympic." The extreme breadth is 94 ft. and the displacement at a load draft of 34 ft. 7 in. is 53,000 tons. The displacement of the "Olympic" when drawing 34 ft. 6 in. is 3000 tons less. Chief interest centers in her machinery. Three-screw propulsion is effected by four-cylinder, triple-expansion engines, 54, 84, 97 and 97 by 75 in., on the wing screws and a low-pressure turbine on the center screw. The latter will receive steam at about nine pounds absolute pressure and exhaust into condensers at one pound absolute. At 165 r.p.m. the turbine will develop more than 16,000 hp. The great advantage of such equipment is that the machinery can be worked at reduced power with practically the same efficiency as at full load.

The annual report of Lloyd's Register, recently issued for the year ending June 30, 1914, calls attention to the increasing use of steam turbines, and especially those which are geared to the propeller. At present there are 23 vessels now being built under Lloyd's classification in which geared turbines are to be fitted, six vessels which will use direct turbine drive and six which will have the three-screw combination installed in the "Britannic." Employing the reduction gear allows both turbine and propeller to be driven at speeds most efficient for each. The U. S. Collier "Neptune" has shown the adaptability of reduction gears, and with the higher turbine and lower propeller speeds suggested by the original trials, good results are expected.

In the U. S. Collier "Jupiter" electric drive was installed. In the year and a half in which she has been in commission she has steamed about 14,000 miles and has been thoroughly tested under all conditions of service. The speed of the nine-stage Curtis turbine is 1990 r.p.m. and of the two induction motors driving the propellers, 110 r.p.m. In showing an economy from 20 to 25 per cent. greater than her sister ships, the boat has more than vindicated the claims of the designers. As a result the Navy Department has decided to equip the battleship "California" with electric drive.

Another feature mentioned in the report was the increasing use of large Diesel-engine motor ships. At present 27 vessels holding Lloyd's classification have an aggregate of 50,000 i.hp. in Diesel engines, and there are twenty more now building.

Coal and Smoke

For a long series of years the coal produced in this country has doubled every decade. For the past year the estimated production is 550 million tons, or about 5 tons per capita. At this alarming rate, increasing with each succeeding year, the supply will be exhausted at no distant date. Conservation of the supply is thus becoming more urgent. While the cheapness of the fuel has discouraged concentrated effort, some progress has been made. Classification of the coal is finding a constantly widening field of application, the obstacles common to the burning of powdered coal are being overcome and the washing and sizing of Western coals is resulting in a decided gain. Such plants as the one installed this year at Hauto, Penn., utilize what was formerly a waste at the mines, and in supplying the surrounding territory with electric energy conserve the supply of coal worth shipping.

Considerable progress has also been made in smoke suppression. Most of the large cities in the country are now actively engaged in abating this nuisance, although there is a general hesitancy in appropriating sufficient funds for the purpose. Pittsburgh in particular has become more active in the past year. The city is the largest consumer of bituminous coal in the world and its annual soot fall has reached the enormous figure of 1031 tons per square mile. Truly the opportunities for "cleaning up" are great, and with the incentive awakened surprising results may be expected.

Europe is also awaking to the possibilities of smoke prevention. Twenty-four English and Scotch cities are making soot observations with standardized apparatus and methods. Educational classes for engineers and firemen have been started with a view to teaching them improved methods of burning coal. Progress is necessarily slow, because of the limited powers conferred by existing laws and because societies for the suppression of smoke are dependent upon membership fees and donations for the funds required to carry on the work. Finland is active in smoke abatement and Hamburg has a smoke-prevention society made up of manufacturers to the number of 473. The society is a voluntary association of large consumers of fuel bound together by the common interest of reducing smoke and bettering the efficiency of their boilers.

Electrical Advancement

Oct. 21 last commemorated the thirty-fifth anniversary of the invention of the incandescent lamp. On the above date in 1879 Thomas A. Edison first successfully made a carbon filament glow. It was the beginning of interior electric lighting in small units, the arc having preceded the incandescent by a few years, although to a limited extent.

Perhaps the most notable development in switchboards was that for the control of the Panama Canal Locks, which was completed during the early part of the year. The 35,000-kw. generator for the Philadelphia Electric Co. has already been mentioned. Among the more special apparatus is the Kapp phase advancer. It consists of three small, direct-current motors connected in circuit with the rotor of an induction motor. The small machines set up an electromotive force in opposition to that produced by the slip of the rotor and in this way increase the power factor to unity or above.

In England and on the Continent considerable attention has been given to this problem of phase advancing. In the former country an installation in connection with a 330-hp. induction motor has been made quite recently. A new method of self-synchronizing rotary converters has been developed and is being extensively adopted by British manufacturers. The General Electric Co. has perfected a revolving compensator with one collector ring for obtaining the neutral connection with three-wire operation. It is to supersede the familiar separate stationary compensator and two-collector-ring arrangement.

The use of synchronous condensers of large capacity for voltage regulation as well as power-factor correction has been introduced in connection with the Big Creek development of the Pacific Light & Power Corporation. It may be recalled that this company employs the highest transmission voltage yet attempted, 150,000 volts. Outdoor substations continue to grow in popularity and the practice of washing air for cooling electrical apparatus has become more general during the past year. Improvements have been made in oil switches for meeting the general tendency toward higher voltages, and more satisfactory designs of power-limiting reactances have been developed. Equally important with the development of new devices is a set of safety rules governing the use of electrical apparatus, which has been compiled during the past year by the Bureau of Standards. A radical revision of the old rules was made in the basis of rating machinery. From a thermal standpoint a rating no longer is established by a standard rise in temperature under prescribed conditions of load but the hottest spot in the insulation is made the deciding factor. There is no provision for overloads causing a temperature higher than specified. The owner must take all risks if he desires to exceed the limit.

Gas and Oil Engines

In the gas-power field there has been little new in producer work or in gas-engine developments. Ehrhardt and Sehmer of Saarbrucken, Germany, have increased the power, and incidentally the efficiency, of their engines by thoroughly scavenging the burnt gases and introducing the fresh charge under pressure. A blower driven by a motor or by a turbine supplied with steam from a waste-heat boiler delivers the air and gas under a pressure of 10 to 15 lb. Due to the lower temperature from scavenging and to the pressure, a heavier charge and a better mixture of live gas are obtained. The effect is to raise the mean effective pressure and to improve conditions generally.

A distinctive advance has been made in the recovery of waste heat from gas engines through the Merriam process, as developed by the Bruce-Macbeth Co. By forcing the water in a closed circuit through the jackets at a velocity five to ten times normal, the temperature can be raised to 300 deg. without endangering the cylinder. Thus steam under pressures as high as 50 lb. can be generated and the heat usually wasted in the jackets is utilized.

During the past year important experiments have been conducted by the Engineering Experiment Station of the Pennsylvania State College to determine the applicability of kerosene, alcohol, motor spirits and mixtures of gasoline and kerosene as substitutes for gasoline in engines, also the effect of water injection with these different fuels. Some interesting results were obtained and it is evident that these investigations are timely, for in the United States alone in 1914 it is estimated that 25 million gallons of gasoline was consumed.

The immense combination steam-gas engines for the Ford Co. are nearing completion. The large Humphrey pump has been given mention. During the year several firms have started to build Diesel and semi-Diesel oil engines and several oil engines of the two-cycle, heavy-duty type have been put on the market. An interesting innovation in the delivery of oil fuel has been introduced by the government at Fort Baker, Calif. Oil is piped through the streets in the same way as water and gas. It is delivered to residences and other buildings at 30 lb. pressure for use in furnaces, for heating and cooking and in oil engines for power. This installation and the one at the Presidio, San Francisco, are believed to be the first of their kind ever attempted on a large scale.

Water Power

During the past few years the Pacific Coast has come forward with a greater increase in water-power development than any other section of the United States. Immense projects have been completed recently and others are in prospect, but even with the rapid progress that has been made only 7 per cent. of the total potential water power in the three Coast states has been developed. Tennessee, Georgia, the Carolinas and Minnesota have also been active. During the year the low-head 10,500-hp. development at Coon Rapids, which is to serve Minneapolis, was put into commission. The recent agreement between the Secretary of Agriculture and the state water commission of California on the use of water-powers within the national forests will facilitate developments in this territory. The Adamson bill, which passed the House of Representatives on Aug. 4, was a noteworthy attempt to ward off a monopoly in water power still open to title. The regulation of service and rates was to be left to the states. With this provision the governors in their annual conference at Madison, Wis., were in accord, as they unanimously favored state control of natural resources, notwithstanding their declarations to the contrary in former years.

Engineering Societies

Leading engineering societies of the country are becoming more active than ever before in the interests of their respective fields. As their rosters contain the engineering brains of the country, it is natural to expect that they should formulate standards of design, inspection or testing, and through the exchange of ideas on leading topics guide practice more swiftly into channels of economy and safety. It is gratifying to note that their recent work has been particularly well done and should result in lasting benefit. At a meeting early in the year between representatives of the various engineering societies concerned and the manufacturers' committee, practically all differences between the two schedules of flanged fittings were eliminated. There is still a conflict of opinion concerning the name by which the final schedule shall be known, but a committee has been appointed to smooth out this difference.

The work of the committee appointed by the American Society of Mechanical Engineers to draw up standard specifications for the construction of steam boilers and other pressure vessels and for their care in service has been recorded in these columns. The tentative report of the committee has been sent to leading authorities of the civilized world and at a special meeting all parties interested, including steel and boiler manufacturers, were invited to discuss the report. At the annual meeting held in December it was expected that the committee would be able to present its recommendations revised in the light of the discussions and in final form at the spring meeting in 1915. The report is voluminous and is of the greatest importance to engineers and the public at large, as it involves every item of consequence in relation to the safety of steam boilers, from the specifications of steel to the qualifications of men in the boiler room. The boiler makers have already organized to urge the adoption of these rules by all of the states so that their product may be standardized the country over. Due to the magnitude of the movement more progress with the various state legislatures may be expected in the year to come than in all the years that have gone before.

The report of the power test committee of the same association has now been revised and is being put into final form. Its purpose was to standardize the methods of testing the various types of prime mover and auxiliary apparatus. It will constitute one of the most comprehensive publications ever issued by the society.

Plans for the International Engineering Congress to be held in September of next year at the Exposition are well under way. It is to be conducted under the auspices of five leading national associations and will be presided over by Col. George W. Goethals, who has accepted the office of honorary president.

Boiler Explosions

During the first half of the year 1914 there occurred 340 boiler failures of a more or less serious nature. The number reported killed was 120 and injured 240. The estimated monetary loss was reported in 80 cases only; the total for these was, however, $246,000, making an average of about $3000. The greatest loss, $100,000, was from fire following the boiler explosion. The losses resulting from minor failures are not often given, therefore the average loss is higher than would be the case if all were included. Of the strictly power-plant failures 60 were tube failures, 30 were due to cast-iron headers in water-tube boilers, and 17 blowoff pipes gave way.

Cast-iron heating boilers, as used or neglected, are shown to be a menace of no small proportion. More than 70 are reported to have failed. To repeat a statement of a year ago, "more attention should be given to this type of boiler."

License and Inspection Laws

Relative to the passage of state license and inspection laws, last year's work was barren of results. The National Association of Stationary Engineers continued the work it has been conducting for years, and as usual appropriated funds for this purpose. Fewer legislatures in session and a difficulty in convincing those that were, are the reasons given. To obtain uniform laws the association has offered to coöperate with the American Society of Mechanical Engineers.

In Canada a committee of chief boiler inspectors from the different provinces is drawing up a uniform set of regulations which will be adopted by the entire dominion. During the year rules for the inspection and operation of stationary boilers in the Canal Zone were issued by an executive order of Governor Goethals.

For the safe use and handling of refrigerants the Fire Prevention Bureau of New York City has formulated a set of regulations which went into effect five days ago. Boston also has some ideas on the subject. If regulation is needed in these cities, it is needed in every city or state in the country. The regulations, however, must be sound and safe, and a uniform code is by all means desirable.

Isolated Plant vs. Central Station

The controversy between isolated-plant and central-station interests continues, and no abatement may be expected until the legitimate field for each is more definitely established. Indications, however, point toward progress for the former. Such notable examples as the Ford Buildings in Detroit, the Federal Building in Chicago and many others in which isolated plants have effected large savings are proving beyond the question of a doubt the extravagance of buying current, at a rate profitable to the producer, when heating is to be done. The prolonged delay and final reopening of the Edison rate case in New York City also points in the same direction. Discrimination against the small user of current who cannot compete is having its effect either in a reduction of rates by public service commissions or in crystallizing sentiment toward municipal ownership. At the meeting of American mayors in Philadelphia last November the sentiment for municipal ownership of all public utilities was remarkably strong. The body was representative of cities large and small from one coast to the other. If the convictions of the mayors are backed by a majority of their respective constituents, city-operated plants should soon be the rule and not the exception. Pasadena, Cleveland, Detroit, in their street and public lighting, and many other cities are showing that a municipal plant is a profitable investment when run on a business basis.

Honor Roll

Last year medals innumerable were awarded for bravery, generalship and what not pertaining to war, but for scientific achievement the only two recipients of which we have knowledge were Prof. John E. Sweet, who was presented the John Fritz medal, and Charles F. Brush, of arc-light fame, with the Edison medal. Earlier in the year the former was given the degree of doctor of engineering by Syracuse University. The honorary degree of master of science was conferred upon Gano Dunn, president of the J. G. White Engineering Corporation, in recognition of accomplishments and distinction in science and electrical engineering. The Nobel prizes were suspended. Of the various national engineering societies in this country closely related to the power-plant field the following men were elected to the presidency: John A. Brashear, American Society of Mechanical Engineers; C. O. Mailloux (second year of term), American Institute of Electrical Engineers; H. H. Scott, National Electric Light Association; F. L. Ray, National Association of Stationary Engineers; Samuel R. Lewis, American Society of Heating and Ventilating Engineers; Louis Doelling, American Society of Refrigerating Engineers.

Necrology

Men of prominence in the field who passed away during the past year are mentioned in the following list: Prof. W. D. Marks, well known in engineering circles; E. E. Nolan and William Cooper, of the Westinghouse Electric & Manufacturing Co.; George J. Weber, former president of the Weber Gas & Gasoline Engine Co.; John C. Kelley, founder and only president of the National Meter Co.; Franklin Phillips, president of the Hewes & Phillips Iron Works; Edwin M. Hall, treasurer of the Jefferson Union Co.; Eugene McSweeney, president of the United States Graphite Co.; Prof. E. J. Houston, co-inventor with Prof. Elihu Thomson of the first successful arc-lighting system; Columbus Dill, known by engineers throughout the country; George Westinghouse, the well known inventor and engineer at the head of the Westinghouse interests; John F. Shearman, perhaps better known by his nom-de-plume, Peter Van Brock; Edwin M. Coryell, for many years consulting engineer for the Cameron Steam Pump Works; James W. Thomson, chief engineer U. S. N., retired; Walter Laidlaw, secretary of the International Steam Pump Co.; H. R. Gilbert, manager of the Continental Works of the National Tube Works Co.; W. F. Crane, member of the family known all over the country as engineers; John Erwood, consulting mechanical engineer and inventor of the various valves and water-tube boiler bearing his name; George Willard, formerly connected with the Murray Iron Works Co.; M. Carels, one of the founders of the firm of Carels Frères; Sir Joseph W. Swan, one of the early inventors of the incandescent electric light; Frank L. Busey, engineer of Buffalo Forge Co.; George N. Nistle, vice-president of the Illinois Engineering Co.; Quimby N. Evans, senior partner of the firm of Evans, Almirall & Co.; Edward B. Denny, past-president of the National Association of Master Steam and Hot Water Fitters; Edwin F. Williams, an authority on steam engines and a prominent designer; John B. Allen, a prominent engineer and salesman, formerly vice-president and general manager of the Allis-Chalmers Co. and later Western sales manager for the Westinghouse Machine Co.; Albert B. Franklin, a well known heating and ventilating engineer; J. H. Millett, president of the Crosby Steam Gage & Valve Co.; T. G. Meier, vice-president and treasurer of the Heine Safety Boiler Co., and Col. E. D. Meier, president of the same company and one of the most eminent mechanical engineers in the country, and Charles A. Moore, president of Manning, Maxwell & Moore and identified with the Shaw Electric Crane Co., the Consolidated Safety Valve Co., the Ashcroft Manufacturing Co., the Hancock Inspirator Co., and the United Injector Co.

Engineers' Wages

That the wages of engineers are not the same in Wichita, Kan., as they are in Foxboro, Mass., worries one of our contributors in this issue (page 18). He went to the trouble of sending about seventy-five letters to engineers in widely separated parts of the country and found that there is no consistency in the salaries paid engineers in similar sized plants. After all it is not surprising; doctors right in the same city get widely different prices for the same operation (sometimes their fee depends on what the patient is able to stand financially). So it is in all professions and trades (except where unions have artificially fixed the scale of wages); workers are rewarded according to their ability, and their availability. Relative competence makes for differences in wages, and supply and demand have as much influence on the labor market as any other. Mr. Pagett has made an interesting little research into a subject we are all much concerned about, but we do not look for any changes in conditions in consequence of it.

Central stations in Germany are showing less loss of business, because of the war, than would be naturally expected, according to a report. Thi would seem to prove that they are a more hardy kind of vegetation than isolated plants. *Auch*, weeds are harder to kill than things you want to raise.

Someone has said that "while figures do not lie, liars sometimes figure." This is not to cast any reflections on those who have taken part in the discussion of the engine for the Karpen plant (page 27), but to emphasize the possibility of arriving at results which prove one thing, or the contrary, according to the assumptions that are made before, during or at the end of the calculations. One guess is as good as another and neither can be bolstered up with mathematics. It is still a guess, however much it may be concealed in figures to give it an air of truth.

Correspondence

Why Did the Gage Hand Vibrate?

Our six 66-in.x16-ft. return-tubular boilers are connected to a common header from which steam is taken for two 30, 52 and 61½x36-in. cross-compound pumping engines. Between the hours of six and nine in the morning and evening, the hand of the recording steam gage vibrated considerably. This action continued for five days, or until the oiler opened wide the valve to the gage, allowing the hand to vibrate rapidly. When the valve was closed to the normal opening, the vibration ceased and has not occurred since.

We are wondering what the cause of the trouble was, and would be pleased to read what some readers think was the cause.

A. E. Aldrich.

Newman, Calif.

Engine for Karpen Plant

The article in Power of Oct. 27 dealing with the Karpen factory plant is well worth the attention of every operating engineer, as it illustrates some of the problems entering into the choice of an engine. However, in the writer's opinion, the results obtained were not quite fair to the compound engine.

Before entering upon that phase of the subject attention is called to the efficiency allowed the generator of the compound unit. It is evident that this machine was of inferior make to show only 90 per cent. efficiency. The writer is fairly familiar with the standard makes and in no case has an efficiency as low as this been encountered when the machine was larger than 75 kw. The correct thing would have been to substitute a better generator.

Then, as regards the extra charge for oil for the compound engine, it would seem that $100 is too much to add. In the yearly report at the end of the article, it was shown that the cost of all the oils used in the entire plant was only $112.64 for six months; surely the oil charge for the simple engine only would not exceed $100 per year. If this be true, then the additional oil used on a compound engine would not exceed $25; for the cylinder oil would be almost the same as on a simple engine, while the engine oil should be approximately the same in either case.

Approaching the question of fuel cost of the two installations, it must, first of all, be understood that in arriving at the solution of the question as to the best unit to install, the steam-heating question must also be considered. It is evident that with the steam heating eliminated, the compound engine would be the one to purchase. But the steam heating complicates the problem and it is necessary to consider its effect on the steam cost.

First, take the simple engine. It is to develop 250 kw. 10 hr. per day for 300 days, with a water rate of 24 lb. per i.hp.-hr., engine efficiency 93 per cent., dynamo efficiency 92 per cent. Then the amount of steam passing through the simple engine hourly during the eight heating months would be

$$\frac{250 \times 24}{0.93 \times 0.92 \times 0.746} = 9404 \textit{ lb.} \qquad \text{(A)}$$

The B.t.u. passing into the heating coils at a pressure of 16 lb. abs. would be

$$9404 \times 1034.1 = 9{,}724{,}676 \qquad \text{(B)}$$

This amount of heat is absorbed by the heating system and should be charged against it. In live steam at a pressure of 140 lb. abs. it is equivalent to

$$\frac{9{,}724{,}676}{1192.2} = 8157 \textit{ lb.} \qquad \text{(C)}$$

Whether expressed in B.t.u. or in equivalent pounds of live steam, this is the heat the simple engine has supplied the heating system and its cost must be charged against it.

With an evaporation of 7 lb. of water per pound of coal, the latter costing $3 per ton, the charge per hour against the heating system would be

$$\frac{8157 \times \$3}{7 \times 2000} = \$1.748 \qquad \text{(D)}$$

Likewise, since the simple engine handled 9404 lb. of steam, the charge against both engine and heating system per hour would be

$$\frac{9404 \times \$3}{7 \times 2000} = \$2.015 \qquad \text{(E)}$$

For ten hours per day for eight months the cost would be

$$\$2.015 \times 10 \times 200 = \$4030$$

It is self-evident that the difference between (D) and (E) is the actual cost of the heat used in the simple engine. Thus, per hour, this amounts to

$$\$2.015 - \$1.748 = \$0.267 \qquad \text{(F)}$$

Taking up the operation of the compound during the eight heating months it is found that the engine has a water rate of 20.5 lb. per i.hp.-hr. Developing 250 kw., with an engine efficiency of 88 per cent. and a dynamo efficiency of 90 per cent., the steam passing through the engine per hour would be

$$\frac{250 \times 20.5}{0.90 \times 0.88 \times 0.746} = 8674 \textit{ lb.} \qquad \text{(G)}$$

The heat units given up to the steam-heating coils would then be

$$8674 \times 1034.1 = 8{,}969{,}783 \textit{ B.t.u.}$$

Since all the exhaust from the simple engine was to be used, then if the compound engine was to be installed there would not be sufficient exhaust steam. This would necessitate using live steam to make up the difference. Since the simple engine would supply 9,724,676 B.t.u. and the compound only 8,969,783 B.t.u., the difference would be

$$9{,}724{,}676 - 8{,}969{,}783 = 754{,}893 \textit{ B.t.u.}$$

Expressed in equivalent pounds of live steam at 140 lb. abs., this would amount to

$$\frac{754,893}{1192.2} = 633\ lb. \quad \text{(H)}$$

The operation of the compound would therefore cause the consumption of not only the steam passing through it, but also of a quantity of "makeup" steam. The total amount per hour would be

$$8674 + 633 = 9307\ lb. \quad \text{(I)}$$

The fuel cost per hour would be

$$\frac{9307 \times \$3}{7 \times 2000} = \$1.99 \quad \text{(J)}$$

Then the cost of steam per hour which should be charged against the compound engine would be

$$\$1.99 - \$1.748 = \$0.242 \quad \text{(K)}$$

Since the engines were to operate for two-thirds of the working year, ten hours per day, under these conditions, the charge against the simple engine would be

$$\$0.267 \times 200 \times 10 = \$534$$

and against the compound engine

$$\$0.242 \times 200 \times 10 = \$484$$

Taking up the peak load of 75 kw., which occurs for three hours per day for 100 days each year, it is necessary to go through the same process. These calculations, simplified, are as follows: Steam passing through simple engine

$$\frac{75 \times 3 \times 100 \times 24}{0.93 \times 0.92 \times 0.746} = 846,395\ lb.$$

Cost of this steam

$$\frac{846,395 \times \$3}{7 \times 2000} = \$181.37$$

Equivalent live steam supplied coils

$$\frac{846,395 \times 1034.1}{1192.2} = 734,153\ lb.$$

Cost of steam for coils

$$\frac{734,153 \times \$3}{7 \times 2000} = \$157.32$$

Steam passing through the compound engine

$$\frac{75 \times 3 \times 100 \times 20.5}{0.90 \times 0.88 \times 0.746} = 780,721\ lb.$$

Equivalent steam furnished heating system

$$\frac{780,721 \times 1034.1}{1192.2} = 677,188\ lb.$$

Amount of live steam that must be added on account of compound engine not supplying enough

$$734,153 - 677,188 = 56,965\ lb.$$

Cost operating compound and heating system

$$\frac{(780,721 + 56,965) \times \$3}{7 \times 2000} = \$179.50$$

Fuel cost operating compound engine

$$\$179.50 - 157.32 = \$22.18$$

Fuel cost operating simple engine

$$\$181.37 - 157.32 = \$24.05$$

Considering the four months where 30 per cent. of the exhaust steam is wasted, the simple engine is using

$$\frac{250 \times 10 \times 100 \times 24}{0.93 \times 0.92 \times 0.746} = 9,404,389\ lb.$$

The cost of the steam passing through the simple engine is

$$\frac{9,404,389 \times \$3}{7 \times 2000} = \$2015.23$$

The equivalent live steam supplied the heating system and used is

$$\frac{(9,404,389 \times 1034.1)}{1192.2} \times \frac{70}{100} = 5,710,078\ lb.$$

Cost of exhaust heating

$$\frac{5,710,078 \times \$3}{7 \times 2000} = \$1223.59$$

Charge against simple engine

$$\$2015.23 - \$1223.59 = \$791.64$$

The compound engine during this time would use

$$\frac{250 \times 10 \times 100 \times 20.5}{0.88 \times 0.90 \times 0.746} = 8,674,678\ lb.$$

Cost of steam

$$\frac{8,674,678 \times \$3}{7 \times 2000} = \$1858.86$$

Charge against compound engine

$$\$1858.86 - \$1223.59 = \$635.27$$

Then the total fuel charge against the simple engine would be

$$\$534 + \$24.05 + \$791.64 = \$1349.69$$

The total charge against the compound engine would be

$$\$484 + \$22.18 + \$635.27 = \$1141.45$$

The summary of total charges would then become

	Simple Engine	Compound Engine
Fixed charges	$1435.92	$1568.00
Fuel	1349.69	1141.45
Extra oil	......	25.00
Total	$2785.61	$2734.45

So that, even in the face of an excessive depreciation charge, the compound proves more efficient.

The engineer calculated that 25 per cent. of the two total charges would be eliminated by using shavings. This is wrong since both heating and power are under consideration. If power were purchased then the shavings could be used in supplying the live steam to the heating system so that the entire fuel charge against either engine represents coal purchased. But assume that the engineer's contentions are correct, then the fuel for the simple engine would be represented by coal, $1012.27, and shavings, $337.42. Then since the total fuel charge of the compound is $1141.45, this would be divided as follows: Shavings, $337.42; coal, $804.03. This is true as the amount of shavings available is the same regardless of the kind of power. Then the summary becomes

	Simple Engine	Compound Engine
Fixed charges	$1435.92	$1568.00
Coal	1012.27	804.03
Extra oil	......	25.00
Total	$2448.19	$2397.03

L. H. Morrison.

Dallas, Texas.

The above discussion is interesting as it attacks the problem from a different angle than the method employed by Mr. Ory. The latter figured each machine independently and divided the cost for steam between the engine and the heating system on the basis of the heat units utilized. Mr. Morrison does the same thing for the simple engine. With the compound engine, he supplies the same amount of heat to the heating system by finding the deficiency in the exhaust, reducing it to its equivalent in live steam and charging it, along with the steam actually utilized, against the compound engine.

In the cost of fuel, per year, he finds a difference of $208.24 in favor of the compound engine. By Mr. Ory's method the saving in fuel effected by the use of a compound engine amounted to $67.25. Using the same fixed charges and reducing the extra oil required by the compound from $100 to $25, Mr. Morrison finds a balance of $51.16 favoring the compound engine. In his figuring Mr. Ory shows a gain of $164.83 for the simple engine.

Although it was not so stated in the article, the oil item of $100 was intended to include additional supplies required. The exact amount to charge is, of course, a matter of judgment, but in the writer's opinion the item should be much nearer $100 than $25. The efficiencies for the compound unit were placed low, as a price $766 lower than for the simple engine indicated light and cheap construction. Naturally, this would result in lower economy and greater depreciation.

An item which would affect the balance considerably, not touched upon in the above discussion, is the cost of the compound engine. A compound unit of equal quality should cost about one-fourth more than the simple unit, or, in round numbers, $15,000. Then reducing the depreciation to the 5 per cent. assumed for the simple engine, the fixed charges are higher by $232 and $364 more than for the simple engine. Raising the efficiencies of the compound engine and generator to those of the simple unit would slightly reduce the fuel cost for the compound, but there would still be a considerable balance in favor of the simple engine.

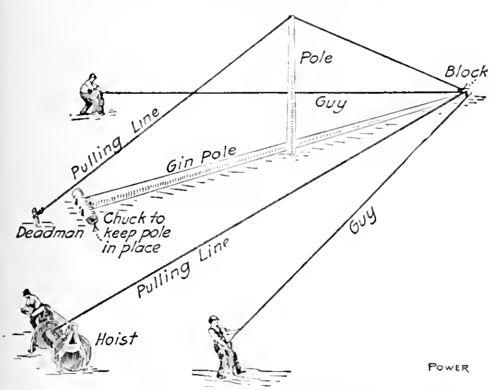
The above figures are, of course, arbitrary, as they are all based on assumptions, but, generally speaking, when practically all of the exhaust steam is used in the heating season and 70 per cent. of it in the summer months, there is little need for a compound engine. The small saving in coal that might be effected will not warrant the additional expenditure usually required for a good compound unit.

Thomas Wilson.

Chicago, Ill.

Raising a Gin Pole

There are occasional articles in Power regarding the erection of smoke-stacks, but I have never noticed any information on how to raise a gin pole with which to begin the stack-raising job. Here in Alaska we use from forty-



Approximate Positions of Men Raising Gin Pole

to sixty-foot gin poles and raise them off the ground without a mast. We require only three men, two at the guys and one at the hoist.

When the pole is laid in place, the guys are put on, a block of wood or a cable at the butt keeping the pole from moving ahead. A single pulley block is fastened at the top. The pulling line runs from the hoist through the block back to a fixed point or dead-man in line with the gin pole. A pole about fifteen feet long, having a small notch cut in one end, is placed vertically under the pulling line about midway of the gin pole. When power is applied and the pulling line tightens up, the pole is raised off the ground. After it is up some distance, the pole under the cable is released and falls, but the hoist keeps on pulling until the pole is up. (The illustration does not show the fixed points in their true relative positions on account of lack of space.)

This is a simple and quick way to raise a pole.

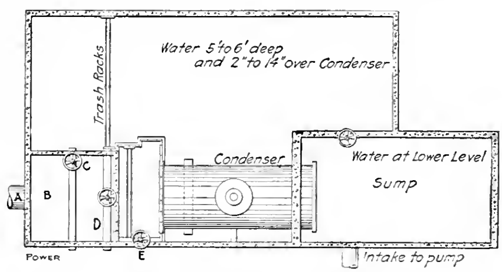
Novel Condenser Setting

While visiting the La Habra Valley Water Co.'s plant, near Whittier, Calif., I saw what I thought was a good condenser setting.

A surface condenser was set in an enlarged section of



Condenser in Intake Canal

the intake canal into which the water flows by gravity from wells in the hills. The general layout is shown in the illustration. The water enters through conduit *A* into receiver *B*. From there it is bypassed through gate *C* or through the condenser tubes by opening gate *D*, and by adjusting the two gates the flow is regulated.

Gate *E* may be used to drain off the water for cleaning out or repairing the condenser or basin. All the other details are as in the average surface condenser plant. The prime object is, of course, saving power by avoiding handling the cooling water with a pump.

C. R. Clark.

Anaheim, Calif.

Finding the Value of Coal

The writer encountered a case recently in which there was a possibility of considerable saving if a certain coal could be economically used. His plant is served by two rival roads which will be designated A and B. A good free-burning coal had been obtained on road A, but its unloading switch was so far from the boiler room that it cost about ten cents a ton to haul the coal. As road B could bring coal directly to the boiler-room door, it was desirable to thus obtain the coal and save the additional expense.

After trying several more or less unsatisfactory coals a coal was found which could be obtained by road B and which, with the same cost per ton on the switch, gave better results by a laboratory test than the coal which had been formerly shipped on road A. Upon testing in the boiler room, however, it clinkered badly and gave a low evaporation. The practical test alone would probably have proved the coal unsatisfactory. As the analysis was good it was decided to experiment further with the coal. In the course of a few days, it was found that by altering the depth of fire carried and the method of firing, the coal could be burned without serious clinkering. The evaporation went up, and this coal has since proved more satisfactory than that formerly used. At the same time, 10c. a ton has been saved on handling.

In this case the plant superintendent acted as his own chemist and he was fortunate in having an engineer who was broad-minded, eager to produce results and to save money for his company.

The writer does not argue that any coal which appears well from a laboratory test can be used economically in regular operation, but a good showing by a coal in the laboratory, if properly considered, will result in an exhaustive test in the boiler room and may be the means of saving much money.

WILLIAM A. DUNKLEY.

Atlantic City, N. J.

Water-Hammer in Blowoff Pipes

In boiler plants where the main blowoff header leads into a catch basin emptying into the city sewer through a small drain, care should be taken to avoid water-hammer. If the basin fills up above the end of the blowoff, the water will flow back into the pipe as it cools slightly; then if another blowoff valve is opened before the water recedes, water-hammer is almost sure to occur. I know of such a case where one man lost his life when a fitting ruptured. Beware of short bends and water in blowoff pipes.

JOHN F. HURST.

Louisville, Ky.

Water End of Pump Was Vapor Bound

In starting four feed pumps in a new power house not long ago, it was discovered that the feed-water heaters were set too low to supply the upper suction-valve chambers of the vertical feed pumps when the water was over 200 deg. F. The erecting and consulting engineers admitted that a mistake had been made, but they were powerless to remedy it. After it had become necessary to cut the steam off the heaters to secure quiet working of the pumps, reducing the feed-water temperature to 150 deg. F., the operating engineers connected a pipe between the upper suction-valve chamber of the vertical duplex feed pump with the return tank, so as to relieve the heater of the high back pressure.

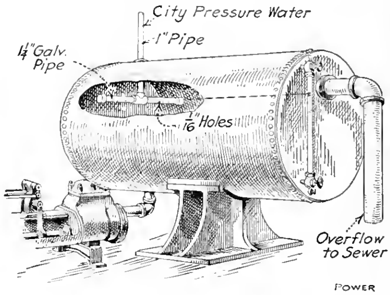
Weaker springs were put on the upper suction valves so that the valves would open and admit water at a lower vacuum than before the change. The vapor which heretofore filled the suction pipe and pump-valve chambers now found an outlet through the vapor pipe. The result was that the pump worked without slamming and the feed-water temperature increased to 210 deg. F.

JACOB R. REZNIEM.

Brooklyn, N. Y.

Oil Skimmer

The illustration shows an oil skimmer which I believe will clear the receiver of most of the cylinder oil. At one end of the receiver is a spray pipe with holes in only one side. City water is turned on when the receiver is



PERFORATED PIPE IN RECEIVER

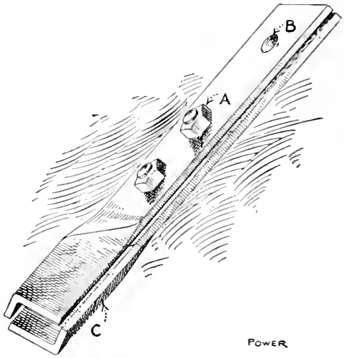
overflowing and the force of the spray skims the oil from the water and drives it toward the overflow and to the sewer. If this is done once a day there will be little or no trouble from cylinder oil.

A. C. WALDRON.

Revere, Mass.

Adjustable Socket Wrench

The illustration shows how a handy adjustable socket wrench may be easily made. One end of two flat bars is formed as shown at *C*. Bolts *A* should be threaded for



HOME-MADE WRENCH

quite a length to afford adjustment. A hole *B* will be found convenient at the top for a bar to turn the wrench. An extension bar may be used to lengthen the wrench when used in a cramped place.

JAMES E. NOBLE.

Toronto, Ont.

Inquiries of General Interest

Common Exhaust Line for Several Engines—Is it good practice to have several noncondensing engines exhausting into one exhaust line?

E. C. P.

It is general practice to have a common exhaust line for several engines, and it works satisfactorily providing the main exhaust line is large enough for handling the exhaust from all the engines without materially increasing back pressure on any of them.

Temperature of Oil Discharged from Step Bearings of Steam Turbines—What temperature is proper for oil discharged from the step bearing of a steam turbine?

B. H. C.

The maximum oil temperature permissible will be determined by the viscosity of the oil for the temperature at which it is discharged. Using a good quality of oil for the step bearings of large vertical Curtis turbines the temperature of the discharged oil is about 150 deg. F., thereby attaining a rise of about 50 deg. F.

Cost of Operating Electric Motor—What would be the cost of operating a 100-hp. motor using current costing 2c. per kw.-hr.?

C. W. R.

One horsepower equals 746 watts, and 100 hp. would equal 100 × 746 watts, or

$$\frac{100 \times 746}{1000} \text{ kw.}$$

With a motor of 91 per cent. efficiency, the input required for an output of 100 hp. would be

$$\frac{100 \times 746}{1000 \times 0.91} \text{ kw.}$$

and with current costing 2c. per kw.-hr. the cost would be

$$\frac{100 \times 746}{1000 \times 0.91} \times 0.02 = \$1.64 \text{ per hr.}$$

Variation of Water Column for Difference of Temperature—When our boiler is operated at 100 lb. gage pressure, and the temperature of the water in the column and connections is 95 deg. F., the water level shown by the glass gage is 30 in. above the point where the water column connects with the boiler. How much higher would the water level show in the glass gage if the temperature were the same as the temperature of the water in the boiler?

M. C. R.

For 100 lb. gage pressure the temperature of the boiler water would be about 338 deg. F. A cubic foot of water at 95 deg. F. weighs 62.06 lb. and at 338 deg. F. weighs 56.01 lb. For producing the same hydrostatic pressure at the foot of the connection the height of water column would be inversely as the density of the water. Therefore with a density corresponding to the temperature of the boiler water the water level would stand

$$(30 \text{ in.} \times 62.06) \div 56.01 = 33.24 \text{ in.}$$

above the foot of the connection—i.e., it would show about 3¼ in. higher level than with the water in the connections at 95 deg. F.

Obtaining Absolute Pressures from Gage Readings—Why can not the dial of an ordinary Bourdon spring pressure gage be laid off to indicate absolute pressures by direct readings?

C. J. R.

The tube of a Bourdon spring gage is moved by the difference of pressure inside and outside of the tube, and for indicating absolute pressure either the interior or the exterior pressure would have to be constant. As ordinarily constructed the exterior of the tube is exposed to atmospheric pressure, and as this is variable the dial is laid off only for pressures above or below the atmosphere. Hence "0" gage pressure is atmospheric pressure, and as the gage indicates the difference between atmospheric pressure and the internal pressure, then when the internal pressure is greater than atmospheric pressure, as in the ordinary pressure gage, the absolute pressure will be gage pressure plus atmospheric pressure. When the internal pressure is less than atmospheric pressure, as in the case of a vacuum gage, the absolute pressure will be the atmospheric pressure minus the difference of pressure indicated.

Heating Value of Steam at 4 lb. and at 80 lb. Pressure—What is the relative heating value of steam at 4 lb. and at 80 lb. gage pressure when used in a pipe coil or radiator and discharged to a trap?

H. W. J.

Considered with reference to the weight of steam received by a radiator and discharged as condensate at the same pressure, the heating value in each case would be its latent heat of evaporation. The latent heat of a pound of steam at 4 lb. gage pressure is about 962 B.t.u., and for 80 lb. gage pressure it is about 891 B.t.u. Therefore, the heating value of steam at 4 lb. pressure would be $\frac{962}{891}$ times, or have about 7 per cent. greater heating value than the same weight of steam received and discharged as condensate at 80 lb. pressure.

Considered with reference to heating effect from a given amount of radiator surface, the steam of higher pressure would also be at a higher temperature and the radiation of heat would be more rapid, depending on the difference between the temperature of the steam and that of the surrounding atmosphere. With the temperature of the surrounding atmosphere at 70 deg. F. in each case, then as the temperature of steam at 4 lb. gage pressure is about 225 and at 80 lb. gage pressure is about 324 deg. F., for the same radiating surface the relative rate of radiation would be (225 — 70) to (324 — 70), or as 155 to 254—i.e., only about $\frac{155}{254}$ or 61 per cent. as much heat would be radiated from a coil or radiator supplied with steam at 4 lb. as from one supplied with steam at 80 lb. gage pressure.

Factor of Evaporation with Superheater—What would be the factor of evaporation for the performance of a boiler with a superheater where the following averages were observed?

Absolute steam pressure in steam drum......	150 lb. per sq.in.
Absolute steam pressure at entrance of superheater	149 lb. per sq.in.
Absolute steam pressure at outlet of superheater	147 lb. per sq.in.
Temperature of steam at outlet of superheater.	478.5 deg. F.
Temperature of feed water	100 deg. F.

W. F.

Considering the superheater as a part of the boiler, the factor of evaporation of the boiler should be based upon the pressure and temperature of the steam at the outlet of the superheater, viz.: 147 lb. absolute and a temperature of 478.5 deg. F. The temperature of dry saturated steam at 147 lb. absolute is 356.9 deg. F., therefore a temperature of 478.5 deg. F. would represent

$$478.5 - 356.9 = 121.6 \text{ deg. of superheat.}$$

Referring to the Marks and Davis steam tables, the total heat of a pound of steam at 147 lb. absolute when superheated 120 deg. F. is 1259.4 B.t.u. above 32 deg. F., and when superheated 130 deg. F. is 1264.5 B.t.u. By interpolation between these values, the total heat per pound of steam at 147 lb absolute, superheated 121.6 deg. F., would be

$$1259.4 + \left[\left(\frac{1264.5 - 1259.4}{130 - 120}\right) \times (121.6 - 120)\right] = 1260.21 \text{ B.t.u.}$$

so that with feed water at 100 deg. F. each pound of feed water evaporated into steam at 147 lb. absolute and 478.5 deg. F. would receive

$$1260.21 - (100 - 32) = 1192.21 \text{ B.t.u.}$$

The latent heat of evaporation of water from and at 212 deg. F. being 970.4 B.t.u. per lb., the factor of evaporation under the condition stated would be

$$\frac{1192.21}{970.4} = 1.2286$$

Engineers' Study Course

Problems in Power-Plant Design--XII

WATER SUPPLY AND FIRE PROTECTION, CONTINUED

The quantity of water required and the horsepower necessary for pumping it from the river to the reservoir have already been approximated, but in designing the pumping outfit it will be necessary to go over the matter a little more carefully.

The maximum supply was based on that required for condensing and was taken as 7000 lb. approximately per min. This made an allowance for the exhaust from auxiliaries and assumed that the total amount of steam supplied to the engine would be discharged into the condenser.

In the final arrangement of the plant it was decided to utilize the exhaust from the auxiliaries in a feed-water heater, and in making the more accurate computation we will make use of Table 1 in last lesson, which takes cylinder condensation into account. Thus

$$\frac{670 \times 15 \times 35}{60 \times 8.3} = 707 \textit{ gal. per min.}$$

will be required. It will be remembered that 670 hp. was required for the entire plant: 15 is the water rate minus 10 per cent. and 35 is the pounds of water required to condense a pound of steam.

In the present case the surface of the river is 50 ft. below the power house, so it will be necessary to locate the pump in a special building at such an elevation that the total suction lift will not exceed 15 ft. With this arrangement a motor-driven centrifugal pump would seem to be well adapted to the conditions presented. Such a machine requires but little attention, it may be shut down from the engine room, and power is easily trans-

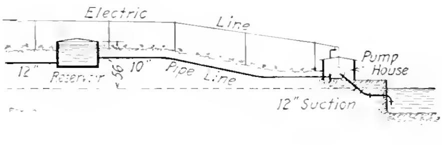

FIG. 1. PUMPING WATER SUPPLY FROM RIVER

mitted from the central plant. There is little choice in a case of this kind between the triplex plunger pump and a centrifugal, but the latter is simpler in construction and may be driven by a direct-connected motor without the use of gears or belts.

In the design of the pumping plant the first step is to find the size of main between the pump and the reservoir, which is usually fixed by the relation between the saving in cost of pipe and the increased cost of pumping against a greater head. A large pipe reduces the friction and therefore saves in pumping expenses, but it costs more to install. Under average conditions a velocity of 2 ft. per sec. for pipes up to 10 in. in diameter, and a velocity of 3 ft. for larger sizes, seem to give about the right balance between the cost of pipe and that of pumping.

A table of velocities and friction heads for water pipe shows that a 10-in. pipe will discharge 750 gal. per min.

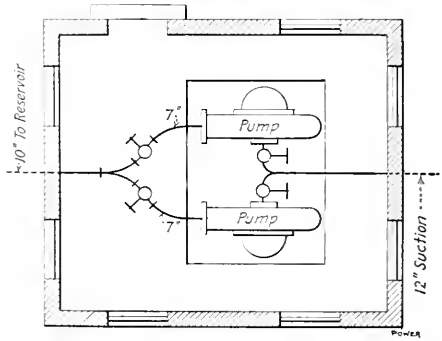

FIG. 2. TWO CENTRIFUGAL PUMPS ON WATER SUPPLY

at a velocity of 3.06 ft. per sec., and with a friction head of 0.18 lb. per in. or

$$0.18 \times 2.3 = 0.41 \textit{ ft.}$$

for each 100 ft. For the entire run of 500 ft. this gives

$$0.41 \times 5 = 2.05 \textit{ ft.}$$

As the run is of comparatively short length, a velocity of 3 ft. per sec. will be assumed and a 10-in. pipe used. Doubling this friction head to include bends and valves, and adding 6 ft. for the elevation of the reservoir, gives a total lift of

$$50 + 4 + 6 = 60 \textit{ ft.}$$

to be pumped against. Assuming a slip of 30 per cent. the pump must have a rated capacity of

$$707 \div 0.7 = 1010 \textit{ gal. per min.}$$

under a head of 60 ft. A table of centrifugal-pump capacities states that a pump with a 21-in. impeller and a 7-in. discharge outlet will deliver 1058 gal. per min. under a 60-ft. head at a speed of 655 r.p.m. This is the size that should be used in the present case. Assuming an efficiency of 60 per cent., the horsepower of motor for driving it will be

$$\frac{707 \times 8.3 \times 60}{33{,}000 \times 0.6} = 18$$

say, 20 hp. to make it a standard size. Two pumping units are provided, Fig. 2, and with the pipe sizes used they may be operated together when a large supply of water is wanted, as in case of fire.

RESERVOIR

It was assumed in a previous article that the reservoir should have a storage capacity equal to that required for a day's run, which we will take as a maximum of 8 hr. and which calls for

$$707 \times 60 \times 8 = 339{,}360 \textit{ gal.}$$

A reservoir 50 ft. in diameter by 30 ft. in height will give an excess capacity of about 100,000 gal. By duplicating the pumping machinery it would probably not be necessary to provide so large a storage reservoir, because in case of a breakdown to both of the pumps the engine could be run noncondensing, and a storage capacity of half the above would be ample for boiler feeding and fire purposes during a temporary shutdown of the pumping plant.

It will be sufficient to provide a concrete reservoir 50 ft. in diameter by 15 ft. in depth, extending 6 ft. above grade. This will make it possible to drain it into the main sewer, and also, under normal conditions, there will be sufficient head to cause the water to flow to the pumps and to the receiving tank and boilers by gravity. Diagrams showing the general arrangement of the pumping machinery, pipe line and reservoir are given in Figs. 1 and 2.

Fire Protection

A system of fire protection consists of two parts—one for outside service, made up of hydrants and their underground connections, and a sprinkler system for inside protection. The rules for laying out a system of this kind vary somewhat in different localities, and the proposed system should be submitted to the fire underwriters for that district before its installation. The following data are general in character and correspond to average conditions.

Water Supply

There should be two independent supplies, one of which should be automatic and capable of furnishing water under a heavy pressure. Common sources of supply are a pond, river or large reservoir from which the water is drawn by a pump, city mains, and elevated or pressure storage tanks. A combination of any two of these will usually give sufficient protection.

Pumps

Standard fire pumps have capacities of 500, 750, 1000 and 1500 gal. per min. The 1000-gal. size is the one most frequently used, although many 750-gal. pumps are installed. The 500-gal. size is only for use in the smallest plants. It is more common to have two smaller pumps than a single large one of 1500 gal. capacity. The pumps most frequently used for this purpose are the direct-acting steam pump, rotary pump and electrically driven pumps, while turbine or centrifugal pumps are also employed to some extent. All of these pumps are made in standard sizes for this purpose. The pumps should always be duplicated and so connected that they may be run either singly or together.

Outside Protection

Hydrants are commonly placed from 150 to 200 ft. apart and provided with two to four hose outlets each, three being the standard. They should be located about 50 ft. from the buildings they are to protect, depending somewhat upon the height. There are two general methods employed for supplying the hydrants, known as the "loop" system and the "dead-end" system; they are sufficiently described by their names. The former is usually preferable, as smaller mains may be used, the supply coming from both directions. The number of hose outlets supplied from mains of different sizes are given in Table 3:

TABLE 3. NUMBER OF HOSE CONNECTIONS

Size of Main, In.	Length of Main, Ft.	Number of Hose Outlets on "Dead-End" System	Number of Hose Outlets on "Loop" System
6	250	3	6
6	500	2	4
4	250	6	10
8	500	4	8
8	1000	3	..

A two-way hydrant should have a 5-in. gate and three- and four-way hydrants have a 6-in. gate. While the largest mains given in the table are 8 in., large plants will often call for 10- and 12-in. mains.

Sprinkler Systems

The spacing of the sprinkler heads will depend somewhat upon the construction of the building. For standard mill construction, the spacing given in Table 4 may be used, with one line of sprinklers in the center of each bay. Pipe sizes are given in Table 5.

TABLE 4. SPACING OF SPRINKLER HEADS

Width of Bay, Ft.	Distance Between Sprinkler Heads, Ft.
6 to 8	12
9	11
10	10
11	9
12	8

TABLE 5. PIPE SIZES FOR SPRINKLER SYSTEM

Pipe Size, In.	Number of Sprinklers	Pipe Size, In.	Number of Sprinklers
1	2	3	36
1¼	3	3½	55
1½	5	4	80
2	10	5	140
2½	20	6	200

When an elevated tank forms one of the supplies for a sprinkler system it should have a capacity of 10,000 to 20,000 gal., 15,000 being about the average.

Pressure tanks may be made somewhat smaller on account of the higher pressure carried. A tank of 6000-gal. capacity corresponds to one of 10,000 of the elevated or gravity type. In practice it is customary to use two or more smaller pressure tanks rather than a single larger one on account of the expense, 8000 to 9000 gal. being about the limit. In general, tanks of this kind are located above the sprinklers, kept about two-thirds full of water and subjected to a pressure of 75 lb. per sq.in., which insures a pressure of 15 lb. when the tank is empty. Both elevated and pressure tanks may be made to connect with a general system of fire mains, from which the sprinkler system takes its supply, provided there is sufficient head to maintain a minimum pressure of 15 lb. at the highest sprinkler heads.

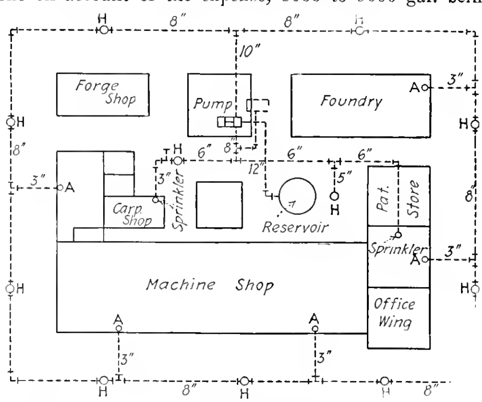

Fig. 3. Layout of Hydrants and Outside Piping

According to Table 4, the following number of sprinklers will be necessary in the rooms to be protected: Office, 40; drafting room, 40; pattern shop, 40; pattern storage, 50; carpenter shop, 24; paint shop, 6; a total of 200.

Assuming that 60 sprinkler heads will require 250 gal. of water per min., the total requirements for one hour for this purpose will be

$$\frac{200 \times 250 \times 60}{60} = 50{,}000 \ gal.$$

which is only about one-third the capacity of the storage reservoir and therefore well within allowable limits.

The general layout of the hydrants and outside piping is shown in Fig. 3. The loop system is employed for the outer system of hydrants, with a dead-end supply for the sprinklers and two yard hydrants as indicated.

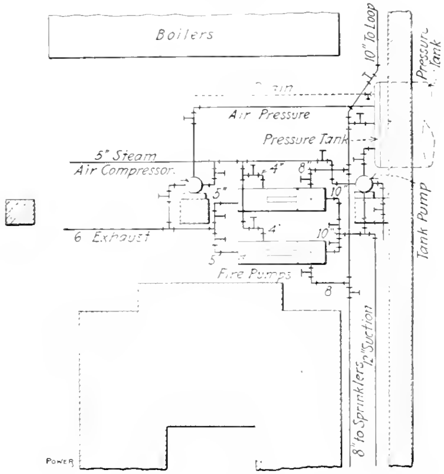

FIG. 4. ARRANGEMENT OF WATER-PRESSURE EQUIPMENT IN POWER HOUSE

Inside standpipes, with hose connections, are provided in the machine shop, office wing, foundry and carpenter-shop storage at the points marked *A* on the plan. While an 8-in. loop has a capacity of but eight hose outlets, it is assumed that not more than this number will ever be in use at one time, although there are 9 three-way hydrants on the line.

The arrangement of the pressure equipment in the power house and the various pipe connections are shown in Fig. 4. A pressure of 100 lb. per sq.in. is constantly maintained on the system for automatic sprinkler supply by means of a pneumatic tank having a capacity of 6000 gal. With the tank two-thirds full and the air space above it subjected to this pressure, there will be at least 15 lb. upon the highest sprinklers when the tank has discharged its entire contents.

The tank is filled by means of a special pump, indicated in the drawing, which should be arranged by means of a float valve to maintain the normal water line automatically and thus offset the effect of any leakage in the system. The pressure should also be maintained automatically by means of a compressor actuated by changes in the system.

Two 1000-gal. direct-acting steam pumps are provided. While one is furnished as a relay, the pipe connections are such that they may be operated together in case of emergency. A pump of the type and capacity used will supply four standard fire streams and will require about 150 boiler-horsepower for operating it.

Scientific Boiler Feeding

By E. W. NICK

It is well known that it is impossible to quickly change the intensity of furnace fires and the rate of boiler feeding with every change of load. When the load changes there should be a corresponding change in the rate of feeding, which should be slow enough to allow a gradual and economical change in the furnace fires.

There are advantages obtained by lowering the water level to secure greater steaming capacity for peak and overloads, and raising it during subnormal and no loads to save heat energy. A continuous feed and a scientifically varied water level are desirable features to obtain by any method of feeding.

When a demand for an additional supply of steam occurs, it is not necessary to immediately increase the supply of feed water. Part of the water already within the boiler and at boiler temperature can be evaporated into steam and this process may continue until the water has dropped to the lowest permissible level. Conversely, when the demand for steam falls off, it is not necessary that the amount of feed water be simultaneously decreased. On the other hand, the amount of water in the boiler can be increased so that the heat which would otherwise be lost is saved and utilized for heating up additional feed water.

Suppose, for example, that the load on a boiler suddenly increased by 100 per cent. If the rate of feeding water were increased at the same time by the same amount, then the furnaces would at once have to generate 100 per cent. more heat in order to keep up the steam pressure. This cannot be done, and therefore the steam pressure drops somewhat and the heat stored in the water is called upon to make steam. Obviously, the last thing to do under such circumstances is to inject a large volume of cold water into the boiler.

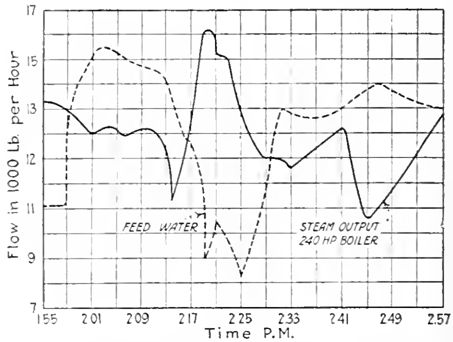

FIG. 1. SIMULTANEOUS READINGS OF FEED-WATER FLUCTUATIONS AND STEAM OUTPUT

If the rate of feeding does not increase when the load increases, then the additional feed water need not be heated and the momentary load on the boiler is increased by only 80 per cent., since the amount of heat required to heat the feed is about 20 per cent. of the total. If the feed water were cut off when the load jumps 100 per cent., then the momentary overload amounts to but 60 per cent.

For high economy, all the boilers in a battery should operate with the load evenly distributed. The efficiency of a boiler falls off gradually as the load is increased and rapidly as the load decreases below normal. It is important that all boilers of a battery work at uniformly high capacities.

Suppose that the five boilers of a battery are working at five capacities and delivering a total of 75,000 lb. of steam per hour with a total battery efficiency of 69 per cent. If the boilers were worked at a uniform high capacity, each of the five boilers would generate exactly one-fifth of the steam and the average battery efficiency would be 72 per cent., or a net gain of 3 per cent.

The unequal distribution of load between the boilers of a battery is caused by differences in condition of fire, of coal, grade of firemen or condition of the stoker, the draft pressure, condition of setting as to leaks, condition of boiler surface as to soot and scale, the position and condition of the dampers, and to the rate of feeding the water.

If a feed-water regulator is so designed that the feed valve cannot assume an intermediate position on light loads, the valve will be closed for long periods and open for short periods. On heavy loads the valve will be wide open for long periods, thus causing a fluctuating steam output and failing to feed in proportion to the rate of evaporation.

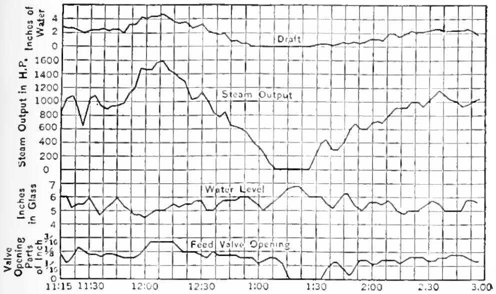

FIG. 2. SHOWING LOAD ARTIFICIALLY VARIED FROM ZERO TO 270 PER CENT. CAPACITY

When feeding by hand regulation, the water tender cannot follow a fluctuating load and at the same time make the proper allowance for the influence of the load and the steam pressure on the height of water observed in the gage-glass. A steam flow meter on each boiler to guide the firemen or stoker attendant has proved successful in regulating individual boiler loads, but hand feed causes wide and misleading fluctuations in steam-flow meter readings. The steam delivery and flow meter reading may be reduced from a heavy overload to practically zero load by the sudden injection of a large volume of cold water. This is illustrated by the curves of Fig. 1, which show simultaneous readings of the feed water and the steam output of a boiler forming one unit of a battery on which there was a constant load, the fireman relying on the steam gage and water column as a guide in regulating the feed water. Under such conditions the advantages resulting from the use of steam-flow meters cannot be realized because the readings cannot be used as a guide to regulation.

The water tender and fireman often work at cross purposes. The fireman assumes that the pressure gage and steam-flow meter readings indicate the boiler and furnace load and the rate at which heat is being absorbed from the furnace by the boiler, whereas the accuracy of the readings may be destroyed and their utility nullified by improper feed.

If every boiler were fed continuously while under load, and if at the same time the water level were varied inversely with the load, this trouble would disappear and all boilers would receive a share of the feed in proportion to the furnace load. If the steam delivery of a boiler, as indicated by the flow meter, is too low, it is corrected by speeding up the stoker, cleaning the fires, opening the dampers and regulating the air supply; then the increased heat generated causes an increased steam delivery, which in turn causes the proper increase in feed supply.

A feed-water regulator should make the rate of feeding dependent upon the furnace load, and so long as each furnace of a battery generates its share of the heat, each boiler of the battery will receive its share of the feed water and generate its share of the steam.

To meet the foregoing requirements an automatic boiler feed regulator should have the following characteristics: On light loads the water level should be high, so that the boiler stores a maximum amount of water and heat. Conversely on heavy loads, the water level should drop, the heat of the furnace being used for evaporating water in the boiler and not heating cold feed.

To secure this fall in water level, the feed valve should close off the feed somewhat, when the load suddenly increases, thus increasing the heat available for evaporating the water already admitted. However, as the water level falls due to evaporation, the regulator must increase the rate of feed until the amount being fed equals the amount being evaporated.

With a sudden decrease in load, the regulator must not decrease the feed until the water level has risen to the maximum and should even open up the feed valve to rapidly inject cold water, so as to absorb the heat which would otherwise be uselessly generated by the furnace. After the water level has reached the maximum permissible height, the feed must be decreased or shut off. Finally, the regulator should be reliable and automatic so that when the load is removed from the boiler the feed water will be shut off.

That these conditions are not impossible of accomplishment with an automatic device is evident from Fig. 2. These readings were taken on a boiler whose load was intentionally varied from zero to 1600 hp., corresponding to almost 300 per cent. rating. The maximum steam output is accompanied by the minimum water level, followed by a rising water level as the load decreased and a maximum water level at the minimum output. The feed-valve opening does not reach the maximum until some ten minutes after the first peak, showing how the water in the boiler is allowed to evaporate down to the minimum level before the feed valve opens to compensate for the increased load.

Similarly, while the load fell to zero at 1:10, the feed valve did not close until some ten minutes later and only after the water level had reached the maximum permissible level and cold water had been pumped into the boiler, so as to store and save heat.

Another proof of the practicability of this method of feed is shown by Fig. 3. This covers readings on the boilers of the Municipal lighting plant, Jacksonville, Fla. The load varied from 1000 to 4000 kw. The water and load lines have the same general shape, indicating that the feed is in proportion to the load. As with the previous chart, however, the feed does not respond to a change in load until the thermal capacity of the boiler has been utilized.

The first example occurred at 4 o'clock, when the load suddenly dropped from over 2000 to just over 1000 kw. This drop in load, instead of causing a decrease in the rate of feed, was accompanied by a rise in the rate of feed from 60,000 to 75,000 lb., the additional water thus pumped into the boiler saving and storing heat. After 4:10 the boilers were obviously filled to the highest permissible level and the rate of feed fell off. The constantly increasing load from this time up to 6 o'clock is accompanied by a corresponding increase in the rate of feed. At the first peak of the load, occurring at 6 o'clock, the amount of water fed to the boiler fell from about 86,000 to 80,000 lb., indicating how this method of feeding helps to carry peaks. At 7:10, when the load went up again to the maximum, the rate of feed fell from 77,000 to 70,000 lb., not increasing again until the peak had persisted for some time, when the water level had fallen and it was necessary to increase the rate of feed to prevent the level from going below the minimum. L. E. Murphy,

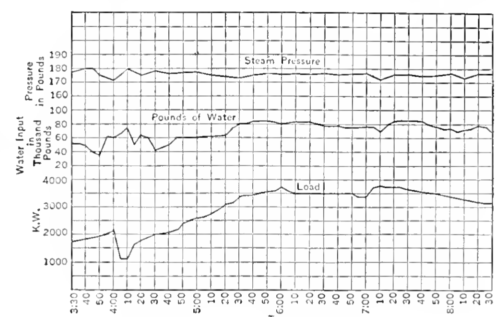

FIG. 3. PERFORMANCES OF FEED-WATER REGULATOR AT MUNICIPAL PLANT, JACKSONVILLE, FLA.

chief engineer of the plant, states that "Our fuel consumption goes up 4 to 5 per cent. for a given kilowatt output when the regulators are not in use."

From the foregoing it is obvious that a continuous-feed regulator makes it possible to use a smaller feed line, smaller valves, and smaller boiler feed pumps for a given boiler horsepower output, or it permits forcing of the boilers without the usual increase in size of lines, fittings and pumps. This is true because the control valve does not close unless the boiler is shut down, and furthermore the valve maintains an intermediate position, so that water is continuously fed to the boiler. As a result, the valve is not called upon to open to its full extent and is operating far below its maximum capacity. On new installations the saving in the cost of fittings covers a large part of the cost of such a regulator. As boilers are driven at higher and higher loads by the use of mechanical draft and stokers, greater feed capacity is needed and this is amply provided by a suitable system of regulation.

When the rate of feeding varies spasmodically, with consequent variations in the steam delivery, the temperature of superheat also varies through a wide range. The hot gases flowing over the superheater tubes transmit to them a practically constant amount of heat, so that if the steam delivery is suddenly decreased by injecting a large volume of cold water, there is a sudden rise in steam temperature. With proper regulation of feeding there are no sudden or spasdomic variations in the feed, hence no spasmodic variations in the steam delivery; consequently, undue fluctuations in steam temperature produced by the superheater are prevented.

With open feed heaters the efficiency is increased when the rate of feed is even and not subject to wide variations. If the demand for feed water is large, due to excessive feed-valve opening, the water level in the storage space falls low and the float-operated makeup valve opens wide, introducing an excessive amount of cold makeup water with a resulting decrease in temperature. On the other hand, if the feed valves are closed too far, the makeup water is shut off, due to the high level of the water in the storage space, and steam may be wasted to the exhaust. Furthermore, if the feed valves remain closed very long the water in the heater overflows to the sewer and wastes both heat and water.

OBITUARY

FRED ULRICH

Fred Ulrich, general sales manager of the Vilter Manufacturing Co., Milwaukee, Wis., died Dec. 10, at his home, 2720 McKinley Boulevard, Milwaukee, after a short illness.

FRED ULRICH

Mr. Ulrich was born in Apolda, Thueringen, Feb. 19, 1852 He studied in the Gymnasium in Apolda, was graduated from the Royal Institute of Technology in Chemnitz, Saxony, and later from the Polytechnic Institute in Karlsruhe.

In the capacity of mechanical engineer he was engaged by several large concerns in Germany for the design, sale and supervision of large machinery installations in the Russian Empire, Finland, etc. He also traveled extensively in Italy and other countries on the Continent.

In 1882 he came to America and was connected with concerns in Cincinnati, St. Louis and Chicago, and in 1885 assumed the position of chief engineer of the Weisel & Vilter Manufacturing Co., now the Vilter Manufacturing Co. In 1888 he became a stockholder and director, and later general sales manager.

During his 29 years' continuous connection with the company he aided materially in developing the business to one of the largest establishments of its kind. In the performance of his duties he visited a great many of the ice-making and refrigerating plants in the United States and Mexico, and his wonderfully retentive memory enabled him to accurately recall small details years afterward. In the solution of all problems his highly trained, keen and observant mind was of invaluable assistance. He was thorough and conscientious in all business matters, always actuated by a high sense of honor and justice, and while generally inclined to be serious, he had flashes of dry humor which disclosed his deep insight into men and affairs. His demise is a distinct loss to his associates and the refrigerating world.

Mr. Ulrich is survived by Mrs. Ulrich, two daughters and a son.

BUSINESS ITEMS

The National Belt Dressing Co., 220 Broadway, New York, is placing "National" belt dressing on the market.

The pipe insulation contract for the new Utah State Capitol at Salt Lake City, for which R. K. A. Kletting was the architect, and Jas. C. Stewart Co., contractors, was recently awarded to the H. W. Johns-Manville Co., 41st and Madison Ave., New York.

Due to the death of Quimby N. Evans, the copartnership heretofore existing between Q. N. Evans, J. A. Almirall and W. C. Adams, has been dissolved and the corporation of Almirall & Co., Inc., No. 1 Dominick St., New York, has succeeded to that business.

The Goulds Manufacturing Co., manufacturer of triplex, centrifugal, hand and spray pumps, Seneca Falls, N. Y., has just opened a new office in Atlanta, Ga. The office will be located in the Third National Bank Building and will be in charge of Mr. O. B. Tanner, district manager.

A booklet which will interest every man seeking improved boiler results has just been published by the American Boiler Life Company, 19 North Market St., Boston, Mass. It tells things about scale removal, about the prevention of scale and pitting and foaming that are not only interesting but instructive. Copies are mailed on request. The title of the booklet is "Steam Boilers and Boiler Feed Water."

The Mesta Machine Co., of Pittsburgh, Penn., has recently acquired the rights from the Stumpf Una-Flow Engine Co., of Syracuse, N. Y., to build the Stumpf Una-Flow type of engine in the United States. The agreement not only gives the Mesta Machine Co. the patent rights of Professor Stumpf, but includes the use of the knowledge gained by the practical experience, during the past five or six years, of European builders of Stumpf engines. The large number of engines of this type in operation in Europe gives conclusive proof of its superiority in regard to simplicity, economy, etc.

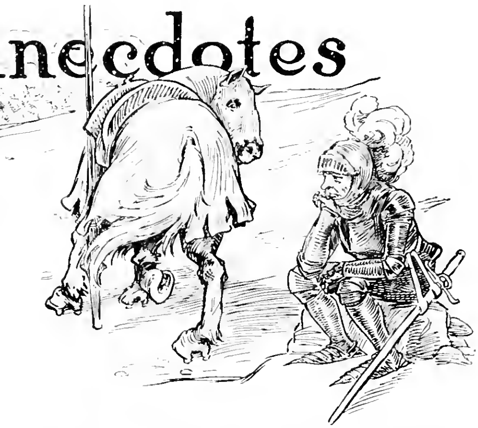
Purposeful Anecdotes



Better Be Sure Than Sorry

For the want of a nail, a shoe was lost,
For the want of a shoe, a horse was lost,
For the want of a horse, a rider was lost,
For the want of a rider, a battle was lost,
For the want of a battle, a kingdom was lost.
And all for the want of a horseshoe nail

IT IS NOT HARD to get authority to purchase a safety device after the need of it has been driven home by a sacrifice of property and perhaps life. It is another matter to convince the management of such a need where an accident never occurred.

The owner of a certain factory installed a complete system of accident-prevention appliances—at least it was intended to be complete. Every gear, pulley, belt or stairway was protected with the most elaborate devices in the market, but—

When the engineer complained that his part of the plant was being overlooked, and that if anything happened to his engine, all the machinery, protected or otherwise, would be dead, maybe for months—when he suggested this, the owner told him that he had ample protection already.

"What could happen, John?" he asked: "how could the engine run away or overspeed when it has the best governor ever invented, and you or your assistant, Charlie, are always in the engine room?"

It's hard work for some men to beat the boss in an argument, and many a good suggestion for betterment, or safety, has been lost because of lack of self-confidence—of being too timid to "talk up" to the management.

So, the subject was dropped, after the owner of the factory had, as he thought, beaten some reason into the engineer's thick head.

Then came the day when the stage was set for a first-class accident. All the conditions were perfect. The machinery had been working like clockwork; not a hitch anywhere, and the owner recalled, with a smile, the engineer's preposterous attempt to have him safeguard the engine—the engine that cost so much and worked so beautifully. John was on the third floor making some small repairs, directly over the engine room. Charlie, his assistant, sat in the old cane chair, sleepily watching the twinkling spheres of the governor as they swung after each other.

Suddenly, Charlie sat up with a jerk. The shining balls had ceased to swing and lay quiet beside the stem. But the engine was running—yes, but at what a speed. Frightened, Charlie was fascinated—lost his head, and rushed to the telephone to summon help. Before he could get the operator, a new noise caused him to drop the receiver and run for the open door. The big wheel was turning like lightning and the beautiful new engine was tugging as if it would rise from the concrete. Nobody but a madman would go near the throttle now, and Charlie was not quite a lunatic yet. Bursting into the office, he yelled "Something is wrong. Where's John?" but before the startled owner could reply, a horrible grinding noise was heard in the direction of the engine room, and the walls of the building vibrated to a shock that almost shook the men off their feet.

The flywheel had let go. Tearing their way upward and outward, through floors, heavy beams, shafting and machinery, fragments of the wheel were discharged as if propelled by guncotton. Pieces fell over a hundred yards away, demolishing everything in their path.

With pale faces and trembling chins, the two men moved cautiously to the place where the engine room used to be. Nothing could be seen because of the dense cloud of steam that roared through the broken main, but when the subsiding pressure allowed the vapor to escape through the torn roof, the owner and assistant engineer saw—and understood.

"Go and find John," said the owner. A few minutes later Charlie returned. His soiled handkerchief was pressed to his eyes. The men looked at each other.

"Did you find him?" asked the owner.

"Yes," said Charlie, in a choking voice—"Poor Jack."

Sentiment and business are not good bedfellows, and it was not long before the owner began reconstruction. The advice of the dead engineer was recalled in bitterness of spirit. The financial loss was heavy, the plant being closed for nearly three months for repairs and installing a new engine and transmission, including a fine new flywheel, bigger than the old one.

Visitors to the new power plant saw something not on the old engine which excited considerable curiosity. This was a modern, automatic engine stop, provided with connections which enabled the engine to be stopped from convenient stations located anywhere in the factory. It was arranged also to stop the engine automatically if there was any advance of speed over a prescribed maximum. Furthermore, it could be operated electrically, and one method of operation did not interfere in the least with the others.

There will never be a flywheel explosion in that plant again—at least so long as the engine stop stays on the main where the ill-fated John often wished to see it. The new man stops his engine twice daily by pressing a button, and takes pleasure in telling visitors how, when a breaking shaft once threw all the load off and the engine began to race, the engine stop lever clicked quietly once, and the steam was shut off instantly.

No engineer can tell when, or why, or how much his engine will race under certain emergencies. Governors of the usual type are probably no more reliable than the engine itself They are auxiliary safeguards, subject to their own peculiar derangements. Belts will slip and gears will clog unexpectedly, and once an engine begins to race there is only one thing to do—shut off the steam. If the engineer has nerve and happens to be there, he will close the throttle, unless the flywheel lets go first. A reliable engine stop attends to that matter whether the engineer is asleep in his bed or talking politics to the fireman in the boiler room.

(*By J. St. C. McQuilkin*)

Power Plant of American Engineering Company

SYNOPSIS—A small power plant embracing interesting features of design. The arrangement and equipment are such that the plant is easily and economically operated and provision is made for obtaining daily records of performance.

The ground plot on which the power plant of the American Engineering Co., Philadelphia, Penn., is built, is bounded on three sides by city streets. This placed a restriction which was further complicated by the intersecting streets not being at right angles to one another. The requirements were sufficient engine and boiler capacity, together with all auxiliaries and coal- and ash-storage capacity, and so arranging all the equipment that operation would be easy, convenient and economical.

Since one of the three streets contained a railroad siding, it was important to have the coal-bunker and coal-handling system convenient to the siding and also to provide space for a private siding for unloading coal.

The generating capacity of the plant is 540 kw., or 737 hp., made up of one 13 and 22 by 18-in. tandem-compound engine directly connected to a 150-kw., 250-volt, direct-current generator; two 13 and 23 by 16-in. tandem-compound engines, each directly connected to a 165-kw., 240-volt, direct-current generator; and one 12x12-in. single engine directly connected to a 60-kw., 110-volt, direct-current generator. Figs. 1 and 2 show the engine room.

In addition to the foregoing, the engine room contains the forced-draft equipment for the stokers, consisting of one steel-plate blower directly connected to either of two 5x5-in. vertical engines. All of the engines run noncondensing, the exhaust steam being used for heating the boiler feed water and also for heating the shops and offices.

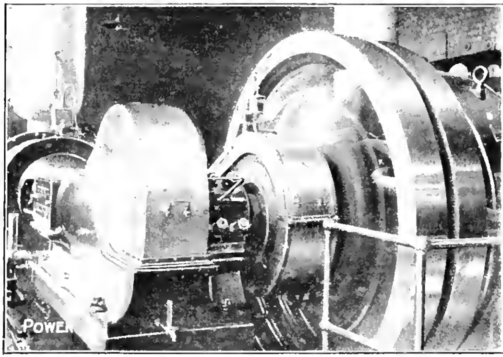


Fig. 1. One of the Main Engines and Generators in the Power Plant

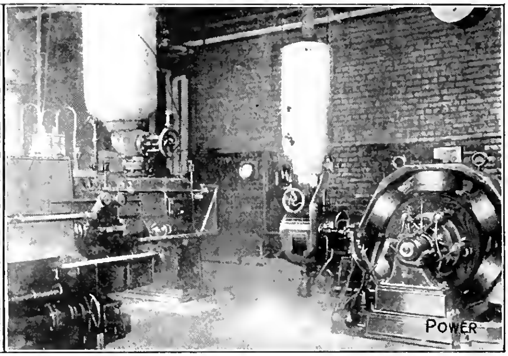

Fig. 2. The Small Unit and Steam End of a Compound Engine

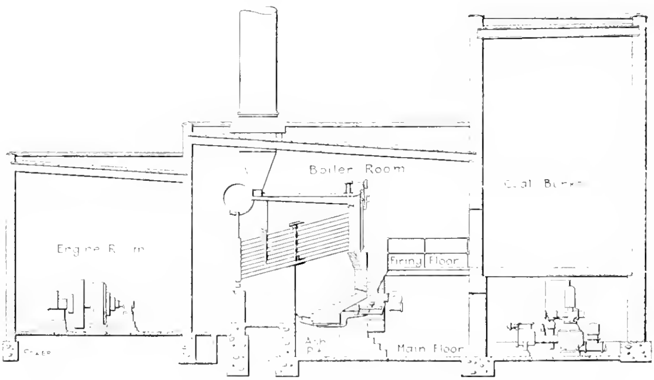

Fig. 3. Section on Line A A of Fig. 8

The boiler room has three cross-drum water-tube boilers, each having 1500 sq.ft. of heating surface and is equipped with a gravity under-feed stoker. There are also two 6 and 4 by 6-in. outside-packed duplex feed pumps, two feed-water heaters and a V-notch recording water meter (Fig. 1).

The plan of the power house (Fig. 8) shows the location of the equipment and railroad switch, and Fig. 3 shows a sectional elevation through the engine room, boiler room and coal bunkers. The compactness of this arrangement is such that there is practically no waste space, the equipment is not crowded and there is plenty of room to make the repairs and adjustments.

The combined layout of boilers, stokers, ashpit, coal bunkers, ash hoist and firing floor is interesting. The lower boiler room is practically on the street level, with the boilers and stokers so set that the lower floor is also the level at which ashes are removed from the pits.

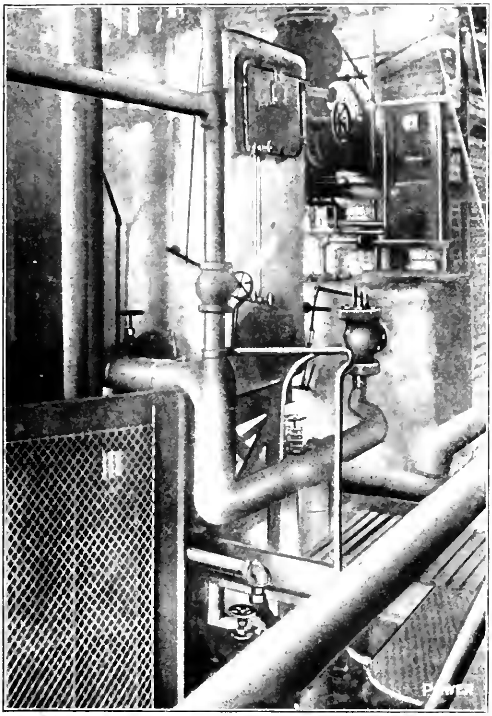

FIG. 4. FEED-WATER HEATERS AND V-NOTCH RECORDER

The upper or firing level is flush with the top of the stoker coal hoppers and is also level with the bottom of the coal bunker. The firing floor extends from the boiler fronts to the coal bunker. In the other direction, the floor is only the width of the boilers, a narrow passageway connecting the firing floor of the battery of two boilers to the firing floor of the boiler set singly.

Platform scales are built into the firing floor in front of the coal bunkers. The coal is wheeled from the bunker to the stoker hoppers, each wheelbarrow of coal being weighed and then dumped into the stoker hoppers.

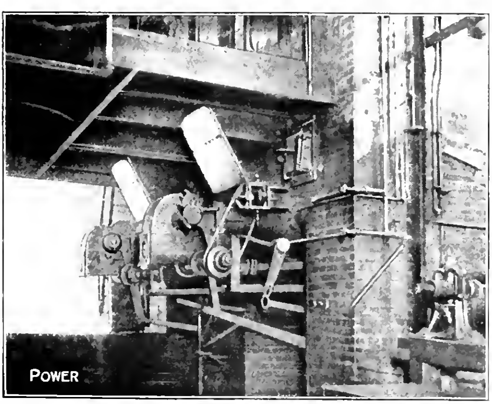

FIG. 5. STOKERS BELOW CHARGING PLATFORM

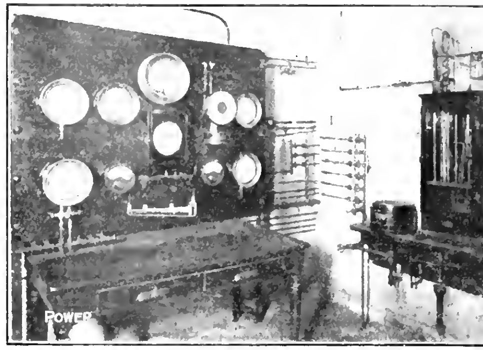

FIG. 6. RECORDING INSTRUMENTS IN ENGINEER'S OFFICE

Figs. 5 and 7 are views of the boiler room from above and below the firing floor. Slack coal is usually used and is dumped from the car through a cast-iron grating into a bucket conveyor which deposits it in the bunker. Any lumps which will not pass through the grating are broken through, making a crusher unnecessary.

The ash is wheeled to a conveyor on the same level as the ashpits and then elevated to a bunker so arranged that a truck can back under it and the ash can be discharged for final removal.

A chief engineer, an oiler and a stoker operator con-

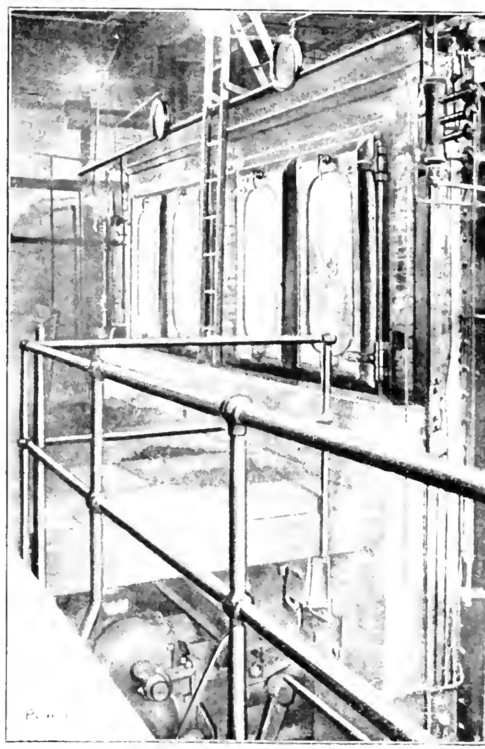

FIG. 7. CHARGING PLATFORM, STOKERS BELOW

stitute the operating force. The stoker operator tends the water, weighs the coal and removes the ashes.

The boiler gage glasses are in plain view from either the firing floor or ashpit level, and the feed valves are controlled from either floor, thereby making it unnecessary for the operator to make trips from one to the other level to regulate the water. The rate of coal feeding and the air pressure required for burning it are controlled automatically in accordance with the demands for steam, therefore the fireman is not required to continually watch the steam gage nor regulate the drafts, etc.

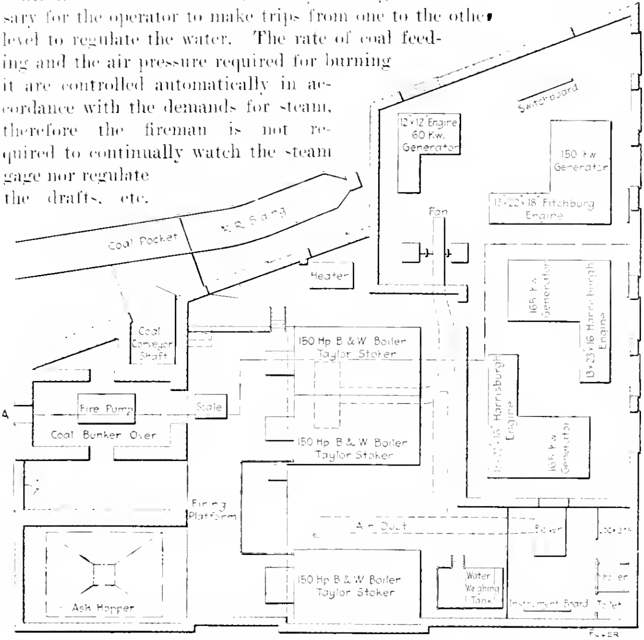

FIG. 8. PLAN OF POWER PLANT

The stoker hoppers are of sufficient capacity to give the operator ample time to remove the ashes without giving them any further attention. The plant is so compact and conveniently operated that two men could easily run it. However, since the cost of fuel is the main item of expense in any power house, it was deemed advisable to use an extra man, thereby giving the chief engineer time in the boiler room to see that the maximum fuel economy is maintained.

No. 3 boiler is equipped with an independent feed pump, weighing tanks, fan equipment and a set of recording instruments for recording simultaneously all varying conditions throughout the boiler and furnace. Thus, experimental and test work can be carried on without interfering with the normal operation of the plant. These instruments are connected to be used on any of the three boilers, thus affording the chief engineer accurate information on conditions and assisting in maintaining high economy.

The instruments, mounted on a panel (Fig. 6), are a steam-pressure gage, feed-water thermometer, air-pressure gage, differential draft gage, and flue-temperature thermometers and all the recording instruments. There are also a steam-flow meter and a recording CO_2 meter. They cover all conditions subject to variation and show graphically the relations of one to the other. All instruments are checked periodically.

In addition to the electrical load, which includes five electric traveling cranes and a fan for the foundry cupola, steam is used to drive an air compressor in the shops, for the steam hammers in the forge shop and for test purposes on the engine-test floor. From the character of the load it can readily be seen that the load has wide limits.

The steam pressure is automatically held practically constant at 160 lb. The stokers are driven from the fan shaft, and a damper regulator, connected into the main steam header, controls the speed of the forced-draft fan. The regulator operates on about two pounds' variation in steam pressure. In varying the speed of the fan, the air pressure and the rate of coal feed are controlled simultaneously. Once the correct ratio of air supply to the coal feed is obtained, no further hand adjustments are necessary.

New Composition Valve Disk

A new composition disk for steam service has been perfected by Jenkins Bros., 80 White St., New York City, and will hereafter be used in all of the company's standard pattern globe, angle, cross and radiator valves.

The disk will be known as No. 119. The composition is hard, but becomes tough and flexible in service when under steam pressure. It shows freedom from cracking and flaking and is durable with steam pressures up to 150 lb.

The Volume of Air Handled by a fan is proportional to the speed, and the power required to drive the fan varies as the cube of the speed. That is, to double the amount of air will require eight times the horsepower.

Opelousas' Municipal Lighting Plant

SYNOPSIS—The following is taken from a communication from A. C. Jones, superintendent of the municipal light and water plant of Opelousas, La., and recites some of the struggles of a small plant in a town of about 5000 inhabitants. Due to the comparatively high price of coal, and the local conditions an oil-engine plant appears to have shown considerable saving over the former steam plant.

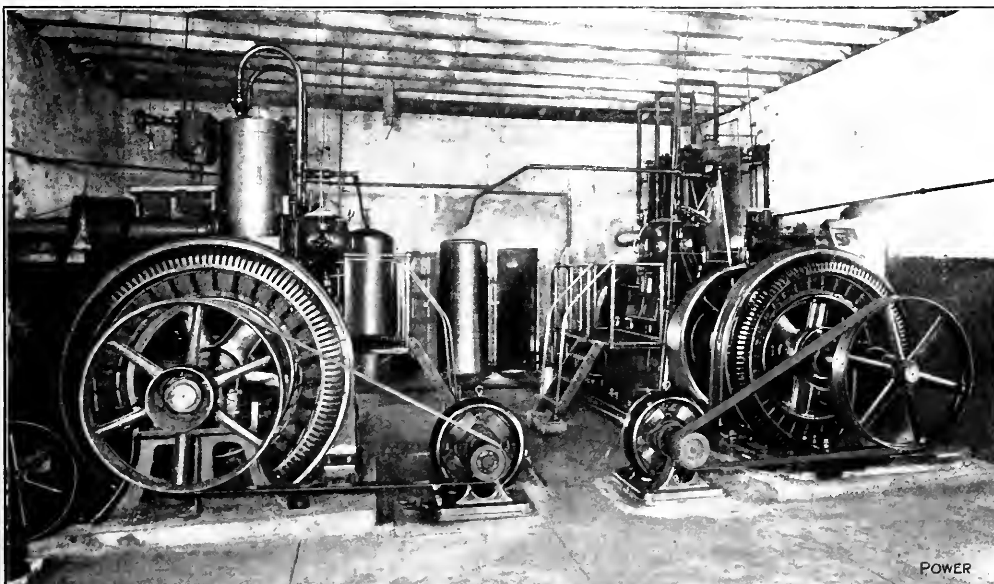
The electric-light and water-works plant was installed by this city in 1897, and consisted of one 110-hp. center-crank steam engine, two return-tubular boilers, one 50-kw. alternator, and one 40-light arc machine. There were also two water-works pumps each of 500-gal. capacity. This equipment was kept in service for a number of years and another alternator and engine were added, after which the arc machine was discarded and alternating inclosed arc lamps replaced the open arcs. This equipment gave good service and the city was able to operate it satisfactorily until about 1909 when fuel started to increase in price to a point that meant serious loss unless something was done to decrease the amount consumed. As soon as the plant started to lose more than the city could afford, the management was unable to get enough money to keep the machinery in repair. Moreover, due to local conditions, the load fell off considerably.

Finally, after spending about $1000 in repairs, a new steam plant was recommended and purchased, consisting of a tandem-compound, four-valve engine direct-connected to a 150-kw. alternator and a B. & W. boiler. This was a first-class outfit, but the results were not much better than with the old plant.

By the early part of 1911 the city finances had reached a desperate state, and it seemed that the plant would have to be shut down. The receipts from electric and water service were insufficient to pay the fuel bills, so that it had become a regular custom to borrow money from the banks to pay for fuel. The employees had to go to the banks and borrow their salaries on their own notes and at the beginning of the next year the city council would pay these notes, with interest, out of the license funds.

A new city council took charge of the city's affairs in 1912, and realizing that radical changes had to be made in the electric-light and water-works plant, arranged to increase the tax rate three mills for two years and borrowed $6000 on it. With this money there was purchased an oil-engine plant consisting of a 100-hp. Mietz & Weiss engine, direct-connected to a Fort Wayne alternator, a generator panel, a feeder panel, one 500-gal. Lawrence pump direct-connected to a 35-hp. three-phase motor, and a 12x10-in. Ingersoll-Rand air compressor with short belt drive from a 35-hp. motor. This installation cost a little over $11,000. Since the management had only $6000, it was necessary to arrange to pay out of the money collected from the electric and water service; this was fixed at $200 per month with interest.

This first unit was put into regular service in December, 1912. As it was not large enough to carry the peak load, it was necessary to run the steam plant for about three hours each night, but in spite of this the December report showed a profit of $427.82, and each month since has shown a profit.



Engine Room of the Opelousas Plant

Some time after this a second oil-engine set of 100-kv.-a. capacity was purchased, together with a 300-gal. motor-driven pump. This installation was completed Jan. 1, 1914. It cost installed $10,842, leaving a debt of $5842 on this part of the plant, which was to be paid from revenues at the rate of $250 per month with 5 per cent. interest. The plant is now paying each month $450 with interest, in addition to paying all labor and operating expenses out of collections for electric and water service. The city pays the plant $321 per month for street lighting and water service.

To improve the service the present superintendent put up 25 lightning arresters and grounded the neutral on the secondaries. This practically stopped all trouble due to lightning, which had previously been a great source of trouble. In fact, it had been customary after a heavy flash of lightning for the operator to go to the telephone and ascertain what damage had been done, so as to make repairs before dark, if the storm happened during the day time.

The water-works system is supplied with water by two motor-driven centrifugal pumps. The water in the well is 42 ft. from the surface of the ground, so that it is necessary to use an air lift to pump to the reservoir. This air is supplied by the motor-driven air compressor.

The electric service is all metered and the rates are as follows:

250 kw.-hr. or less per month, 10 cents.
300 kw.-hr. or less per month, 9 cents.
350 kw.-hr. or less per month, 8 cents.
All over 350 kw.-hr. per month, 7 cents

There is a minimum charge of 50 cents per month on 1 to 10 lights, 75 cents on 10 to 20 lights and $1 on all over 20 lights. There is practically no motor load connected except in summer for driving fans. The December load is a little over 100 kw. and the mid-summer peak load about 60 kw.

It might be mentioned that the price of oil in this locality is from $3.65 to $4 per ton and oil $1.10 per barrel, although it has reached as high as $1.55.

New Kincaid Stoker

"Fire light and often" is the injunction frequently given the fireman by the engineer who has made a study of the factors conducive to high boiler efficiency. With hand firing, the impediments to the complete success of this plan are: First, it entails more work on the part of the fireman so that he is inclined to lengthen out the intervals or, if he follows instructions, it reduces his capacity. Second, the necessarily frequent opening of the fire-door admits large quantities of excess air, reducing efficiency and tending to offset the advantages otherwise obtainable.

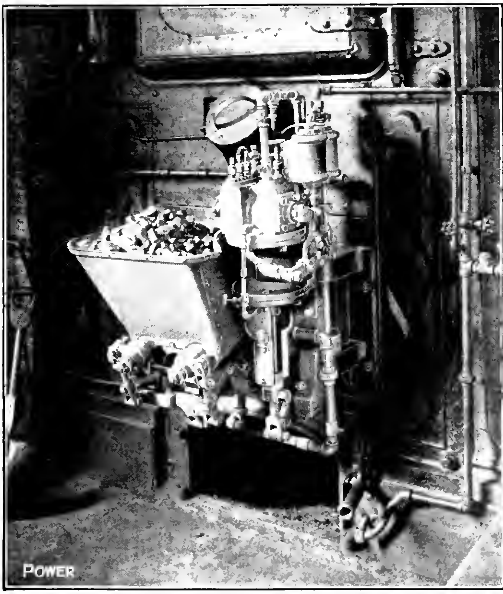


Fig. 1. Kincaid Stoker Hinged to Boiler Front

Fig. 2. Entire Stoking Mechanism Swung Free from Fire-Door

The Kincaid stoker, illustrated herewith, is designed to secure the full advantages of frequent firing of small charges while excluding the impediments just mentioned. When small charges are fed rapidly and regularly to the fire, good combustion is secured with practically any grade of fuel because the unbalanced fuel-and-air supply is eliminated. With hand-firing when fresh fuel is thrown on the grate, the air supply to the freshly covered portion of the fire is insufficient. Another difficulty is that with coal of a clinkering nature, large charges result in large clinkers. The clinkers are not only difficult to handle, but they are objectionable for the more important reason that they interfere with the uniform distribution of the air supply, which is indispensable in securing good combustion.

The stoker under discussion catapults anywhere from 3 oz. to 2 lb. of coal per charge at the rate of from 10 to 75 charges per minute, depending upon the requirements of the boiler. The coal is distributed evenly over the area of the fuel bed, as will be evident from the following description.

Fig. 1 shows the stoker in position. The apparatus is hinged on a frame bolted to the boiler front and no change in setting or boiler front is required other than the removal of the fire-door and the attachment of a fire-door frame. Being hung on hinges, the stoker may be swung clear, as in Fig. 2, for cleaning, trimming or hand-firing, should occasion arise.

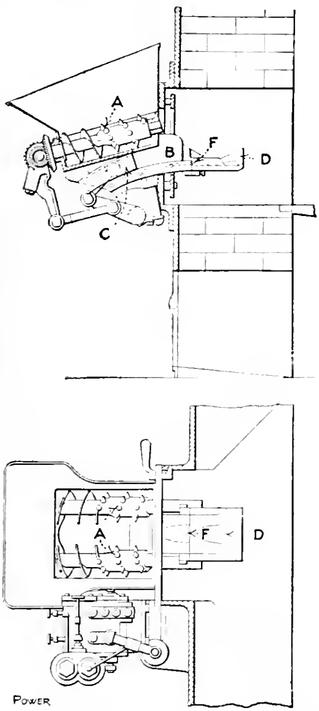

Fig. 3. Side and Top Views of Stoker, Showing Crushing Rolls and Spreading Plate

Referring to Fig. 3, the coal is fed toward the furnace in regulated quantities by means of the worms and crusher rolls *A*. The crusher rolls make it possible to use coal of any size from slack to 8-in. lumps or even mixed sizes such as mine-run, etc.

The coal drops into a rectangular space *B* in front of the ram *C*. The ram is actuated by a steam piston shown at the right of the hopper in Fig. 1. The worms *A*, Fig. 3, work intermittently so that when the ram is delivering a blow against the coal in space *B*, no coal is being fed forward. When the ram is withdrawn for the next blow, the same motion actuates the worms through a predetermined portion of a revolution. Thus, the same quantity of coal is fed to the ram for each successive blow. This quantity may be varied by changing the "throw" of the ratchet arm which turns the worms.

Steam is admitted to one side of the piston which drives the ram by means of a rapidly acting valve in much the same manner that air is admitted behind the piston of a pneumatic hammer. The acceleration of the ram is rapid, but at the end of the stroke, the piston is cushioned by a small quantity of steam trapped in the end of the cylinder so that there is practically no mechanical shock when bringing the ram to rest.

By means of a simple, adjustable throttling mechanism the pressure of the steam admitted behind the piston may be successively varied to secure strokes or blows of four different intensities. Hence, the first or weakest stroke delivers a charge of coal over the first or front quarter of the fuel bed; the second stroke delivers to the second quarter, and so on. The spreading of the coal is accomplished by means of the nozzle plate *D*.

The exhaust from the ram cylinder is led to a $\frac{3}{8}$x3-in. rectangular nozzle at *F*. The events are so timed that a blast of exhaust steam emerges from *F* at the instant that a flying charge of coal reaches the nozzle plate. Consequently, the steam catches, partly carries and assists in spreading the coal over the various portions of the fuel bed. Naturally, the intensity of the blasts of exhaust steam varies directly with the intensity of the stroke of the ram. Even spreading of the coal depends upon the contour of the nozzle plate *D*, which is varied to suit furnaces of different shapes and proportions.

The fluctuations in the demand on the boiler are accommodated by varying the number of charges of coal thrown per minute and by varying the size of the individual charge. The former method is usually employed, while the latter is resorted to only in cases of extreme variation. This change in speed is accomplished by means of a small steam pilot piston, the speed of which is controlled by a water dashpot to which it is yoked. The resistance of the water piston is varied by constructing or enlarging the passage through which the water is forced to flow from one end of the cylinder to the other. This arrangement permits of both hand and automatic control.

The stoker is manufactured by the Kincaid Stoker Co., 507 East Pearl St., Cincinnati, Ohio.

Tagliabue CO_2 Thermoscope

The Tagliabue CO_2 Thermoscope is a new device in this country, but it was fully described on p. 428 of the Sept. 23, 1913, issue of Power, as manufactured by an English company. Now it is being manufactured in this country by the C. J. Tagliabue Manufacturing Co., 18-88 Thirty-third St., Brooklyn, N. Y.

This device is used to indicate the percentage of CO_2 in flue gases. It reads directly on a plain scale and requires no correction for atmospheric conditions.

First Class Engineer almost burned his eyes out measuring between two switchboard blocks with a brass-bound rule.

Thoughtlessness—A man working on a live 2300-volt panel reached as far as he could to lay a blow torch upon the metal window casing of a reinforced-concrete building. His reach was a little short and that saved him, but the foreman saw him and gave him a week to think it over.

Draft Readings on a Stirling Boiler

By S. H. Viall*

SYNOPSIS—Deals with the importance of taking draft readings at different points in a setting and how they may be analyzed and compared with those from a standard setting.

On boilers having natural draft, the reports of many tests give the draft intensity at the stack side of the damper or at some point in the breeching, but they do not mention the available draft over the fire. With open ash-pit hand-fired boilers it is the difference in pressure between the boiler room and the furnace that tends to cause air to pass through the fuel and governs the rate of combustion and in turn the capacity of the boiler. Other information is necessary besides the draft at some point in the breeching. The arrangement of the baffling, the accumulation of flue dust or other factors that affect the size and shape of gas passages all have a bearing on the coal-burning capacity of the unit.

In the article, "Draft Loss through Boilers" (Power, June 2), valuable information on the average loss of draft intensity through different types of boiler is given. It is common to find power houses operating at capacities lower than would be available if intelligent attention were given to the draft conditions. In some plants more boilers are used than should be required, while in other plants trouble is experienced in maintaining the steam pressure.

The writer will briefly describe the work done at a certain plant and show how the information given in the article referred to can be used to advantage in analyzing conditions in other plants.

Fig. 1 illustrates the points at which draft readings have been taken in Stirling boilers operating on natural draft and giving satisfactory service as to capacity and efficiency. The average of these readings reduced to a percentage of the draft at the stack side of the damper, considered as 100 per cent., is shown by curve No. 1 of

TABLE 1—PERCENTAGE OF DRAFT AVAILABLE THROUGH STIRLING BOILER 100 PER CENT AT G

No. of Curve	A	B	C	D	E	F	G
1	4	33	41	49	68	93	100
2	3	13	23	35	48	97	100
3	3	18	52	61	77	80	100
4	4	25	35	48	60	69	100
5	4	21	36	43	57	66	100

Fig. 3, and the data are given in Table 1. This curve corresponds closely to the data given for the standard Stirling boiler, Fig. 18, on page 769 of the June 2 issue.

Fig. 2 illustrates the boiler setting at a plant which was having difficulty in generating sufficient steam to carry the load. It was known that the boiler was not overloaded and that it was clean both inside and out. The truth was that the furnace could not burn enough coal. Draft readings were taken at the points indicated. The connection between the boiler and breeching was as shown. An opening was drilled through the steel breeching connection between the damper and the boiler at the point *G*. Although this point is on the boiler side of the damper, while in Fig. 1 the corresponding point is on the stack side, the two locations are comparable on account of the loss in Fig. 2, due to a turn in the gas pass between *F* and *G* and also to the loss in taking the gases downward in the breeching. The first sets of draft

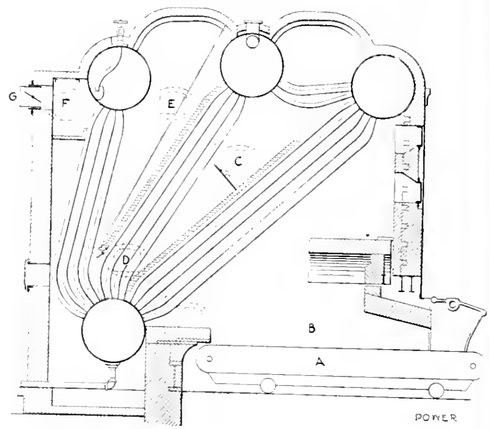

Fig. 1.

readings taken on the setting, Fig. 2, are given by curve No. 2 and in Table 1.

The loss in draft from one point of reading to another is shown more clearly by the curves than in the tables. By referring to Fig. 3, it will be observed that there is a considerable drop between points *F* and *E*, curve No. 2, as compared with the drop between corresponding points on curve No. 1; the latter is the curve for average conditions. Investigation as to the cause of this drop showed that the passage for the gases between the rear drum and the top of the baffle on the rear tubes was only 10 in. high. Tile was removed from the rear bank of tubes down to a level with the shelf at the breeching connection. This increased the opening from the drum to the shelf to 9 ft. Ordinarily this opening would be considered excessive, but as the breeching connection was a downtake of odd design to a tunnel below the floor, and as, after the change, the average temperature of the gases at *G* was only 10 deg. higher, and this with a higher rate of combustion, it is apparent that the action taken was warranted.

A second set of draft readings was taken and appears in curve No. 3. It will be noticed that the available draft over the fire is greater than in curve No. 2. The loss from *G* to *F* is greater, but the loss from *F* to *E* is small. The curve is approximately normal to point *C*, but the drop between *C* and *B* is excessive. It will be observed that the percentage of draft available at *C*, curve No. 3, is more than the percentage available for the corresponding point on the normal curve, No. 1, while at point *B*, on curve No. 3, there is less draft available than for the corresponding point on curve No. 1. This shows clearly that the restriction between these two points is greater than the average.

Further investigation showed that the baffle at the rear of the front bank of tubes was close to the front drum,

*Assistant chief of Smoke Inspection Department, City of Chicago also that the Stirling arch extended to within 4 in. of the front tubes. The gas passage between the drum and front baffle was enlarged and about 9 in. of brick cut from the arch.

A third set of draft readings was then taken, and the results are shown in curve No. 4. It is shown that the available draft over the fire is higher than in curve No. 3, also that the drop from *G* to *F* has increased. Likewise, the drop throughout the rest of the boiler has shown a slight increase except at the points on the fire side of the enlarged openings. The increase in draft loss between *G* and *F* of curves Nos. 3 and 4, as compared with curve No. 2, is due to the presence of a greater volume of gas per unit of time on account of increased coal consumption per square foot of grate. More fuel was burned by the additional air supplied to the furnace.

The drop in draft intensity from *C* to *B* on curve No. 3 is greater than on curve No. 2. The openings between these two points were of sufficient area when handling the gases produced at the lower rate of combustion. When this was increased the volume of gas was greater and the areas between *C* and *B* proved to be too small. After the conditions shown by curve No. 4 were established, there was no further change made in the baffling, because the available draft was sufficient to produce the capacity necessary to carry the load. In other words, satisfactory commercial conditions had been provided and in the estimation of the management any benefit to be realized by further work would not justify the extra labor.

Curve No. 5 is plotted from a set of draft readings taken at a later date than those of curve No. 4, but with boiler and furnace conditions as nearly the same as it was possible to reproduce them in the ordinary operation of the plant. This curve shows that draft conditions vary

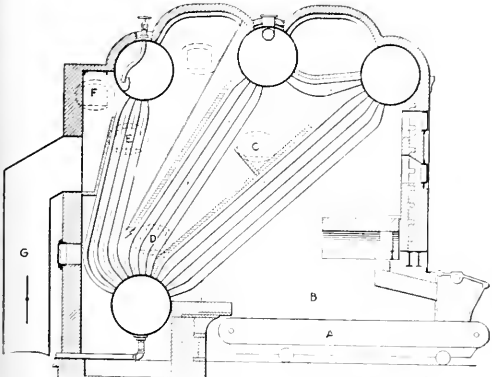

Fig. 2.

from time to time, although readings from the same plant under similar conditions will in a general way check closely.

The draft readings given for curves Nos. 2 to 5, inclusive, are not merely one set of readings, but are the average of several different observations. For example, a set of readings would be made as quickly as possible at the different points indicated. At intervals this work would be repeated until there were six or eight such sets of observations. These data were then averaged and the averages tabulated for record.

It is possible from what has been said for one to assume that all the baffling should be taken from the boiler, thereby increasing the draft intensity in the furnace to a maximum. It is true that such action might increase the fuel-burning capacity of the furnace to the utmost,

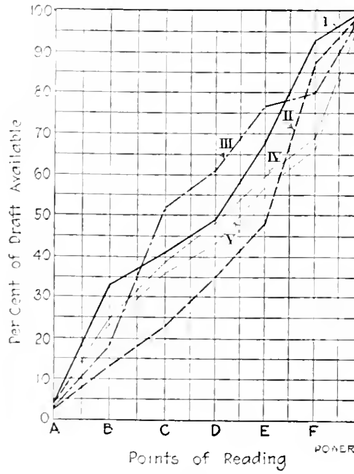

Fig. 3.

but the boiler efficiency would be low. The purpose of the baffling is to cause the heated gases to traverse the absorbing surface in such a manner as to give maximum efficiency of heat transfer. It must be borne in mind, though, that any one item in the operation of boilers can be carried to an extreme. Capacity and efficiency must be considered with relation to cost of installation, attendance, repairs, flexibility, etc. It has been found that the available draft through the average Stirling boiler with a fire 6 to 7 in. thick, using Middle Western coal with natural draft and giving satisfactory commercial returns, should be about as given in curve No. 1.

The course the writer usually pursues in analyzing draft conditions in a boiler is about as follows: Make several sets of observations of draft at the various points through the boiler. For this purpose use a draft gage constructed so that it can be read easily and accurately to hundredths of an inch. Find the average reading for each point as in Table 2. Consider the reading at the

TABLE 2—DRAFT INTENSITY THROUGH STIRLING SETTING IN HUNDREDTHS OF AN INCH WATER GAGE

No. of Curve	A	B	C	D	E	F	G	Date of Reading
2	2	8	14	21	29	58	60	Oct. 13, 1910
3	2	12	34	40	51	53	66	Oct. 20, 1910
4	2.5	16	25	31	39	45	65	Oct. 24, 1910
5	2.5	17	25	30	40	46	70	Oct. 28, 1910

stack side of the damper as 100 per cent. Calculate the ratios between the readings at the various points and at point *G*. Express these ratios in percentages as in Table 2, and construct curves similar to those shown in Fig. 3. For convenience of study, it may be advisable to make each curve a different color. Compare the curves thus found with the normal curve for the type of boiler under consideration. Draft troubles may then be quite easily corrected because quickly located.

Some Transformer Connections

By Gordon Fox

SYNOPSIS—How to determine the polarity of a transformer, connect it properly, and obtain the desired voltage combinations.

When two alternating-current circuits are to operate in parallel they must be in synchronism, which requires equality of voltage and frequency and coincidence of phase. It is not within the province of the stationary transformer to change frequencies so that only circuits of the same frequency can be paralleled. But transformers do change voltage and can easily change relative phase relations, so that where more than a single transformer is involved it is necessary to exercise considerable care to maintain the proper voltage and phase conditions.

Consider the case of two transformers connected in open delta as at *a* in Fig. 1. Here one phase is in a 60-degree relation to the other and the voltages of the secondary phases are all equal. Reversing one transformer secondary, as in *b*, changes its phase position 180 degrees, so that it now bears a 120-degree relation to the phase of the other transformer and the three secondary voltages are no longer equal.

Likewise in a three-phase three-transformer connection it is an easy matter to connect in one phase reversed: in fact, more so than with two transformers. For instance, Fig. 2-a shows three transformers of the same polarity connected properly in star and the phase relations are indicated. Reversing one of the secondary phases, an easy mistake, causes the voltage and phase relations to be entirely changed: this is shown in Fig. 2-b. Similarly, with two transformers of one polarity and the third of the opposite polarity connected as in Fig. 2-a, the phase relation of Fig. 2-b would be obtained.

The term polarity as applied to transformers refers to the relative location of the primary and secondary leads. The terms positive and negative polarity have been empirically chosen to represent the two possible relations of primary and secondary leads. A transformer is said to have positive polarity if, when a primary lead is instantaneously positive, the secondary opposite it in the case is instantaneously negative. Fig. 3-a shows diagrammatically the arrangement of coils in a transformer having positive polarity and indicates the relative instantaneous directions of the currents in the coils. This will be more evident in connection with an explanation of the test to determine polarity.

It is quite a simple procedure to test the polarity of a single-phase transformer. A voltmeter is desirable for the work but lamps can generally be used satisfactorily. The terminals are connected as in Fig. 3-b, one primary lead being connected to a secondary and the terminals *A* and *C* connected across a convenient low-tension, alternating-current line, say, 110 volts. Voltages *A-B*, *A-C* and *C-D* are then measured or their relative values determined with a lamp: If *A-C* is greater than *A-B*, the determined with a lamp. If *A-C* is greater than *A-B*, the it has negative polarity.

The polarity of transformers being determined, their relative phase relations must be kept constantly in mind when connecting them. This is best done in the case of single-phase circuits by making a rule to connect all positive polarity transformers with their leads straight and negative polarity transformers with their leads crossed. In the latter case, only one set of leads should be crossed, of course, preferably the secondaries. For the sake of uniformity it is well to adhere to a standard practice. Fig. 4 shows two transformers of positive polarity and one of negative polarity banked.

When single-phase transformers are connected on three-phase systems care must be used to preserve the proper phase relations. This can most easily be followed through if for individual cases the relative phase positions of the transformer windings are indicated on the diagram of connection. Fig. 5 represents a bank of three single-phase transformers connected in delta-star, showing the relative positions of the windings. The position of the primary windings may be arbitrarily selected, the selection being consistent with the actual physical connection. The secondary winding phase relations follow at once from the positions of the primary windings. It is then necessary only to figure the proper connection of the secondary to get the desired result.

To follow through the connections in Fig. 5, first assume that the transformers are all of like polarity; it really makes no difference whether they be positive or negative so long as they are all alike. If one transformer is of opposite polarity from the others, the same reasoning can be followed out and then the secondary of the differing transformer can be reversed. The primary three-phase wires are represented by *X*, *Y* and *Z*. Since the primary is to be delta connected, transformer No. 1 can be connected with its primary leads across any two of the primary wires; for instance, *X* and *Y*. Then the phase relation of the primary can be arbitrarily shown as designated *a-b*. Next connect the primary of transformer No. 2. These leads may be connected across either *Y-Z* or *X-Z*, the diagram showing the former. The phase relation is once more arbitrarily selected in such position that *b-c* makes a 60-electrical-degree angle with *b-a*. Next, connect the primaries of transformer No. 3. This transformer must now be connected between the wires *X* and *Z* to obtain the delta, the phase relation being represented by *a-c*, making 60 electrical degrees with *a-b* and the same with *c-b*.

In making the secondary connections, it will be best to lay out the transformer-phase relations first and make the terminal connections to correspond. For a star connection such as desired, there must be 120 electrical degrees between phases. Lay off *e-f* parallel to *a-b*. This phase makes an angle of 60 degrees with the horizontal and 30 degrees with the vertical. In transformer No. 2, *e-g* makes a 60-degree angle with the horizontal and a 30-degree angle with the vertical. By placing the points *e-e* to coincide, the desired relation is obtained between the phases of these first two transformers, namely, 120 degrees.

Next, consider transformer No. 3. This phase, graphically represented, must extend horizontally to the left, and will do so if lettered as shown. Since the points *e-e-e* form the star in the diagram they will do so in the actual connection. The leads F-G-H are the three-phase wires for the secondary circuit.

In a similar manner, a delta to delta, star to star, or star to delta connection can be laid out and connected. A little study in laying out the diagram will save time and trouble and will assure a correct connection at the first trial.

Not infrequently it is desired, for testing or other purposes, to secure a voltage other than standard. Figs. 6, 7 and 8 show three arrangements of single-phase transformers which may be used in emergencies or for special purposes. Fig. 6 shows an auto-transformer connection for securing a 10 per cent. boost in the line voltage. Fig. 7 is a step-down arrangement providing a higher secondary voltage than that resulting from the ordinary transformer connection. In this case half the secondary is connected bucking the primary, thus reducing the effective primary turns and decreasing the ratio of transformation proportionately. The capacity of the transformer is cut nearly in two since only half the secondary is available to carry secondary load. In the case cited, with a ratio of transformation of 5 to 1, the voltage across one-half the secondary would be 110 with the usual connections; whereas, with the connections shown, it would be 122. Where the ratio of transformation is high, the difference would be small. A connection similar to that of Fig. 7, in which half the secondary is made to boost the number of effective primary turns, would change the transformation ratio so that a voltage of 100 would result in the other secondary coil, providing the original ratio was 5 to 1 and the primary voltage remained the same.

Fig. 8 is an arrangement utilizing two transformers with the primaries in parallel and secondaries in series to give double the rated voltage of the transformer secondaries. An arrangement of this sort could be easily made to utilize transformers on hand in a plant where an increase in voltage is desired.

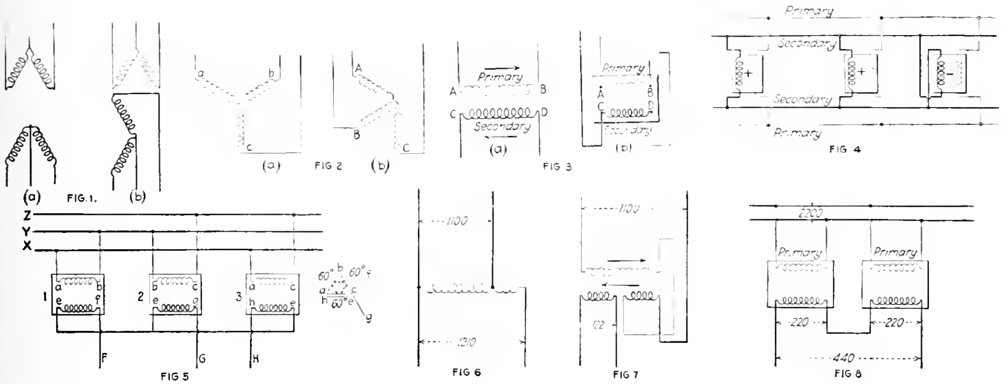
Sometimes in connection with three-phase work it is desirable to obtain a range of voltage. This can be done within certain limits by manipulating the connections. With a given primary connection the secondary star connection provides 1.73 times the voltage from the delta connection. By changing both primary and secondary for both arrangements and utilizing various combinations, quite a flexible and broad voltage range is attainable.

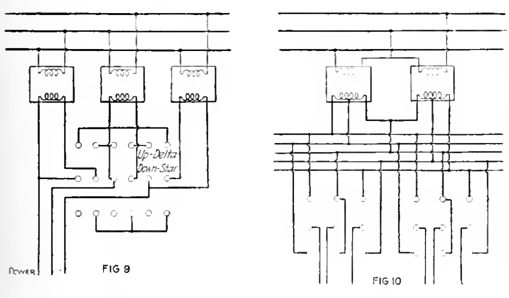
Assume three single-phase transformers with 2300-volt primary windings and 115-230-volt secondaries. The table shows the number of available three-phase secondary voltages which can be secured by different connections. If the transformers are provided with 10 per cent. taps, as most standard transformers now are, the range can be still further enhanced. With such a number of connections it may appear difficult to make the necessary changes. Fig. 9 shows a switch arranged to make it possible to change easily from star to delta and *vice versa*. A little study will make the connection plain. By providing such a switch in both primary and secondary circuits the changes can be quickly made.

TABLE OF TRANSFORMER CONNECTIONS

Primary Connection	Secondary Connection	Primary Volts	Secondary Volts	Remarks
Star	Open delta	2300	66 or 115	Using middle taps of two transformers.
Star	Star	2300	115	Using all middle taps.
Star	Delta	2300	133	Outside terminals.
Delta	Star	2300	199	Using all middle taps.
Delta	Delta	2300	230	Outside terminals.
Delta	Star	2300	398	Outside terminals.

One case in which an arrangement of this kind sometimes proves useful is to provide reduced starting voltages for motors. If there be but a single large motor fed from a transformer bank, it may be feasible to do away with an expensive compensator by simply connecting the transformer secondaries in delta at starting and then throwing over to star for running. The ratio of torques compares with the lowest point on ordinary com-





VARIOUS TRANSFORMER COMBINATIONS

pensators. This arrangement is not suitable where more than one motor is involved. Another arrangement which can be used for a number of motors is shown in Fig. 10. This is merely an open delta in which the 50 per cent. taps are used to secure the lower starting voltage. Since the starting torque of motors at 50 per cent voltage is low, this arrangement cannot be used where heavy starting duty is required. The additional wiring may prohibit its use for an extensive system, but in not infrequent cases it can be, and is, used to advantage.

Lack of Synchronism in Check-Valve Action

By S. F. Jeter

In the changes in the Massachusetts boiler rules, as given in the issue of Sept. 15, p. 395, under Section 2, paragraph 25, it is proposed to require a separate check valve on the return pipe to each boiler instead of one check valve on the main return pipe, as is now the rule.

Such a change would certainly be a step in the wrong direction, for it has been amply demonstrated in practice that check valves arranged in parallel cannot be expected to act in synchronism under small differences in pressure. The failure of these valves to act in unison is due to a tendency to bind and a slight difference in the weight of the valves where they are of the same size; but chiefly due to the differences in area exposed to pressure on the two sides of the valve produced by the difference in the amount of seated area in valves of the same size. In the case of valves of different sizes the difference in the ratio between the seated and the effective area under the valve causes the failure of such valves to act in unison. I recently observed a case of trouble resulting from this cause, which aptly illustrates the difficulties that may be expected if this change is made in the rules.

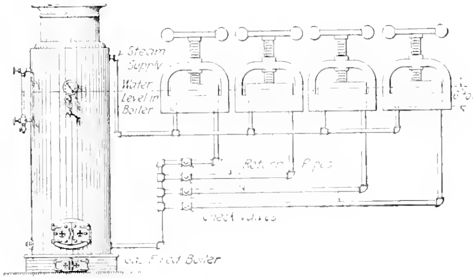


Fig. 1. The Original Installation

An establishment which required heated platens for a series of presses had an automatic gas-fired boiler to furnish the steam during the summer months in place of the larger boiler. The original arrangement was as shown in Fig. 1, where the normal water line in the boiler was about six to eight inches above the steam spaces in the presses. It was advised that there should be installed a pump or some form of lifting trap (since it was impractical to lower the boiler) in order to get steam into the platens of the presses, as was required. A tilting trap was installed (Fig. 2), but the apparatus failed to operate properly. The trouble was that the water line in the boiler would drop rapidly and get entirely out of sight in the glass, which would necessitate closing down, as the boiler's water capacity was limited. Any tendency of the water stopping at any point in the system would lower the water line to a dangerous point.

It was decided that the check valves on the returns did not act in unison and that water collected in one or more of the platens due to the failure of the check valves to open. The separate return pipes were replaced with a single pipe and check (Fig. 3) and the trouble was removed. The distance from the bottoms of the platens to the level of the return pipes where the check valves were

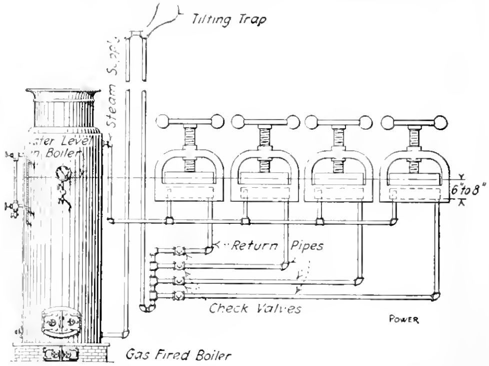

Fig. 2. First Connection to Trap

located was about fourteen inches, which clearly demonstrated that these particular check valves, which were all of the same size and make and were purchased at the same time, could not be relied on to work nearly enough in unison to prevent a change in water level of fourteen inches. No water could begin to collect in the platens until this difference of level was maintained by one or more of the check valves failing to operate under this head.

Differences of water level considerably less than the above would be dangerous in many kinds of heating boilers. Of course, with a single check valve for several boilers there is the risk that the attendant may close the steam valve on a boiler without closing the stop valve on the individual return pipe to the same boiler, but that danger is less than the danger from the condition mentioned. A better arrangement than either would be to have the return connections located at or above the lowest safe-water line, as was suggested in the issue of July 28, p. 133.

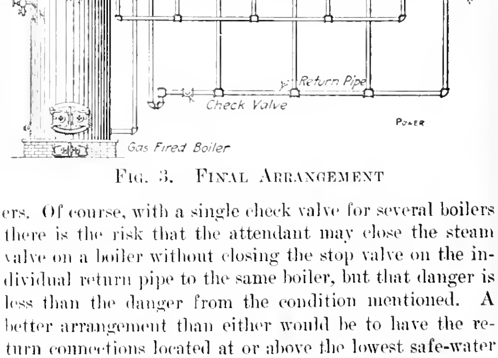

Fig. 3. Final Arrangement

Standard Iron Co.'s Steam-Turbine Power Plant

By O. C. Thomas

SYNOPSIS—The charcoal-iron manufacturing plant of the Standard Iron Co., Ltd., is on an inlet of Georgian Bay, at Perry Sound, Ont. The power house is of interest in possessing a turbo-blower and in the variety of purposes to which steam turbines have been applied. Although furnace gas was available, the convenience of gas-fired boilers and the direct rotary drive of steam turbines, together with ease of starting up, made turbines preferable to gas engines.

The steam generators of this plant, Fig. 1, consist of three flush-front, horizontal return-tubular boilers having furnaces designed for either coal or blast-furnace gas. Each boiler is rated at 200 hp. and has 2000 sq.ft. of heating surface; the shell dimensions are 78 in. diameter by 20 ft. long. The boilers are designed for a working pressure of 150 lb., in accordance with the Massachusetts boiler rules. The products of combustion are discharged into a 5-ft. diameter, 125-ft. guyed stack.

Steam Turbo-Blower

For supplying air blast to the furnace a turbine-driven blower is employed with a capacity of 12,000 cu.-ft. of free air per min. delivered at from 6 to 8 lb. per square inch and running at 4000 r.p.m. All bearings are fitted with forced lubrication, oil being delivered from a gear pump driven from the main shaft and circulated through an oil cooler and filter before being returned to the bearings.

Air is taken in through a 1/4-in. mesh wire-gauze screen and filter outside the building and carried in a duct under the turbine-room floor to the blower. There are nonreturn and relief valves in the air main to the furnace. The turbine end of the blowing unit consists of an impulse steam turbine, taking saturated steam at a boiler pressure of 150 lb. and exhausting into a low-level jet condenser at 28-in. vacuum, referred to 30-in. barometer. The steam consumption is 13.9 lb. per brake-horsepower-hour. Noncondensing working is provided for by a 10-in. "Multiflex" atmospheric relief valve and a gate valve for isolating the condenser. A steam separator is placed between the turbine and the lowest point in the main steam header. The overall dimensions of the turbo-blower are 5 ft. and 15 ft. by 6 ft. 2 in. in height from the bottom of the bedplate.

For driving the removal pump of the jet condenser, a 14-hp. steam turbine is used, running at 1850 r.p.m. The condenser is placed in a basement below the turbine to facilitate the flow of injection water. The vacuum is maintained by an engine-driven dry-air pump, shown at the left of Fig. 1.

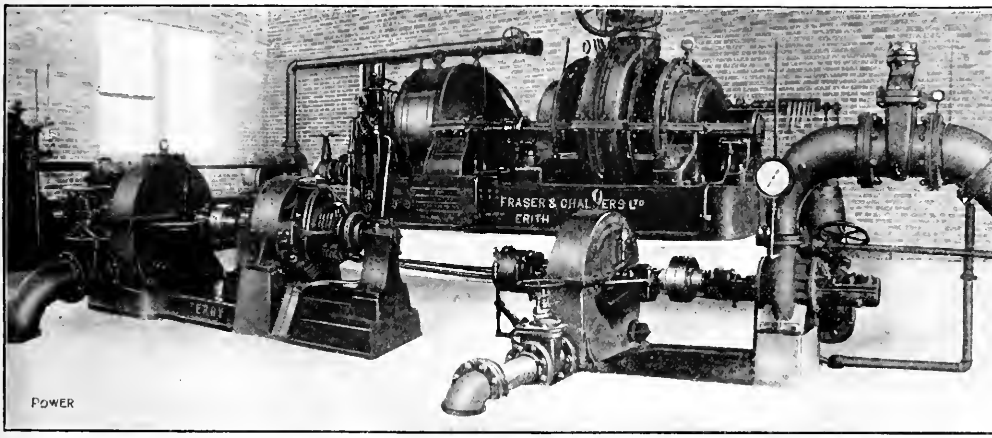

Fig. 1. Turbine-Driven Blower, Generator and Condenser Water-Removal Pump

Electrical and Pumping Equipment

Other apparatus in the power house includes a 40-kw. turbo-generator for lighting and power purposes, one 5- and one 8-in. turbine-driven centrifugal pump, two duplex outside-packed boiler-feed pumps, and a closed feed-water heater, through which the auxiliary units exhaust their steam. The 40-kw. direct-current generator runs at 2800 r.p.m., being driven by a noncondensing steam turbine taking 37½ lb. of steam per brake-horsepower. The 5- and 8-in. centrifugal pumps driven by turbines are for general service and deliver cooling water to the furnace.

The 40-hp. turbine driving the 5-in. pump takes 1500 lb. of steam per hour noncondensing. These pumps, together with the condenser, draw their water from a 14-in. suction main running from the bay, 256 ft. from the power house. The lake-water level is 15 ft. 6 in. below the centrifugal-pump centers and 13 ft. below the condenser-injection inlet. The pumps are primed by a steam ejector.

The two duplex feed pumps have normal capacities of 108 gal. per min. each and are situated in the boiler room; they are arranged to draw water either from the condenser hotwell or from the main centrifugal pump-suction line. The feed-pump discharge is led through the feed-water heater on its way to the boilers, a bypass cutting out the heater for cleaning, etc.

Steam is conducted from each boiler by a 6-in. branch and an isolating valve leading into a 6-in. steam main to the turbine room, where, by a vertical drop of 17 ft., the pipe passes to the level of the trenches in the concrete floor, through which the branches to the different units are led. The vertical length of main does away with any necessity for an expansion bend and facilitates

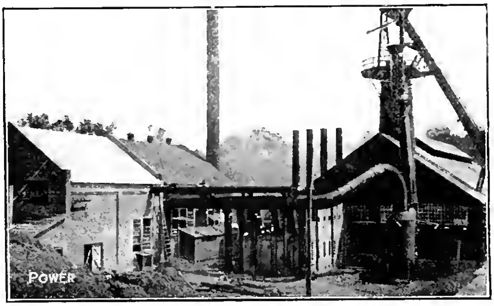

Fig. 2. Power House and Piping to Furnace

drainage, which is designed to gravitate toward the steam separator. Water of condensation is removed by an automatic steam trap directly attached to the separator. Although steam piping in trenches is not usually advantageous, the fact that in this instance all the turbines are placed above the piping renders remote the chance of damage by water. The high-pressure main and branches above 2½-in. in diameter are of extra-heavy, wrought-steel pipe with screwed-on flanges. For 2½-in. diameter and less, screwed fittings are used.

The blower turbine is connected to the condenser by a cast-iron exhaust bend and a corrugated copper expansion joint. All the other units exhaust into a galvanized wrought-steel exhaust main connected to the feed heater. Isolation of the heater is attained by closing a gate valve next to the heater and opening another on the exhaust main leading to the atmosphere. These valves will also be used in cold weather to build up a slight back pressure for exhaust-steam heating. A relief valve is fitted to the main in a conspicuous position to draw attention to any undue rise in pressure.

The water connections to the centrifugal pumps and condenser are of cast-iron flanged pipe with long-radius elbows, and taper pipes make connections with the pump branches. The main suction line is of flanged piping, and was tested for air leaks to a pressure of 30 lb. per sq.in.

In addition to a necessary foot valve at the intake, check valves are placed in the branches to the condenser and feed pumps, and there are water-sealed gate valves in the branches to the centrifugal pumps. The velocity of water in the suction main under normal operating conditions is 280 ft. per min., and the friction head loss between the lake and the pumps is estimated at about 2.7 ft., omitting the resistance of the foot valve.

A solid rock formation immediately below the engine-room floor made it inexpedient to place the power house at a lower level, and prohibited the construction of an intake flume. The satisfactory working of the present arrangement shows that any other scheme would have been an unnecessary expense. The feed piping to the boilers is extra heavy, similar to the main steam piping, and each branch to a boiler has the usual stop, check and feed-regulating valves, the latter arranged at the front of each boiler at hand level. With two exceptions, all water and feed valves are of the straightway type.

The plant was started up and the blast furnace, Fig. 2, "blown in" on Aug. 21, 1913, and on Aug. 24 the furnace was tapped and several tons of charcoal pig-iron drawn off. The simplicity of operation of this power plant is worthy of comment. In the first place, the boilers are gas fired and therefore need but little attention. The only reciprocating motive power is that driving the air pump, and it is automatically oiled. As the rest of the apparatus is steam-turbine driven, the whole plant can be easily operated by one man, and his duties are practically limited to watching the feed water and keeping the log book entered up.

The contractors for the equipment were the Rudel-Belknap Machinery Co., Ltd., Montreal; the turbines were supplied and erected by Fraser & Chalmers of Canada, Ltd., Montreal.

Tricks of the Trade

By F. W. Harris

Thompson was a passenger- and freight-elevator salesman selling both hydraulic and electric elevators. He not only sold elevators for new buildings, but he would sell an electric to replace a hydraulic elevator, giving incontrovertible reasons to justify the change. He would also sell a hydraulic elevator to replace an electric, and give equally solid data to justify this change. In fact, he was a true salesman.

He had been after old John True for a long time to get him to throw out a "worthless" hydraulic machine and put in an electric, and he was spurred on by the fact that he had a customer who had a "worthless" electric elevator which he planned to replace by a hydraulic.

Thompson found, by spending a little money on cartage and erection and furnishing a little additional material, that the shift could be made with profit to himself and temporary satisfaction to both customers.

Old John operated his hydraulic elevator from the city water mains and Thompson visited the water bureau.

"I am from True & Sons," he stated. "We have mislaid our bills for the last two years and I wondered if I could get a statement of the amounts for these years."

He found that the bill for two years was $195. Old John refused to be convinced by his arguments and particularly scouted the claim of lower cost for the electric. "You don't know what it costs me to run my elevator," he objected; "you are just guessing at it."

"Not exactly guessing, Mr. True. We elevator men can figure closely. Now, I know the distance you have to lift and I can give a close estimate of the average load carried and the number of trips made per day. I know the water rate in this city and the rest is a mere matter of higher mathematics."

Old John looked at him over his glasses and growled: "Higher mathematics, eh! And what do you make it by your higher mathematics?"

"Well, considering general business conditions during the last two years, your water bill should have been a little under $200 for the two years; say $195."

"Wait a minute until I get the bills."

The old man went over the file slowly and finally came back with two bills which he totaled. Then he looked over his spectacles at Thompson with a new respect in his eyes.

"Say," he said, "you are surely a close figurer. It cost exactly $195."

Whereupon Thompson got out his orderbook.

Small Isolated Plant Pays Big Dividends

By Thomas Wilson

SYNOPSIS—This small plant, which is earning from 17 to 21 per cent. on the original investment after fourteen years of service, is equipped with high-speed engines and practically all of the exhaust steam is utilized.

From central-station sources it has been frequently stated that the commercial life of a plant should be limited to fifteen years. There is no doubt that some plants are ready for the scrap pile at the end of this period and that others might better be equipped with more efficient machinery, but in the majority of isolated plants the time of usefulness and efficiency far exceeds the limit named. This is particularly true where heating is to be done. Where there is use for the exhaust steam the engine rate is not of prime importance, for if the supply of exhaust is curtailed, live steam from the boilers must fill the demand and the total is as high as ever.

A plant which has been in use for fourteen years in a

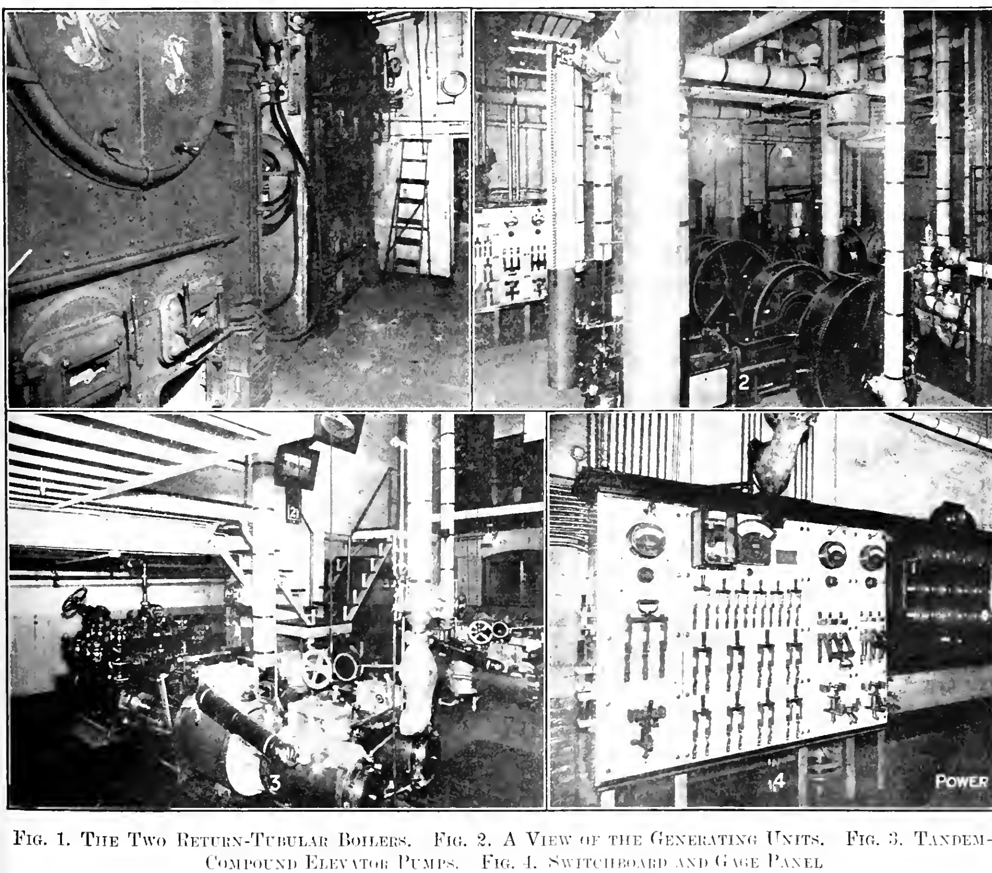

Fig. 1. The Two Return-Tubular Boilers. Fig. 2. A View of the Generating Units. Fig. 3. Tandem-Compound Elevator Pumps. Fig. 4. Switchboard and Gage Panel

Northern city and is good for as many more is here described. The casual observer would think that the plant is only four or five years old as the engines, pumps and accessories have the freshly painted appearance of being new and are in the best of condition. Besides, an examination of the records shows that the plant is as efficient as many of more recent design.

The firm does a wholesale hardware business, and makes harness, awnings, tents and does some forge work. It has two large frame buildings from two to eight stories high. In plan, the main building measures 420 ft. on one side, 450 ft. on the other and is 100 ft. wide. The other building is 125x140 ft.

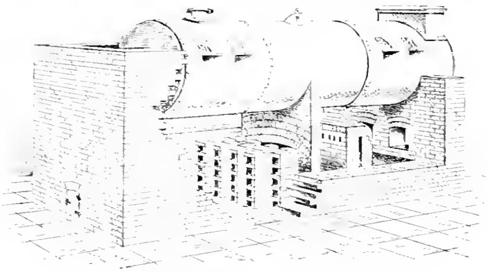

Fig. 5. Type of Boiler Setting Used

The equipment consists principally of two 72-in. by 20-ft. tubular boilers; two 75-kw. direct-current dynamos, each driven by 11x18x14-in. tandem-compound engines running at 270 r.p.m.; one simple 11x12-in. engine driving a 45-kw. machine at the same speed; two feed pumps, one a 7x4¾x8-in. duplex and the other a simplex, 7⅝x4½x9-in.; one duplex 18x10x12-in. fire pump; two 12x4½x18-in. tandem-compound duplex elevator pumps and six hydraulic elevators operated under an oil pressure of 800 lb. in connection with an accumulator. Four of the elevators are rated at three tons, one at one ton and the other at 1500 lb. There are also some locomotive-type air compressors, a 5¼x4¾x5-in. duplex house pump, one 8x12x12-in. vacuum pump, a feed-water heater and some minor equipment.

The fire-tube boilers (Fig. 1) are 6 ft. in diameter and 20 ft. long, have seventy 4-in. tubes and the joints are of the butt-and-strap type. Under an operating pressure of 125 lb., they have been worked for the fourteen years with only minor repairs. The water, obtained partly from driven wells and from a bay, is of good quality, and a small amount of compound, costing about $25 per year, has been used to keep the boilers clean. One boiler, forced at times above rating, carries the load except during the coldest weather. Under the boilers are shaking grates measuring 6x5 ft. To the grate surface of 30 sq.ft., a heating surface of 1740 sq.ft. bears a ratio of 58 to 1. The breeching is of uniform size, 4 ft. square, and enters a rectangular brick stack, 7x4 ft. and 140 ft. high. To the connected grate surface the area of the breeching bears a ratio of 1 to 3.75 and the stack area a ratio approximating 1 to 2. It is evident that the cross-sections of both breeching and stack are abundantly large, but no doubt some allowance has been made for the higher resistances of square passages.

Semibituminous egg coal is delivered by rail and dumped from cars on a siding into a hopper underneath the track. It is raised by a chain belt of home manufacture to a bin in front of the boilers and hand-fired onto the grates. There are two doors to each furnace and the alternate method of firing is used.

The furnace is of the special design shown in Fig. 5. It consists first of a hollow bridge-wall with an opening leading out under the grate. Near the top and at the back of the bridge-wall heated air passes out through a series of openings to mix with the gases of combustion and supply sufficient oxygen for the volatile. In the firing doors there is provision for admitting air over the fire; the boilers are operated with the ash doors removed. Back of the bridge-wall and extending down from the boiler shell is an arch under which the gases must pass into a checkerwork of brick piers. The latter maintain a high temperature in the combustion chamber so that the gases, mixed thoroughly in their passage under the arch and among the piers, burn at a high rate of combustion.

Water for the boilers in the heating season comes from a tank receiving the returns of the heating system. By means of a ball and float, makeup water is supplied from the house tank on the seventh floor. Duplex-feed pumps force the water to the boilers through a vertical closed heater 30 in. diameter and 12½ ft. high and a single-pipe economizer in the breeching 2 in. diameter and 60 ft. long. In the heater the temperature of the water reaches 150 deg. and is raised to 204 by the economizer. That the latter has been in service nine years and is still in good condition is attributed to the fact that the water enters the pipe hot (150 deg. at least), so that there is no opportunity for sweating and collecting pasty masses of soot on the exterior.

Heating is required nine months in the year from the 23,500 sq.ft. of radiation. The smaller building has a two-pipe system with a vacuum pump at the end of the line; the main building has a single-pipe Paul system.

DAILY REPORT OF POWER PLANT

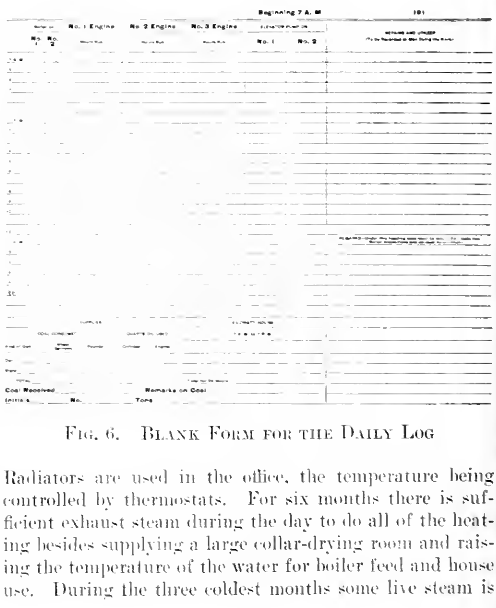

Fig. 6. Blank Form for the Daily Log

Radiators are used in the office, the temperature being controlled by thermostats. For six months there is sufficient exhaust steam during the day to do all of the heating besides supplying a large collar-drying room and raising the temperature of the water for boiler feed and house use. During the three coldest months some live steam is required, and at night throughout the cold season it is necessary to draw on the boilers, as the load is always light and the supply of exhaust steam is limited. The conditions then are unusually favorable. For nine months in the year, all of the exhaust steam is utilized and during the remaining three months part of the available supply goes to the feed-water heater, the drying room and the hot-water tank.

For ten hours the load averages about 650 amp., although it fluctuates considerably, due to the throwing on and off of some of the larger motors. After 10 o'clock at night and on Sundays it is only nominal. The connected load is 130 motors, these totaling only 208 hp., as many of them are used on sewing-machines, stitchers, envelope-sealers, adding machines, etc., and consequently are of small size. All operate at 110 volts and with the exception of a few shunt machines are compound wound.

For illumination there are, in round numbers, 5000 sixteen-candlepower lamps.

It has been the custom to run one of the compound-engine units for the greater part of the day. From 3 to 5:30 p.m., during the peak load, and on dark days the simple engine is used to help out, and after 10 in the evening it is the only engine running.

TABLE 1. POWER PLANT EXPENSES AND EARNINGS AT CURRENT RATES FOR 1911

Expenses

Coal, $3.45 per ton	$4,653.57
Switching and unloading	180.00
Engine oil used for all purposes	10.00
Cylinder oil	86.36
Grease for engines and motors	1.05
Hydraulic oil for elevators	56.52
Waste for engines, elevators and motors	56.52
Engine repair	70.81
Boiler repair	7.55
One-half of chief engineer's salary	800.00
Second engineer's salary	1,033.75
Two firemen's salaries	1,678.90
Paint and varnish	6.00
Fixed charges: Interest, 5%; depreciation, 5%; insurance and taxes, 1% on plant cost of $30,000	3,300.00
Total expenses and charges	$11,971.03

Earnings

2	Generators	Direct-current	75-kw	Main units	115 volts, 270 r.p.m.	General Electric Co.
1	Engine	Simple	11x12-in	Main unit	125 lb. steam, 270 r.p.m.	A. L. Ide & Sons
1	Generator	Direct-current	15-kw.	Main unit	115 volts, 270 r.p.m.	General Electric Co.

Fig. 6 illustrates the daily report sheet used at the plant. The accompanying tables show the operating costs for 1911 and 1912 under the conditions just enumerated and the earnings when charging current rates for the same services. In computing the expenses only half of the chief engineer's salary was charged, as but half of his time is devoted to the plant. The fixed charges are those prevalent in the city, as are the rates assumed for electric current and heating. The rate of $7 per day for the six elevators is an estimate, as is the 2c. per 100 cu.ft. for pumping. In 1911, the plant paid a dividend of $5227.84 on an initial cost of $30,000. This is a dividend of 17.4 per cent. For 1912, a net earning of $6450.24 raised the percentage to 21.5, figured on the original investment, with no reduction to the depreciated value. To the present value of the plant the earnings would bear a much higher ratio.

To arrive at the cost per unit of generating current is difficult, as the steam for the pumps and engines has not been separated; the same applies to the labor and supplies. An approximation would be to deduct the earnings for other services from the total expenses and divide by the kilowatt-hour output. For 1911, the balance left for the generating plant would be

$$\$11,971.03 - \$9866 = \$2105.03$$

Dividing by the output, 244,429 kw.-hr., gives

$$\$2105.03 \div 244,429 = \$0.0086 = 0.86c. \textit{ per kw.-hr.}$$

For 1912, the balance would be

$$\$12,660.87 - \$9912 = \$2748.87$$

Dividing by the output gives a cost per kilowatt-hour of

$$\$2748.87 \div 306,637 = \$0.00896 = 0.896c.$$

While these figures are only an approximation, they show that the plant is giving good service and that its commercial life is not seriously endangered.

Reconstructing Water-Tube Boiler Settings*

By Osborn Monnett†

SYNOPSIS—With a hand-fired furnace the boiler should be horizontally baffled, and department No. 8 furnace is recommended. Some interesting low-headroom installations.

Cleaning up hand-fired settings in connection with water-tube boilers is comparatively simple if the boilers are of the horizontally baffled type, as ordinarily there is enough headroom for a good hand-fired furnace and the proper combustion-chamber areas. In working over this kind of setting, the No. 8 furnace should be used. (For reference, see page 266 of the Aug. 25 issue.) Vertical baffles in a water-tube boiler must be horizontal before there is any hope of cleaning up the setting.

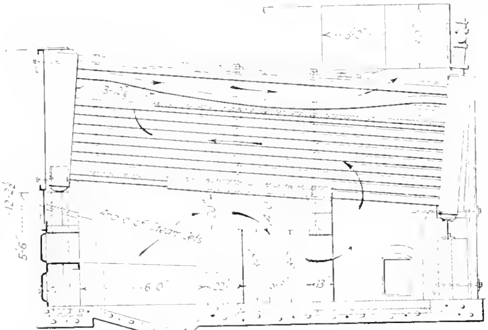

Fig. 1. Drumless Edge Moor Water-Tube Boiler, 215 Hp., and Hand-Fired Furnace

Sometimes an installation must be made under restricted headroom, particularly in office-building plants where the architect usually neglects the boiler-room space until the construction has gone so far that no adequate headroom is available. There are, of course, other circumstances that sometimes govern the doing of low-headroom jobs on new work.

Fig. 1 is a typical installation which, as an afterthought, was made in a modern office building. The original intention was to use central heating service. There was 14 ft. for headroom and the problem was solved by installing a drumless Edge Moor boiler with a combination T and box tile hand-fired furnace, having the deflection arch described in previous articles. The dis-

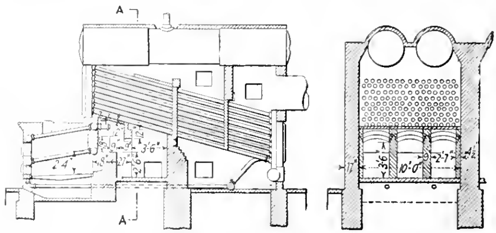

Fig. 2. A 400-Hp. Water-Tube Boiler and Down-Draft Furnace with Sprung Arch to Provide Travel and Mixture

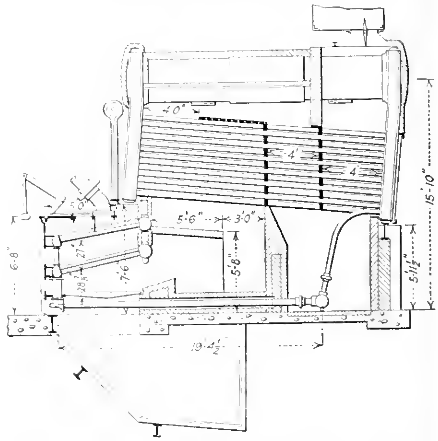

Fig. 3. Babcock & Wilcox Boiler, 300 Hp., with Full Extension Down-Draft Furnace and Mixing Arches

†Smoke inspector, City of Chicago

tance from the floor to the bottom of the front header was 5 ft. 6 in., and from the top of the front header to the floor it was 12 ft. 2½ in. With proper operation this setting can be expected to give good results.

Vertically baffled water-tube boilers are sometimes equipped with down-draft furnaces, both full extension and flush front, but the combination generally makes a bad smoker. The flush front setting must be horizontally baffled before it can be cleaned up. With the full-extension furnace it is possible to interpose brickwork construction which will increase the flame travel and mix the gases before they strike the heating surface.

Fig. 2 illustrates a full-extension, down-draft setting for a water-tube boiler, in which an arch 5 ft. 6 in. long has been sprung back of the bridge-wall, with sufficient throat area past the arch to allow the gases to escape. The bridge-wall action is good, as the radiation from it has the effect of maintaining the temperature of the gases, and as the gases impinge against it in changing their direction, combustion is aided materially. In new down-draft furnaces and water-tube boilers, the latter always should be horizontally baffled and the furnace have deflection arches.

Fig. 3 shows another down-draft installation set full extension. As shown in the drawing, the construction

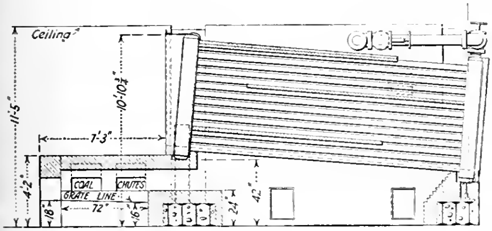

Fig. 4. A 375-Hp. Drumless Edge Moor Boiler and Burke Furnaces Set in Headroom of 11 Ft. 5 In.

calls for a high-temperature zone over the bridge-wall and a deflection arch in three spans before the gases pass to the heating surface. These compromise settings must be taken for what they are worth in cleaning up existing plants rather than as satisfactory settings for new installations.

Fig. 4 illustrates an interesting case where a 375-hp. drumless Edge Moor boiler served by Burke furnaces was set in a headroom of 11 ft. 5 in. Here are conditions which are sometimes met when putting a new power plant in an old building. In this case the building stood on a floating foundation, consisting of a mass of concrete and railroad iron in which it was impossible to do any excavating. At the same time it was impossible to raise the ceiling as it would then interfere with valuable floor space in the office building above. Therefore, the boiler installation had to be sacrificed and the design shown herewith was adopted. One of its features was the location of the safety valves. The headroom was so restricted that they had to be set, one on the side of the header, with a U-tube connection into the steam space of the boiler. Notwithstanding the conditions, these settings have been running successfully for years without smoke and without any unusual difficulty with the boilers.

Waste Hot Water Heats Feed-Water

By F. B. Hays

The writer recently designed a chemical plant in which several novel engineering features were embodied. The most interesting, from a power standpoint, was the manner in which the boiler feed water was heated.

The plant contained a battery of three boilers, two being in service while the third remained idle for clean-

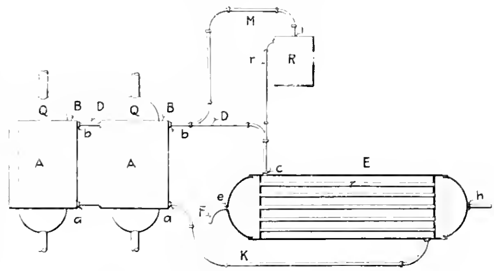

Fig. 1. Jacket of Chemical Tanks as Feedwater Heaters

ing or emergency. The steam was used directly in reduction tanks, becoming a part of the final chemical composition manufactured. This left no exhaust steam for heating feed water, and as there was much waste heat in the plant, it was not considered advisable to use live steam. Cooling water used to reduce the temperature and prevent explosions in the chemical reduction tanks was going to waste. After a careful study of the operating conditions in the reduction tanks it was decided that the cooling water could be used for heating the boiler feed water, and the latter kept at a fairly even temperature provided a suitable heater was installed. The heater shown in Fig. 1 was finally chosen.

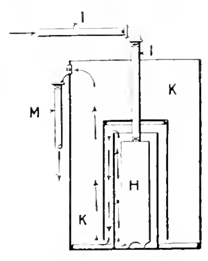

Fig. 2. Section of Overflow Box

The general arrangement of the whole system is shown in Fig. 1, in which are the reduction tanks *A*, where temperatures ranging from 70 to 600 deg. F. are produced by the chemical reactions; the water jackets *B* surround the cookers *Q* of the reduction tanks, into which the cooling water enters at *a*, and, becoming hot, flows out at *b* and through the pipe *D* into the boiler feed-water heater *E* at *c*. The boiler feed water (cold) passes through the pipe *F* and enters the heater at *e*. It leaves the heater at *h* for the boiler-feed pump, after it has become heated by the cooling water from the reduction tanks, and has in turn cooled this cooling water. The cooling water returns to the reduction tanks by the pipe *K*. The circulation of the cooling water is by gravity.

Due to the high temperature frequently produced in the cookers, provision had to be made to take care of steaming of the cooling water. This was done by means of an overflow pipe *M*, which discharged into the radiator *R* at *i*, from which it flowed into the heater *E* at *r*.

The construction of this radiator is shown in Fig. 2, where I is the pipe by which the water and steam from the reduction tanks enter the radiator, H the tubes where the steam is condensed, K the water tank of the radiator, and M the overflow pipe from the water tank to the feed-water heater. The object of this type of radiator was not only to condense and utilize the steam from the cooling system, but also to keep hot water flowing into the feed-water heater at all times. Since the temperature in the cookers varies as much as 400 deg. in an hour, it will be readily seen why such a device is necessary. On account of this same variation in temperature, the cubic contents of the feed-water heater had to be far in excess of that normally used or required in proportion to the area of its heating tubes, so that it would act as a large heat reservoir, which would not be readily affected by sudden changes of temperature of the feed-water passing through the cookers.

Will Quizz, Jr.

SYNOPSIS—Will Quizz asks about the shape of steam nozzles and is surprised to hear that an enlarging nozzle of the correct proportions will cause an increased velocity of the steam jet.

"Chief, what is the reason for the shape of the nozzles in our turbines? Instead of pointing the little end of the nozzle toward the rotor the big end points there."

"This is done, Will, to give a greater velocity to the steam. Fig. 1 shows that the velocity of steam issuing from a straight nozzle is almost constant for all pressures."

"How can an enlarging nozzle increase the velocity?"

"It is like this, Will: back in 1883 Dr. DeLaval made the first use of such a steam turbine by applying it to milk and cream separators. After experimenting, he concluded that the successful motor of this type should utilize the velocity of the steam rather than its direct action by pressure. His first step, therefore, was to convert the force in the steam into kinetic energy and obtain the highest possible velocity for the steam. He conducted a number of experiments and established the shape of the nozzle which would produce this effect.

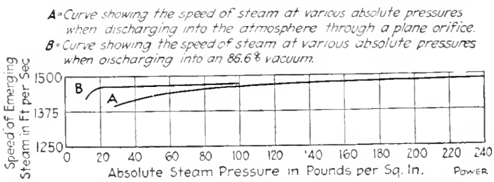

FIG. 1. STEAM VELOCITIES WITH STRAIGHT NOZZLE

"Probably the easiest way to describe this would be by comparing the steam in the boiler under pressure with a lot of toy balloons in a closed vessel under sufficient air pressure, so that each one, instead of being some four inches in diameter under atmospheric pressure, would be compressed to perhaps one inch.

"Suppose then these balloons were allowed to escape through an opening just large enough for one to pass through at a time and into the nozzle of the shape shown. Immediately after passing through the small end they would begin to expand by reason of the reduced external pressure, but if the nozzle did not enlarge in proportion to this expansion it would elongate and increase its velocity as it expanded.

"This elongation necessarily would have to take place in the direction of the flow because the others, following under pressure, would urge it forward and prevent any rearward elongation or even any retarding of the outward flow, so it will be seen that the velocity must increase in order to allow for the expansion. Fig. 2 shows the increasing velocity of the steam issuing from a properly designed diverging nozzle.

"Referring to your steam tables again, Will, you will see that the specific volume of one pound of steam at 465 lb. pressure is one cubic foot. At lower pressures the volume is greater, and at atmospheric pressure one pound occupies about 27 cu.ft. (or 27 times the original volume for a given weight of steam). As the pressure decreases below that of the atmosphere the volume increases rapidly, so that at one pound absolute pressure it occupies 333 cu.ft.

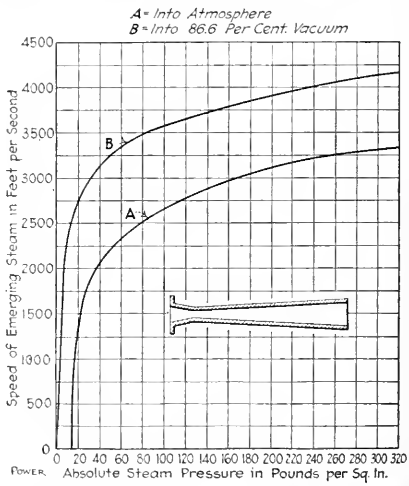

FIG. 2. STEAM VELOCITIES WITH ENLARGING NOZZLE

"The shape of the nozzle—that is, its rate of enlargement—must be proportional to the initial pressure and terminal pressure against which the steam flows, but the more extreme these two pressures are, the more abruptly the nozzle may enlarge. Therefore, nozzles are of different proportions or designs for different boiler pressures and the amount of back pressure or degree of vacuum into which the steam is discharging. With a given area of throat or small section the area of any section beyond is directly proportional to the specific volume and to the dryness of the steam, and inversely proportional to the velocity."

Editorials

Value of the Extra Man

How many manufacturers believe that it would pay to employ an extra man in the engine room, so that the chief engineer would have more time to devote to the boiler room and see that the maximum fuel economy is maintained?

Fuel is the main expense in all power plants, and although many consider it, more ignore it.

In one plant for instance, the owner will not be bothered about the coal, but insists on purchasing the engine and cylinder oil himself. The fuel item would run into thousands of dollars annually; the oil would cost a few hundred.

As pointed out in a first-page cartoon some time ago, the switchboard of most electrical plants carries all the necessary recording and indicating instruments, so that the attendant can keep a record of the output in electrical energy. But out in the boiler room there are only the old safety valve, water glass and pressure gage, with nothing to indicate the performance of the boiler. The bills for coal and supplies come to the office and, although protest may be made against their size, nothing is done to help the engineer reduce them.

In other plants some attempts may have been made to obtain efficient operating results, and perhaps instruments for ascertaining the percentage of CO_2 in the furnace gases have been provided, together with draft gages, steam-flow meters, etc., but if no attention is given them, they might just as well be cut out for all the good they may do.

Pointing out defects is useless, unless measures are taken to remedy them. If help is so limited that there is not time for some one in authority to find the source of loss and to see that matters are changed for the better, then good American dollars are going to waste, because nobody is held responsible for the loss.

Engineers well know the situation, and there are many of them who are striving, even against adverse conditions, to operate their plants economically. There are others who are indifferent, because the men higher up do not do their part in preventing losses.

With so many plant owners and managers lax in this regard, it is refreshing to know that one manufacturing company (see the article, p. 38) realizes the greatest opportunity to save is in the boiler room, and that an overworked engineer cannot give proper attention to securing economical operation. For this reason an extra man is employed in the engine room so that the engineer may give time to getting all possible out of every pound of coal consumed in the boiler furnaces. Moreover, instruments are provided to show the operating conditions, and are so arranged that any one of the boilers can be checked by the instruments.

How many power plant owners believe that if the chief engineer is given the opportunity he can more than save a man's wages by properly managing the boiler room? Why not give him a chance and find out?

Getting New Business

Small electric-light plants may note with profit the accomplishment of the Springfield (Missouri) Gas & Electric Co., which has added two hundred new residence customers to its circuits in sixty days, with no line or transformer expense.

This increase in new business is largely accounted for by the fact that the company offered to put in a few outlets, and did not insist on wiring the houses complete before putting in the service. This naturally appealed not only to owners, but to renters of even small houses. With the service once in, the convenience was apparent, and additional outlets were added here and there, so that what did not represent an attractive connected load at first has gradually become a profitable one.

A small station cannot hope to obtain the same number of new connected houses in the same period as did the Springfield company, but what is to prevent the idea from being worked out on a smaller scale in smaller cities and towns? It would appear to be worth trying.

Water-Power Legislation

Hearings on the Ferris water-power bill, before the Senate Committee on Public Lands, developed that its passage in the Senate will be opposed on two grounds. A small clique of Western senators will oppose the measure because they want the dam sites in the public domain deeded over to the states without condition. The influence of large hydroelectric promoters and operators will be exerted against it because they want power sites given to the companies in perpetuity. The bill as it passed the House proposes that power sites on the government lands shall be leased for not more than fifty years, and that the property shall revert to the government at the end of that period.

It was brought out at the hearings that Canada, Norway, Sweden and other countries where there are large water powers have secured their development under very much the same plan as that now urged by the administration and embodied in the Ferris bill.

Upon the action of the Senate on this bill and on the Adamson dam bill, both of which have passed the House and are awaiting senatorial action, depends whether there shall be any extensive development of water powers in the United States in the near future. Under present laws, such development is almost impossible. So far as Western water powers are concerned, they are practically all in one of two classes: either held in private ownership by large corporations which form what Gifford Pinchot and others declare to be a "water-power trust," or they are within the public domain, under the ownership and control of the Federal government. In the East and South, there are also large potential water powers on navigable streams which can be utilized only by permission of Congress.

The War Department claims jurisdiction over navigable streams, on the ground that any obstruction of these affects navigation, which is under Federal control. In the public domain, there has been some granting of permits for water-power development along streams in forest reserves, which are under the control of the Department of Agriculture. So far as power sites in the public domain outside of the forest reserves are concerned, however, there is no law permitting any leasing or permits. They must either be withheld entirely from use, or given away as farm lands to anybody who asks for them. Judge Finney, of the Interior Department, told at the hearings of one power site acquired by a power company from the government at one dollar and twenty-five cents an acre as agricultural land, and capitalized at twenty-six million dollars by the corporation which secured it.

These water-power hearings have brought out clearly the story of how the water powers of the West are monopolized, and the ramifications of the big power corporations. They have also served to point out forcibly the difficulty that exists in drawing the line between state and Federal authority in the control and regulation of these matters. All the water in the streams is owned by the states. The courts have said that more or less clearly. So far as its use is concerned, however, the Federal government has control over everything affecting navigation, and the courts have not decided just how far back toward the source of the stream that extends.

In the proposed general dam bill, the power claimed by Congress is drawn entirely from its right to control navigation. Even if a corporation owns a dam site, and the state in which the site is located has granted a right to the use of the waters of the stream, the dam-site owner cannot build his dam without the consent of the Federal government, on the theory that the dam might interfere with navigation. In the past, permission for the building of dams and power plants along such streams has been made the subject of special acts of Congress, it being necessary for a company to get a specific act through Congress to enable any dam to be built. In the pending bill, it is proposed to make a general law governing the granting of such permission, and allow the Secretary of War and the Secretary of the Interior, under certain restrictions and conditions, to grant such permits.

The Adamson bill would open to use, under regulation, the unused water powers and power sites in the East, South and Middle West. The Ferris bill deals with the water powers in the public domain, which is almost wholly in the far West. The latter, in fact, makes no proposal for regulating the use of water powers, but deals wholly with power sites. However much power there may be in a stream or a waterfall, it is useless unless there is a place to build a plant for its development. Where these dam sites and power-plant sites are on land owned by the government, the Ferris bill proposes that the government shall lease the sites on such terms as will enable the government to forever control the development of power at that point.

In an effort to propitiate the "states' righters," the Ferris bill proposes that where electricity is used in the same state in which it is generated under a Federal lease, the operations, rates, etc., shall be subject to state regulation, where there is a state utility commission. Where there is no state regulation, the government is to do the regulating. Where power is generated in one state and carried into another state for use, that used in the state where it is generated is to be under state regulation and that in the other state to be under Federal regulation. Where the company does an interstate business, however, not only the current which is sent across the state line, but also the entire assets and affairs of the company generating the power will come under Federal control and regulation. In actual operation, it seems probable that the effect of the proposition, if the bill becomes a law, will be to have both Federal and state regulation over the same enterprises.

The bill proposes that the rental charged by the government for the power site shall be decreased in proportion as the operating company decreases the price to consumers for light and power. Senator Smoot, of Utah, who opposes the measure, ridiculed this proposal in the committee hearings, on the ground that it would be more profitable to the companies to pay the higher taxes and exact the higher rates.

The money derived from leases of power sites is to be placed in the reclamation fund, and after it has once been used for reclamation projects and repaid to the government by the water-users on these projects, it is then to be equally divided between the states and the government.

Encouragement

How many chief engineers encourage their men by expressing satisfaction when work has been well done? How many comment favorably upon the personal appearance of their assistants? What would be the result if appreciation were expressed? Nothing will encourage a man to do his best so much as the knowledge that his work has received recognition. Nothing will cause a man to become disgruntled so much as an attitude of nonappreciation on the part of the chief.

An assistant engineer need not fear being classed as a "dude" because he prefers to go about his work with clean clothes. If he does not keep himself clean and neat, the chances are that he will be slovenly about his work. Some engineers have the appearance of coal passers, and their plant presents the appearance of having seen better days. No self-respecting man can be content to work in a dirty engine room where it is impossible to keep himself in a half-way presentable appearance. Encourage men to do better work, to keep the plant clean, and their own improved appearance will follow.

If a man thinks well of himself, and he will in cleanly surroundings, he will think well of his chief and of the company that employs him.

Not a single passenger out of the 188,411,876 carried in 1914 on all of the 26,198 miles of track of the entire Pennsylvania R.R. system was killed in a train accident.

This looks to us like real forethought and true business acumen on the part of the Pennsylvania R.R. It realizes that the more passengers it kills the less it will have to carry, so it tries not to kill any. Last year it was successful and had a perfect score—no misses.

Indexes to Power are furnished free to all who request them. That for the last half of 1914 will soon be ready. A simple request, addressed to the Subscription Department, Power, will bring one.

Stresses in Convex Heads

In the Dec. 8 issue there is a discussion of my contribution to the issue of July 7 concerning stresses in convex heads. The first remark by Mr. Vander Eb to the effect that the results of my analysis are at variance with opinions previously expressed depends on the point of view. When an abstract analysis of a statical or physical problem is undertaken, all opinions, even those of the mathematician, are irrelevant. The matters pertinent to the analysis consist of, first, the premises upon which the analysis is based; second, the propriety of the mathematical processes that are employed, and, third, the specification of the consequences of the analysis. I fail to see anything peculiar in the fact that an attempted analysis of a problem in statics leads to results at variance with current opinion since current opinion, heretofore, has been at variance with the facts concerning the safety of convex heads.

Concerning the more direct discussion of the analysis by Mr. Vander Eb it is fair to examine the premises upon which my analysis is based for the errors which are said to exist. He asserts that I have neglected the deflection of the dished part of the head "by simply assuming that a purely spherical tension at the circumference is all one need to expect." If anything new in the way of theory of stress in spherical shells, or in portions of them, can be offered, there may be sufficient evidence to enforce the abandonment of the respect for such writers as Rankine, Church, Merriman and Cotterill.

There is nothing more explicit than the statement of Rankine ("Applied Mechanics," p. 290), viz., "hence the whole force to be resisted by the tenacity of the shell is," etc. The statement admits of no shearing stresses or any stress in the spherical shell other than a simple tensile stress. The presence of shearing stresses would cause local deflection from the spherical surface and their absence precludes "deflection."

Referring to Fig. 2, by Mr. Vander Eb (which is substantially the same as Fig. 4 of the July publication), it will be seen that the element of the flange fillet is completely supported by the system of forces as specified. Some of these forces constitute "reactions" on the part of adjoining material which, if properly accounted for, dispose of further consideration of such extraneous material in the analysis. I have shown the justification for the acceptance of the force T as a simple tension unaccompanied by shear stresses on the face DC of the element. If there is any bending of the material of the plate at the section AB, there is at least a "stress couple" and possibly shearing stresses. By the selection of the origin of reference at O', at the middle of the plane AB, all effects of these shearing forces from the moment equations are eliminated.

A little reflection and reconsideration of the detailed analysis in the article of July 7 will show that Mr. Vander Eb is wrong in asserting that the element of the flange fillet is considered as a beam with "free" ends. The remainder of this paragraph in the Dec. 8 article is somewhat questionable in the attempted substitution of impressions, however plausible they may appear, for the logic and conclusions of a statical moment equation that is either right or wrong. In the interest of engineering progress, the elimination of errors should be the ambition of all concerned. I cannot see the justification for the introduction of the forces on the sides of the element (Fig. 3 of the July 7 article) for reasons explained originally.

Mr. Vander Eb overlooks the fact that the analysis contemplates attachment of the convex head to a rigid cylindrical shell as "a yield of the structure at the flange connections would seriously complicate the stress-strain relations." Furthermore, a yield at this point would be incapable of analysis with the present limitation of the theory of statically indeterminate structures.

With much of the remaining discussion I have but little reason to dissent. One criticism of my article, and all similar articles, was overlooked which I will undertake to supply. The analysis may be wrong because it has assumed a homogeneous molecular state of the material in the plate after it has been heated, flanged, cooled and forced into shape and place by any practicable flanging process. There is no means of estimating the magnitude of the initial strains in a dished head, and particularly in the region of the flange fillet. These may be, and in certain cases actually have been, so severe that the heads cracked while they were being riveted to the shell. At the risk of a small increase in cost of boiler construction, a flanged head could be subjected to suitable heat treatment or at least proper annealing when, if ever, the plate may be assumed to be free from internal strain.

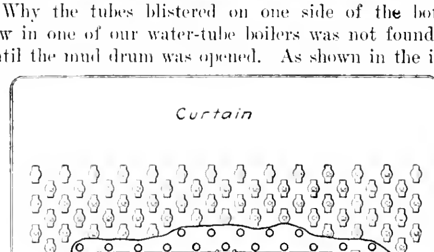
South Chicago, Ill.

Side Tubes Blistered

Why the tubes blistered on one side of the bottom row in one of our water-tube boilers was not found out until the mud drum was opened. As shown in the illustration, the blowoff was connected to a tee inside of the mud drum, into which were screwed two short lengths of pipe supported about 2 in. from the bottom of the drum and having ½-in. holes drilled in the lower sides and the ends capped.



Blowoff Pipe Open at One End

One of the caps had worked off and consequently all of the drainage or blow was from that end. The sediment gradually accumulating at the other end had stopped the circulation in the tubes and allowed them to become overheated.

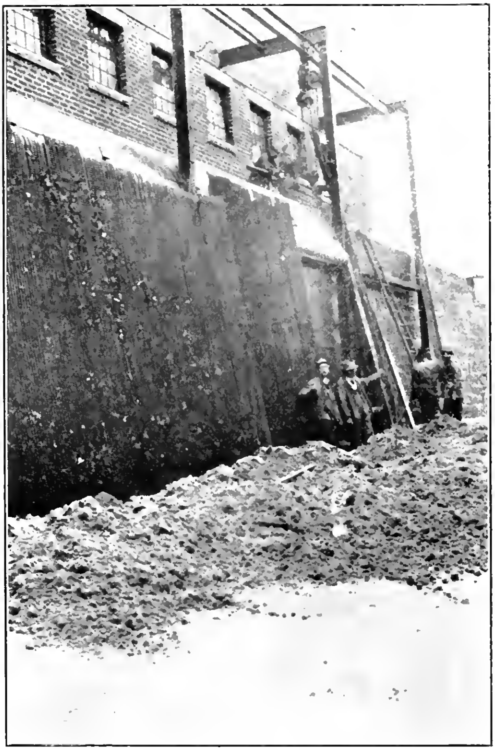
High-Pressure Water for Cleaning

New trash racks were to be placed in front of the water-wheel chambers at the hydro-electric plant in which the writer is stationed. On letting the water out of the head



DIRT AT THE INTAKE SCREENS

race, which is about 16 ft. to the concrete footing on which the bottom of the racks were to rest, the footing was found to be covered with sand to a depth of 4 or 5 ft. Much of this sand was removed by shoveling, but as there was some water dammed up behind this bank, which could be drained out, the sand was washed in almost as fast as it could be shoveled away.

In the plant we have mains carrying water at a pressure of about seventy pounds. The use of this water to do the work was suggested, and the plan was carried out with success. A line of 3-in. pipe was coupled to the water main, and to this pipe a 3-in. suction hose was connected. A nozzle was needed and as none was at hand, we proceeded to make one out of a short piece of 3-in. pipe about 3 ft. long and threaded at one end. The other end was heated in a forge and the edges flattened, leaving an outlet 1½ in. diameter and flared back to the diameter of the pipe. This nozzle was coupled to the hose and the full pressure turned on. The sand was thoroughly stirred and in a short while most of it was carried off. The rest was kept constantly stirred by the water, and the racks, section by section, quickly dropped into place. The illustration shows the head race.

Starting Small Motor

We have a small direct-current, shunt-wound motor that had been used satisfactorily for driving a bottle-washer by throwing directly across the line in starting. When it was belted to a jig-saw, where there was more friction, it had to be helped in starting. Believing that the heavy starting current might have so weakened the shunt field as to reduce the torque, the writer placed a bank of lamps in series with the armature, upon which the motor started easily, although the running speed was reduced somewhat.

It appears that above a certain point an excessive armature current in a shunt motor reduces the torque instead of increasing it.

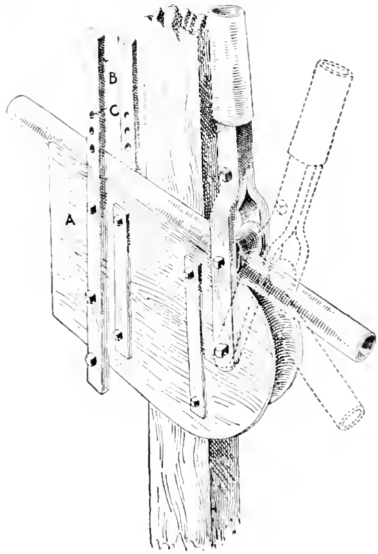
Pipe Bender

In a plant where it was necessary to bend pipe of various sizes from 1 to 2½ in., the simple pipe bender shown did good work.

A 2-in. hardwood plank 18 in. long by 12 in. wide,



PIPE BENDING FORM CLAMPED ON POST

rounded off at one end to a 6-in. radius, was fastened to a post in the shop. Two pieces of 1½x½-in. flat steel *B*, one on each side, and extending 5 in. above the top of *A*, had a number of ¾-in. holes for a pin to hold the various sizes of pipe. On the rounded end was fastened a swinging arm or lever and roller held in place by a bolt through two pieces of 1½x½-in. flat steel, and pipe extensions of different lengths furnished the required leverage to bend the various sizes of pipe.

The method of operating is to hold one end of the pipe to be bent in the space between *A* and a pin in *C*, and bring the roller to bear slightly, then draw the pipe forward an inch or two and repeat the operation until the required bend to any number of degrees is completed. This apparatus is inexpensive, easy to construct and is convenient for making offsets and lateral bends.

Quinebaug, Conn.

Gaskets for Plugs of Compressor Valves

In the Nov. 10 issue, Mr. Herr asks for information about material for gaskets for plugs in ammonia-valve bonnets.

There are four kinds of valve bonnets for ammonia compressors. The most common form is such as is found on the Linde type of machine. It is held in place by studs or capscrews and the gasket fits into a recess so formed that the male part of the bonnet holds the valve cage down to its seat in the casting. Almost any ordinary gasket, rubber, lead or other material, will make a tight and lasting joint. One-sixteenth-inch lead or rubber sheet packing is much used, but if the joint is troublesome the use of one-sixteenth-inch rubber packing of nearly pure gum is advisable.

Before inserting the gasket, it should be noticed that the top of the valve cage projects about one-sixty-fourth of an inch beyond the surrounding surface. If the cage has been ground into the seat and the top is below this surface, an extra gasket must be used which fits the valve cage only and acts as an extension to it, allowing the bonnet to hold the cage tightly in place. Neglect of this will allow leakage between the head or cylinder casting and the cage, proving no better than a leaking valve. This style of bonnet is found on compressors of many makers.

There is a bonnet where the valve cage is set in the compressor head and held to its seat by a ring or nut; the bonnet is screwed into the head outside the ring. Rubber gaskets are supplied by the builders of the machine and never give any trouble when inserted properly.

Then we have the style of bonnets used on the old Boyle and Pennsylvania Iron Works compressors. Here a yoke is used, the studs being screwed into the compressor head and an iron strap reaching from one stud to the other, with the valve bonnet between the two studs. A setscrew passes through the strap and when screwed down forces the bonnet to its seat. The same material can be used for gaskets as in the Linde type, but pure gum is preferable as it is soft and does not require such pressure as does lead to make a tight joint.

There is another type where the valve cages are put in from the cylinder side of the compressor head and the bonnet screws onto the threads on the outside of the upper end of the valve cage. The cage is kept from turning by a dowel pin. Sheet lead one-sixteenth-inch thick is the proper thing for these gaskets as the turning effect of the bonnet might tear or misplace a rubber one. If the joint is a particularly troublesome one, put a gasket of one-thirty-second-inch pure gum beneath the lead. There is no reason then why the joint should not be tight unless there is some defect in the casting or the valve cage is too long, the top of it striking the inside of the bonnet before the gasket is pressed tight.

The temperature of an ammonia compressor should never be so high that it will melt lead. Use plenty of water over the jacket or send the suction vapor to the compressor in a slightly saturated condition. Properly cut and inserted gaskets of either one-sixteenth-inch sheet lead or of good sheet rubber will keep these from leaking unless something is mechanically wrong.

The nuts, capscrews or screwed bonnets of compressor valves must be frequently tried with a wrench as the changes of temperature to which they are subjected will cause them to become loose.

A. G. SOLOMON.

Chicago, Ill

Cylinder-Head Packing

A good gasket, which will hold where rubber will not, may be made of copper wire if the surfaces are reasonably smooth and true. The copper should be annealed by heating it red hot, then dipping it into water once or twice, or until soft enough. Gaskets may be made of any size suitable to the work from ⅛ in. to $^1/_{64}$ in. After the wire has been annealed, draw it around the cylinder head and twist it a couple of times, and then flatten the twist a little thinner than the wire.

Either solder the ends or wind candle wicking around the joint. Put the cylinder head on and draw up evenly on all the bolts, and then hammer a little on the head over the wire to flatten it. Next, take up snugly on the bolts. Soldering the gasket to the head will keep it in one position all the time and will be convenient if the head is to be removed frequently.

JOHN P. KOLAR.

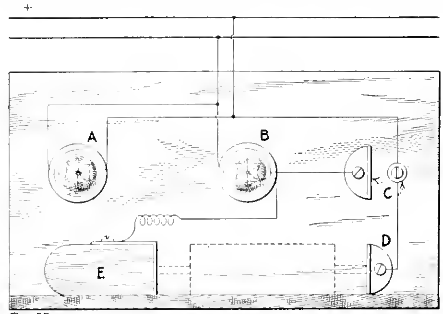
Lamp and Fuse Tester

I have a simple and convenient tester for lamps and fuses, the wiring plan of which is shown in the illustration. The metal part of the socket *A* is slit and opened



LAMP- AND FUSE-TESTING BOARD

so that the lamp need not be screwed in, but simply pressed in.

B is a lamp screwed in permanently as an indicator in testing plug fuses at *C* by placing the end on the bottom connection and the side in contact with the metal side. If the fuse is good the lamp at *B* will light up.

Contacts *D* and *E* are for testing cartridge fuses. The dotted line shows a fuse in place with the sliding, metal-bound block *E* pressed against one end. The outfit can be mounted on a marble slab or asbestos-covered board to suit one's fancy.

James G. Sheridan.

Brooklyn, N. Y.

Pottery Clay in Fireclay Service

In the Dec. 15 issue of Power appeared an article on the use of cement for furnace lining as practiced by the Robert Gair Co., Brooklyn, N. Y. This called to mind an experience I once had in repairing the setting of a 250-hp. water-tube boiler in a remote part of the West Indies.

One day we found ourselves short of fireclay, due to a delay in shipment, and it was necessary to repair the boiler setting at once, and replace practically all the firebrick around the door arches, etc. We tried to buy or borrow enough fireclay to do the work but everyone seemed to be short at the same time.

In the neighborhood was a small pottery plant, so as a last resort we decided to see how good a fireclay this unburned pottery clay would make. We were surprised to find that it lasted longer than the brick and fireclay around it.

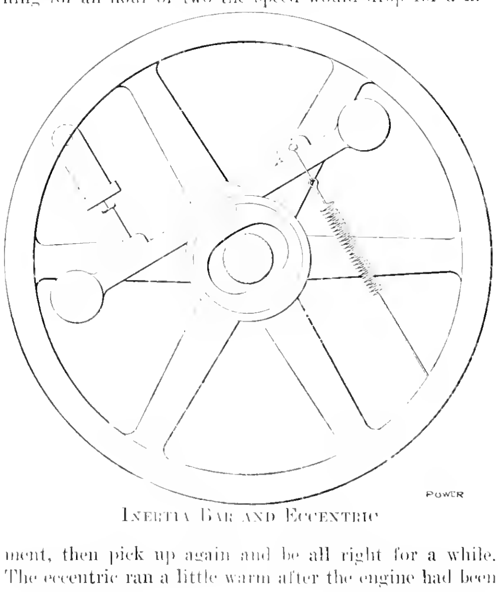
Whitinsville, Mass.

Trouble with Inertia Governor

An inertia governor of the type shown gave considerable trouble on account of its sluggish action. After running for an hour or two the speed would drop for a moment, then pick up again and be all right for a while. The eccentric ran a little warm after the engine had been off for repairs and the eccentric straps were tightened up. The added friction, however, retarded the governor, causing earlier cutoff and reduced speed. When a paper liner was put in the trouble stopped.



Inertia Bar and Eccentric

At another time the same engine ran unsteadily. Changing the adjusting screw in the oil bypass of the dashpot helped some, and when a lighter grade of oil was substituted, the engine governed satisfactorily.

Sometimes the roller bearing, which has $\frac{5}{32}$-in. rollers, wears slots in both the bushing and the pin. This retards the action of the governor, but a new set of rollers, a pin and bushing will make it entirely new.

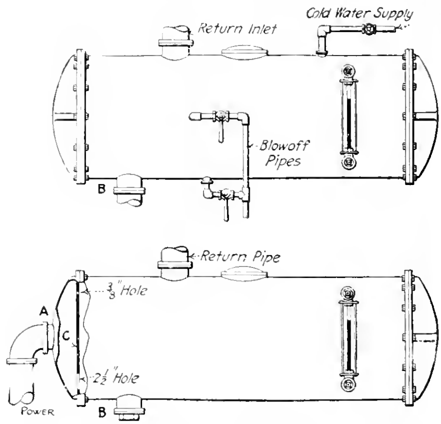
Governors of this type must work very freely, otherwise they cause a great deal of trouble.

J. C. Hawkins.

Hyattsville, Md.

Oil from Heater Got into Boiler

The top diagram shows a combined feed-water heater. In our plant the returns from the heating system and the exhaust from other pumps and engines return to this heater. There is no oil separator in the exhaust line from the pump, consequently oil gets into the heater.



Heater before and after Being Remodeled

As originally installed, the apparatus gave no trouble so long as the man in charge was careful to use the blowoff cocks to rid the heater of oil. One night the fireman pumped the heater dry, not noticing the lowering water level until too late. There was considerable oil in the heater at the time and it got into the boiler.

To avoid further trouble, the suction line to the heater was made to enter the tank in the center of the head as shown at *A*, while the original suction line *B* at the bottom was plugged. Between the head and shell there was placed a sheet-iron plate *C*, $\frac{1}{8}$ in. thick. At the top a $\frac{3}{8}$-in. hole was bored and at the bottom a $2\frac{1}{2}$-in. opening was allowed in the plate, the water going out of this hole on its way to the pump. The function of the $\frac{3}{8}$-in. hole is to prevent the pump from siphoning the water in the heater over into the suction line. With this arrangement we are never troubled by oil getting into the boiler.

Washington, D. C.

Former Engineer of La Salle Hotel Defends His Administration

The attention of readers of POWER is called to the article appearing in the Nov. 3 issue of that paper, page 628, in which statements were made that the power plant in the Hotel La Salle, Chicago, Ill., was not operated efficiently during the years 1910 and 1911. The following facts and figures are in contradiction to these statements.

The Hotel La Salle was opened in 1909 under strike conditions of the mechanical trades, there being thousands of dollars' worth of unfinished work which had to be finished after the house was opened. Also revision of plans and certain changes necessary to be made to suit conditions made an enormous amount of extra work to be completed by the engineering department and necessarily created a large expense for labor and material, which was chargeable to the engineering department, but should not have been charged as an item of operation.

It was required by the management at that time that the house be thoroughly ventilated at all times, which required all ventilating fans to be operated constantly at their scheduled speed for furnishing the quantities of air required. Voluntary information handed the writer from a person who served in the mechanical department under Mr. Bird, present chief engineer, states that replacing the 16-cp., 60-watt lamps through the house with 25-watt tungstens shows a saving of 43? kw. on lighting load alone. This change was often suggested by the former engineer, but was not entertained by the management. He also states that over 100 hp. in motors were closed down, the greater part being on ventilation. Relative to these items, it is beyond contradiction that there is any credit or discredit due either engineer, as the same saving would have been effected had the company seen fit to make such changes in service before.

It is not the purpose of this article to reflect on the present management of the plant, but simply to submit to your readers such facts and figures as will contradict the misleading statements reflecting on the former management.

The steam traps mentioned in the article of Nov. 3 were one of the best known makes, which gave excellent satisfaction, and owing to the complete system of piping there were but very few traps required for the handling of all condensation from the entire house, each trap being fitted with test valves below the valve in the main discharge pipe in order to test the traps for leakage. Each trap was tested daily by closing off the discharge valve and opening the test valve, allowing the trap to discharge into the atmosphere, to determine if the trap was working properly, it seldom being necessary to renew seats or valves. It is therefore flatly contradicted that there was any loss of steam from this source.

Also during the time the hotel plant was operated by the chief engineer previous to Mr. Bird's time, vacuum cleaners were in constant use. They were three in number, and a great deal of the time during the day the three were in use at once. Probably POWER has not been informed that these are now used but very little.

Another item which should have reduced the operating expenses of the plant was the discontinuing of several hundred lights around the banquet-hall windows and 19th floor. During the previous engineer's time at the La Salle Hotel, these lights were required to burn from lighting time in the evening until 1 a.m. It can readily be seen that by discontinuing these lights the load would be greatly reduced, which also has no reflection upon the engineer.

There were always constant changes being made in rooms, kitchens and other portions of the house for the first two years which required an extra force of men, all of which came under the chief engineer's charge and were chargeable to his department, although not an item of plant operation.

We wish to state further that during the coal shortage in the winter of 1910, the hotel company, not being under contract with any coal concern, made it necessary to burn whatever coal was on the market, and the greater part of the time coal was used that ran 20 per cent. ash, making it necessary to run from one to two boilers more than should have been run if good coal could have been obtained, to say nothing of the high prices they were compelled to pay. No steam was allowed to go to waste at any time, as a daily record was kept of the amount of water evaporated and the coal burned. These records were absolutely correct, as the meter was inspected once each month by an expert from the Worthington Meter Co., and if any repairs were found necessary, they were made by him. Evaporation was kept up to the highest possible point at all times as the test made by a prominent engineering company of Chicago will show.

In reference to the operation of the different electrical units, it was found to be impossible to change their schedule at that time as the official test also shows they were operated at their most economical point. No steam ever escaped from exhaust pipes in winter except in very mild weather or perhaps for a short interval at lighting time in the evening, while engines were being changed. All rooms were supplied with artificially cooled air in the summer months that were designated to receive it.

The cutting off of this service would also reduce the operating cost, but with no credit to the present engineer or discredit to the former, as the entire plant might be shut down and have no expense at all. It is a well known fact that during the former chief engineer's time at the hotel, the power plant was a credit to a house of its kind. It was light, clean, well kept and with smooth running machinery. Today it will speak for itself. It is a very easy matter to cut down expense at the sacrifice of the plant.

Such furnace changes as were made speak for nothing unless a higher CO_2 or a higher evaporation can be obtained, which the previous article has failed to show, but which is shown by the test made by the engineering company to be above the average evaporation for the best equipped plants. It is plain to see, according to the article printed in POWER of Nov. 3, that no tests of any kind were made by Mr. Bird to determine the amount of work done. The article merely states that "eight pounds of water were evaporated per pound of coal," but for all the figures shown it might be four or it might be fifteen, but not so in this article, as the facts and figures are here in detail and are signed by a company recognized as high authority on scientific tests. Note the evaporation, also cost of generating current, and then compare with the article printed on pages 629 and 630 in POWER, Nov. 3 issue.

It is also a fact that the man who operated the hotel plant previous to Mr. Bird is a person holding a very responsible position with a large and well established firm, he having charge of several large plants, all of which generate their own power and are equipped with high-class machinery, which plants employ a very large force of engineers and mechanics.

No mention was made in the Nov. 3 issue of POWER of the new elevator pump being installed in the La Salle Hotel since Mr. Bird's time, which cost several thousand dollars and from an engineer's standpoint being wholly unnecessary, as the original pumps never failed to handle the nine hydraulic cars all in service at once at high speed, with always one pump in reserve, and at no time were any of the cars shut down except for repairs and then only after 12 o'clock midnight as it required the six passenger cars to handle the enormous number of guests in the hotel at that time. Also the installation of a new hot-water heater, from the same point of view, would be considered unnecessary, as the heater originally installed never failed to furnish sufficient quantities of hot water when the house was filled to its capacity.

Following are some of the important and interesting facts of the tests made by the aforesaid engineering company, a copy of which was given the writer by the hotel management at that time:

Relative to purchasing electrical power: If a lower rate than 1.2c. per kw.-hr. can be obtained from parties selling power, it is recommended electrical energy be purchased during the summer period, viz., May 1 to Oct. 31. The requirements for these six months are approximately 1,540,000 kw.-hr. The average cost to generate 1 kw.-hr. operating as at present is 0.72c. during winter season, 2.2c. during summer season and 1.46c. average for the year.

TOTAL OPERATING COST FOR LIGHT AND POWER

	Winter Period	Summer Period	Total for Year
Proportional operating cost generating steam	$8,152.95	$30,742.75	$39,195.70
Engines and generators, maintenance, material and supplies	527.86	464.11	991.97
Interest on capital invested in engines, generators, switchboard and intermediate wiring ($49,400 @ 6%)	1,482.00	1,482.00	2,964.00
Insurance and taxes on above apparatus ($49,400 @ 2%)	294.00	294.00	588.00
Depreciation on above apparatus ($49,400 @ 1%)	988.00	988.00	1,976.00
Total	$11,741.81	$33,970.86	$45,715.67
Kilowatts generated	1,640,150	1,540,700	3,180,850
Average cost to generate 1 kw.	$0.0072	$0.022	$0.0145

The average cost to generate 1 kw.-hr. of 0.72c. during winter period cannot be expected to improve very much, but it is reasonable to believe that the summer rate of 2.2c. can be reduced. In view of the fact that electrical power generating apparatus is installed and in operating condition, thereby having a fixed charge, also that a permanent engineering organization has been established with its accompanying fixed charges, it will be necessary to obtain a lower rate from parties selling power than 2.2c. per kw.-hr., the present unit cost during summer period. In order to ascertain the actual saving made and the maximum rate that could be paid if electrical power was purchased, the following tabulation was made:

FOR SUMMER PERIOD, SIX MONTHS

	Amount
Coal, 7500 tons, minus 2375 tons*, @ $2.90	$14,862.50
Labor, 3 oilers @ $60 per month	1,080.00
Ash removed, 475 cars @ $2	950.00
Maintenance, material and supplies (from the first table)	464.11
Water, boiler make-up	150.00
Less depreciation on apparatus:	
One boiler and accessories, $13,600, @ 2%	272.00
Engines and accessories, $49,400, @ 1½%	741.00
	$18,519.61
Per kilowatt-hour	1.20

* Coal required for generating live steam necessary to help out exhaust steam demand.

This indicates that a lower rate than 1.2c. per kw.-hr. will have to be obtained in order to make any saving.

General conditions of plant: The power plant as a whole is in good operative condition and shows careful attention on the part of engineers in general upkeep and maintenance of machinery. Indicator cards off engines show good judgment has been exercised in setting valves, adapting them to best suit services that they perform.

Load Factors:	
Total estimated number of lamps (56-watt) in house	22,500
Load factor, per cent.	16
Total connected horsepower motors on 220 volts	431.85
Load factor, per cent	50½

Boiler evaporation test: The data and results of boiler-plant evaporative test are given in addenda herewith. The results are in accordance with good practice obtained from boilers of the type installed and quality of coal fired:

ENGINEERING DATA FOR YEAR ENDING FEBRUARY 28, 1911

1910	March	April	May	June	July
Coal consumed under boiler in tons	2190.2	1888	1880	1770	1769
Pounds water evaporated per pound coal	$5\frac{1}{4}$	$5\frac{2}{3}$	$6\frac{3}{4}$	$6\frac{1}{3}$	$6\frac{1}{4}$
Boiler horsepower generated	727,142	663,678	753,181	654,543	667,857
Lights, kilowatt consumption	156,830	108,160	146,742	142,510	110,000
Power, kilowatt consumption	116,000	110,000	97,828	110,500	108,910
Tons of ice made	193	208	234	249	248
Number cars ashes removed, Illinois Tunnel Co. cars	227	203	176	200	204

1910	August	September	October	November	December
Coal consumed under boiler in tons	2068	2023	1779.8	1718.2	2032
Pounds water evaporated per pound coal	$5\frac{3}{4}$	$6\frac{3}{4}$	$8\frac{1}{8}$	$7\frac{1}{2}$	$6\frac{9}{20}$
Boiler horsepower generated	746,708	833,213	947,876	786,587	806,580
Lights, kilowatt consumption	165,970	184,266	110,065	156,120	128,570
Power, kilowatt consumption	141,000	122,844	100,065	123,560	120,000
Tons of ice made	254	246	248	213	226
Number cars ashes removed, Illinois Tunnel Co. cars	229	223	131	101	150

1911	January	February	Total for Year
Coal consumed under boiler in tons	2084.5	1623.1	22,825.8
Pounds water evaporated per pound coal	$6\frac{3}{10}$	$8\frac{3}{4}$	Av. 6.8
Boiler horse power generated	860,454	865,691	9,313,510
Lights, kilowatt consumption	190,455	160,000	1,759,688
Power, kilowatt consumption	130,455	140,000	1,421,162
Tons of ice made	226	211	2,756
Number cars ashes removed, Illinois Tunnel Co. cars	168	121	2,133

OPERATING COST FOR GENERATING STEAM ONLY

For year ending February 28, 1911

Includes cost labor and material

	Cost for Winter Period	Cost for Summer Period	Total for Year
Boilers	$876.66	$1,231.15	$2,107.81
Pumps	437.91	468.92	906.83
Engine and boiler room	7,932.20	8,287.80	16,220.00
Ash removed	1,983.00	2,369.70	4,352.70
Coal	33,976.40	34,812.28	68,788.68
Water*	240.00	260.00	500.00
Insurance and taxes on steam generating apparatus and portion of building used by power plant ($236,200 @ 2%)	2,362.00	2,362.00	4,724.00
Interest on capital invested in steam generating apparatus and portion of building used by power plant ($236,200 @ 6%)	7,086.00	7,086.00	14,172.00
Depreciation on steam generating machinery ($104,000 @ 4%)	2,080.00	2,080.00	4,160.00
Depreciation of portion of building occupied by power plant ($132,200 @ 2%)	1,322.00	1,322.00	2,644.00
Total	$58,296.17	$60,279.85	$118,576.02

* Boiler make-up water only.

DATA AND RESULTS OF BOILER PLANT—EVAPORATIVE TEST

Total number boilers in battery, 5 at 400-hp. capacity.
Number boilers used in test, 3
Kind of fuel, Illinois coal, Carterville district, No. 3 washed nut.
Kind of furnace, combination water and fire-tube boilers manufactured by Lyons Bros., Depere, Wis.
Grate surface, 3x60 = 180 ft.; 3 x 2600 = 10,800 sq.ft.

TOTAL QUANTITIES

Date of trial	June 28, 1911
Duration of trial	22 hours
Weight of coal as fired	105,078 lb.
Percentage of moisture in coal	5.3%
Total weight of dry coal consumed	99,508 lb.
Total ash and refuse	10,800 lb.
Percentage of ash and refuse in dry coal	10.5
Total weight of water fed to the boiler	718,437 lb.
Water actually evaporated, corrected for moisture in steam	715,204
Factor of evaporation	1.0486
Equivalent water evaporated into dry steam from and at 212 deg. F.	749,962 lb.

Hourly Quantities	
Dry coal consumed per hour	4523
Dry coal per square foot of grate surface per hour	25.13
Water evaporated per hour corrected for quality of steam	32,509
Equivalent evaporation per hour from and at 212 deg	34,089
Equivalent evaporation per hour from and at 212 deg per square foot of water-heating surface	3.156
Average Pressures, Temperatures, Etc.	
Steam pressure by gage	150 lb. per sq in.
Temperature of feed-water entering boiler	212 deg
Temperature of escaping gases from boiler	609 deg
Force of draft between damper and boiler	1.14 in water
Percentage of moisture in steam	0.45
Horsepower	
Horsepower developed	988
Builders' rated horsepower	1200
Percentage of builders' rated horsepower	82.3
Economic Results	
Water apparently evaporated under actual conditions per pound of coal as fired	6.83
Equivalent evaporation from and at 212 deg. per pound of coal as fired	7.13
Equivalent evaporation from and at 212 deg. per pound of dry coal	7.54
Equivalent evaporation from and at 212 deg. per pound of combustible	8.45
Cost of Evaporation	
Cost of coal per ton of 2000 lb. delivered in boiler-room	$2.90
Cost of coal required for evaporating 34½ lb. of water from and at 212 deg equivalent to one boiler horsepower	0.69

Readers should note the editorial in the Nov. 3 issue of POWER, on page 648, under the heading of "Small Leaks and Big Ones." The writer of that article not only shows his ignorance, but the tone of the article all the way through shows his disposition to injure a person with whom he was not acquainted and knows nothing of his ability whatsoever.

Note under heading of "Engineering Data" ending Feb. 28, 1911, that the average evaporation for the year equals 6.8 lb.; also that when good coal was purchased in February, 1911, and October, 1910, the evaporation averaged 8.67 lb. coal as fired.

J. E. LAWRENCE.

Chicago, Ill.

Asbestos-Packed Boiler Blowoff Cocks

All our asbestos-packed blowoff cocks were leaking badly, because the packing was worn and the stems cut. As new packing would cost within 30 per cent. as much as new cocks and believing that a good grade of babbitt would do just as well if not better, a mandrel was made, a set of cocks babbitted, the stems turned, ground in and the cocks placed in service. These worked satisfactorily and the others were repaired in the same way. The job was done by our own men and at much less cost than if sent to the factory.

It is over six months now, and they are still tight.

J. McL. BURNS.

Dover, N. J.

The Fireman Is a Chemist

Chemistry itself is without sin, but the sins of chemists are many. I note with interest a letter on this subject in the issue of Dec. 22, page 880. It is to be regretted that such a mistaken statement as "air is composed of hydrogen, oxygen and nitrogen" should have been allowed to go unchallenged, as it is a common one. It should be remembered, even by one who is not a practical chemist, that the air consists chiefly of nitrogen and oxygen, with some inactive argon, and some active carbonic-acid gas and water vapor.

I suppose the time will come when everyone will know more of the common facts accurately. Such a mistake is not only to be regretted, but it tells us that we must fight the battle for education again and again. Of course, if the air should contain any hydrogen, then the air would itself be not merely a supporter of combustion, but would be partly combustible, which, however desirable, is not the case.

The great lesson is that chemistry is something which is fundamental to almost every line of business and manufacture, and we should all learn to use it as it should be used, with safe and sane common-sense. Let the eternal battle-royal go on in the grand campaign of education. Make fun of chemists, as we fully deserve, but treat Chemistry well; she can speak for herself.

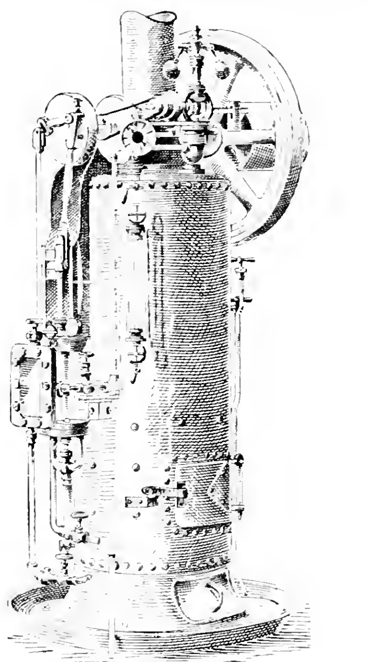
CHARLES S. PALMER.

Newtonville, Mass.

[The original was in error in a sense for it did not state that the hydrogen was not present as free hydrogen, but combined with oxygen in the form of vapor, often augmented by the use of steam jets.—EDITOR.]

Printers' Engine

In the Oct. 20 issue is an article on a self-contained steam plant which is interesting as a relic. The Buckeye Engine Co. had a similar idea and built a self-contained power plant called the "Printers' Engine." It was made in sizes from 1¼ to 15 hp. Recently some drawings which were made in 1872, showing the cylinder set in the



PRINTERS' ENGINE AS BUILT IN 1873

head of the boiler, were found at the works. The type of engine illustrated herewith, however, was successful and a number of them was sold.

D. J. McCONNELL.

Salem, Ohio. Buckeye Engine Co.

Engineers' Study Course

Problems in Power-Plant Design—XIII

Comparing Steam Requirements with Available Exhaust

It was stated in the first article of the series that in designing a combined power and heating plant a comparison should be made between the steam requirements and available exhaust which should cover with a fair degree of accuracy the entire heating season.

In a general way, it is usually economical to employ the exhaust steam for heating purposes and to design the power plant with reference to that arrangement. Or, stated in another way, it is generally advisable, under average conditions, to install power and lighting plants in large buildings and to utilize the exhaust for heating. While this may be true ordinarily, the amount of saving will depend upon a number of conditions which may vary widely in different cases. Among these may be mentioned length of heating season, average winter temperature, type of engines used, method of heating, cost of fuel, water, labor, etc., and also, of the most importance, the relation between the steam required for heating and the available exhaust at different parts of the day.

The total exhaust from a plant in twenty-four hours may be equal to or exceed the heating requirements during the same length of time, but if it is not distributed so as to be utilized, a large amount may be thrown away at certain parts of the day which must be made up at other times by live steam taken from the boilers. From this it may be seen that total amounts of steam for the day are often misleading and a special study should be made of conditions from hour to hour (where there is much variation of load) for representative days of a considerable number of periods throughout the heating season. In the present case the available exhaust was assumed to be practically uniform throughout the year, and, furthermore, was found to exceed the heating requirements, so that a comparison of this kind was not necessary.

In other plants, especially those in office buildings, hotels, etc., where lighting and elevator service form a large part of the load, conditions will be found much more variable and tables or curves for comparison should always be prepared.

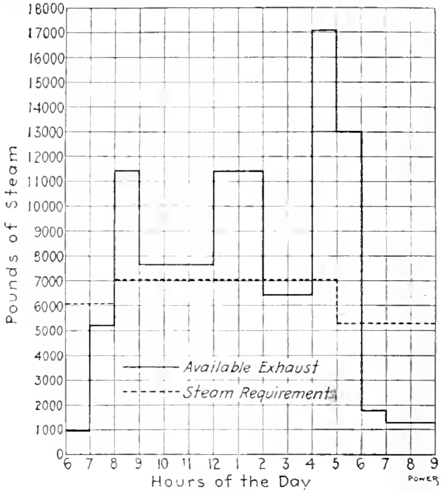
Power and Heat Requirements

In any given case the first step is to make up a schedule which shall represent the power and heat requirements for the heating season.

A good way to obtain average conditions is to divide the season into seven equal periods, extending from the middle of October to the middle of May, and from the weather records of previous years obtain the average temperature of each of these periods. If the plant is operated daytimes only, use the day temperatures, but if it is operated both day and night, as in a large hotel, then make up two lists, one of average temperatures from 6 o'clock in the morning until 6 at night, and the other for the remaining twelve hours. Designate them "day temperatures" and "night temperatures."

Next, make a list of all purposes for which steam is required in the building exclusive of that used for power. These will vary in different cases, but they will ordinarily include one or more of the following: Heating, ventilating, hot water for lavatories and baths, cooking, laundry service, sterilizing, mill work, such as drying, washing, finishing, etc., and dry kilns.

In a new plant the weight of steam required for each of the foregoing purposes per hour, with the exception of heating and ventilating, may usually be obtained from those installing the kinds of apparatus to be used. If the



problem concerns the installation of a power plant in a building already constructed and in use, tests should be made to determine the weight of steam actually required. In addition, the particular hours of the day during which steam is required for the various purposes should be noted as well as the weight used. The requirements for heating and ventilating may usually be computed with sufficient accuracy from the data given in previous articles of the present series, supplemented by certain corrections to be noted presently.

The heating system for a building is commonly proportioned for the coldest weather to which that particular locality is subject. If now the apparatus be provided with a system of automatic control, which shall gage the heat supplied to actual requirements, the weight of steam used per hour will vary directly as the difference between the inside and outside temperatures (neglecting the effect of high winds) and will change with each variation of outside temperature throughout the heating season. If, on the other hand, the entire radiating surface is kept turned on at all times or the heating plant is run at its full capacity, the weight of steam used per hour will be practically the same for all outside temperatures, with a system of direct radiation, provided the inside temperature is maintained at 70 deg. by opening the windows. As a matter of fact, neither of these conditions ordinarily prevails, although the former is very nearly approached with the best systems of pneumatic control.

To approximate the steam requirement for heating with different outside temperatures, the weight of steam used per hour in zero weather must be multiplied by a factor corresponding to the actual outside temperature, and this in turn must be corrected for the type of temperature regulation employed. Assuming that the plant is designed for a minimum outside temperature of zero and the normal inside temperature of 70 deg., and that the system is accurately controlled to maintain this inside temperature without opening the windows or admitting cool air, the proportion of heat required for varying outside temperatures will be found in Table 1.

TABLE 1. HEAT REQUIREMENTS

Outside temperature, deg. F..........	0	+10	+20	+30	+40	+50	+60	+70
Proportion of heat required, as compared with zero conditions.	1.00	0.86	0.72	0.57	0.43	0.29	0.15	0.00

For example, if 1000 lb. of steam is required for heating a given building with an outside temperature of zero only,

$$1000 \times 0.72 = 720 \ lb.$$

will be required when it is 20 deg. above, or

$$1000 \times 0.43 = 430 \ lb.$$

at 40 deg., etc. The next step is to assume certain factors to offset the steam wasted when different means of temperature regulation are employed. These factors can only be estimated, but for average conditions it may be assumed that with the best systems of automatic control the results given in Table 1 will be obtained. With forced hot-water circulation these should be multiplied by 1.2; with vacuum systems by 1.3, and with low-pressure gravity systems by 1.4.

For example, if 1000 lb. of steam is required per hour in zero weather with a low-pressure gravity system,

$$1000 \times 0.43 \times 1.4 = 602 \ lb.$$

will be required when it is 40 deg. above zero. In other words, 40 per cent. more radiation will be in use than is actually required for heating the building and the surplus heat will be wasted through open windows.

When ventilation is provided in large buildings by means of fans, the temperature of the entering air is accurately controlled, and Table 1 may be made use of, the same as for automatically controlled direct radiation. For example, if the weight of steam required for warming the air for ventilation is 3000 lb. per hr. in zero weather, it will be

$$3000 \times 0.57 = 1710 \ lb.$$

when the outside temperature is +30 deg.

After having determined the weight of steam required for all heating purposes for each hour of the average day of the first period, Oct. 15 to Nov. 15, the next step is to estimate the average indicated horsepower required for all power purposes for the corresponding period.

The power requirements will vary with the type of building and will commonly include a portion of the following: Driving machinery, lighting, elevator service, auxiliary pumps, refrigeration, ventilating fans, miscellaneous motors for kitchens, laundries, etc. As the power load will vary at different hours of the day, each hour should be taken up separately and the available exhaust computed for comparison with the steam requirements for heating during the corresponding hour. The total indicated horsepower multiplied by the water rate of the engine, and this result by 0.85, will give the available exhaust. In making a full study of this kind of problem the average day for each of the seven periods should be similarly worked out and the results either tabulated or plotted in curves for easy reference. Having shown the general method to be followed in such problems, it may be well to illustrate it by working out a simple example in detail.

Take the case of an office building requiring power for lighting, elevator service, auxiliary pumps and fan motors, and steam for heating, ventilation and hot-water service. Suppose the maximum requirements for each are found to be as follows: Lighting, 200 kw.; elevator service, 300 i.hp.; fan motors, 12 i.hp.; auxiliary pumps, 20 i.hp. All items rated in indicated horsepower are referred to the main engines and include the friction losses in the various machines. Let the period taken be from Dec. 15 to Jan. 15, when the lighting requirements are at a maximum, and assume them to be as follows:

Hour of Day	Kw.	I.Hp. at Engine
6 a.m. to 7 a.m.	10	18
7 a.m. to 8 a.m.	50	88
8 a.m. to 4 p.m.	70	124
4 p.m. to 6 p.m.	200	350
6 p.m. to 9 p.m.	40	70

In making out this schedule it has been assumed that each kilowatt delivered by the dynamo requires 1.75 i.hp. at the engine. The schedule of elevator service is assumed to be as follows:

Hour of Day	I.Hp. at Engine
7 a.m. to 8 a.m.	100
8 a.m. to 9 a.m.	300
9 a.m. to 12 noon	150
12 noon to 2 p.m.	300
2 p.m. to 4 p.m.	100
4 p.m. to 5 p.m.	300
5 p.m. to 6 p.m.	150
6 p.m. to 7 p.m.	50
7 p.m. to 9 p.m.	10

The various auxiliary pumps, including those for hot-water circulation for heating the building, are run continuously from 6 a.m. until 9 p.m. and require approximately 20 i.hp. at the main engines. Ventilation is provided for the first-floor stores and special offices and the fans are run from 8 a.m. till 5 p.m., at a uniform load of 12 i.hp. at the engine.

As the exhaust will be utilized for heating purposes, simple high-speed engines will be used having a water rate of approximately 30 lb. per hr. per i.hp., of which about

$$30 \times 0.85 = 25 \ lb.$$

will be available in the exhaust for heating purposes.

It is now possible to make out a schedule covering the entire day, giving the total indicated horsepower for all purposes and the pounds of available exhaust for each hour.

TABLE 2 SCHEDULE OF AVAILABLE EXHAUST

Hour of Day	I.Hp. for Different Purposes A	B	C	D	Total I.Hp.	Pounds per Hour of Available Exhaust (I.Hp. x 25)
6 to 7	20	+ 18			38	950
7 to 8	20	+ 88	+ 100		208	5,200
8 to 9	20	+ 124	+ 300	+ 12	456	11,400
9 to 10	20	+ 124	+ 150	+ 12	306	7,650
10 to 11	20	+ 124	+ 150	+ 12	306	7,650
11 to 12	20	+ 124	+ 150	+ 12	306	7,650
12 to 1	20	+ 124	+ 300	+ 12	456	11,400
1 to 2	20	+ 124	+ 300	+ 12	456	11,400
2 to 3	20	+ 124	+ 100	+ 12	256	6,400
3 to 4	20	+ 124	+ 100	+ 12	256	6,400
4 to 5	20	+ 350	+ 300	+ 12	682	17,050
5 to 6	20	+ 350	+ 150		520	13,000
6 to 7	20	+ 70	+ 50		140	3,500
7 to 8	20	+ 70	+ 10		100	2,500
8 to 9	20	+ 70	+ 10		100	2,500

In the above schedule column A represents power for auxiliary pumps; B. electric lighting; C. elevators; and D. ventilating fans.

The next step is to prepare a similar schedule for the heating requirements. Suppose the computations show the total heat necessary for warming the building in zero weather to be 5,700,000 B.t.u. per hr., and for ventilating purposes 2,000,000 B.t.u. per hr. Furthermore, suppose that the weather records for the past five years show the average day temperature to have been +20 deg. for this period. Let the circulating pumps for the heating system be started at 6 a.m. and stopped at 9 p.m., and assume that two hours are required for warming the building up to 70 deg., so that from 6 to 8 in the morning during this month the plant will be run at its full capacity regardless of the outside temperature. Although the building is to be warmed with hot water, the steam requirements will be the same as though it were condensed in the radiators instead of in a special heater.

Taking the latent heat of exhaust steam as 970 and the factor for hot-water regulation as 1.2, we have the following conditions and results: During the period from 6 till 8 a.m. the total capacity of the heating plant will be required and utilized, or

$$\frac{5,700,000}{970} = 5876 \ lb.$$

or practically 5900 lb. of steam will be used per hour. For the remainder of the day this will amount to

$$5900 \times 0.72 \times 1.2 = 5097 \ lb. \ per \ hr.$$

Heat for ventilating purposes amounts to

$$2,000,000 \times 0.72 \times 1.2 = 1,728,000 \ B.t.u.$$

$$\frac{1,728,000}{970} = 1781 \ lb. \ per \ hr.$$

from 8 a.m. till 5 p.m. Buildings of this kind are usually supplied with a hot-water storage tank so that any variation in the demand for hot water during the day is cared for in this way.

In the present case, steam will be on the tank continuously from 6 a.m. till 9 p.m. and it may be assumed that 150 lb. of steam per hour is required for this purpose throughout the day. The data are placed in tabular form, the same as for the power requirements, in Table 3.

TABLE 3. SCHEDULE OF STEAM REQUIREMENTS

Hour of Day	Lb. Steam per Hr. for Heating	Lb. Steam per Hr. for Ventilation	Lb. Steam per Hr. for Hot Water	Total Steam Requirements, Lb. per Hr.
6 to 7	5,900	.....	150	6,050
7 to 8	5,900	.....	150	6,050
8 to 9	5,097	1,789	150	7,036
9 to 10	5,097	1,789	150	7,036
10 to 11	5,097	1,789	150	7,036
11 to 12	5,097	1,789	150	7,036
12 to 1	5,097	1,789	150	7,036
1 to 2	5,097	1,789	150	7,036
2 to 3	5,097	1,789	150	7,036
3 to 4	5,097	1,789	150	7,036
4 to 5	5,097	1,789	150	7,036
5 to 6	5,097	.	150	5,247
6 to 7	5,097		150	5,247
7 to 8	5,097		150	5,247
8 to 9	5,097		150	5,247

As a matter of fact, the outside temperature will vary more or less during the day, but as this is so irregular in its action it is difficult to allow for it unless the number of hours for each temperature is tabulated. For approximate work it is usually sufficiently accurate to use constant temperatures throughout the day and night periods. In the present case a constant temperature has been assumed for the entire heating period from 6 a.m. till 9 p.m. Table 4 compares steam requirements and available exhaust and shows the weight of live steam required and exhaust wasted for each hour during the day.

TABLE 4. SCHEDULE OF COMPARISONS

Hour of Day	Steam Requirements, Lb.	Available Exhaust, Lb.	Live Steam Used, Lb.	Exhaust Wasted, Lb.
6 to 7	6,050	950	5,100	....
7 to 8	6,050	5,200	850	..
8 to 9	7,036	11,400	.....	4,364
9 to 10	7,036	7,650	.....	614
10 to 11	7,036	7,650	.....	614
11 to 12	7,036	7,650	.....	614
12 to 1	7,036	11,400	.....	4,364
1 to 2	7,036	11,400	.....	4,364
2 to 3	7,036	6,400	636	.....
3 to 4	7,036	6,400	636	.....
4 to 5	7,036	17,050	....	10,014
5 to 6	5,247	13,000	....	7,753
6 to 7	5,247	3,500	1,747	.....
7 to 8	5,247	2,500	2,747	..
8 to 9	5,247	2,500	2,747	.....
Total	96,412	114,650	14,463	32,701

Referring to Table 4, it is seen that while the available exhaust for the day is

$$114,650 - 96,412 = 18,238 \ lb.$$

more than the total steam requirements for heating, it is so distributed that 32,701 lb. are wasted and 14,463 lb. of live steam must be taken from the boilers to make up the deficiency. This illustrates the point noted at the beginning of the article—that total steam quantities for the day should not be relied upon when making comparison of steam requirements and available exhaust. To make the comparison complete, this same process should be gone through with for an average day for each month of the heating season.

In large plants, where there is considerable variation in power and heating conditions from month to month, it may be advisable to take shorter periods, say every week or ten days. The accompanying diagram is a plot of the heat requirements and the available exhaust. This shows at a glance the relation of one to the other throughout the day.

American Association for the Advancement of Science

The 66th meeting of the American Association for the Advancement of Science held at Philadelphia, Penn., Dec. 28, 1914, to Jan. 2, 1915, was attended by 1500 to 2000 members and guests coming from every part of the United States. Nearly every university, Federal department, state or city government which employs scientific investigators was represented and the Philadelphia meeting recently brought to a close was undoubtedly the most successful in scope of subjects and in point of attendance of any since the organization of the association in 1847.

There are 12 sections of the association, comprising mathematics and astronomy, physics, chemistry, engineering, geology and geography, zoology, botany, anthropology and psychology, social and economic science, physiology and experimental medicine, education, agriculture.

The programs of the different sections each included anywhere from five to one hundred addresses and communications in their respective fields of scientific research. The sections and 24 affiliated societies held their principal sessions in the various halls, lecture rooms and laboratories of the University of Pennsylvania, which afforded admirable accommodations. Dr. Charles W. Eliot, president emeritus of Harvard University, was elected president of the association for the ensuing year. At the first general session the retiring president, Dr. Edmund D. Wilson, in delivering his annual address, said that "the scientific method is the mechanistic method which produces practical results. The moment we swerve from it by a single step we set foot on a foreign land."

Frederick W. Taylor, one of the vice-presidents of the association, presided at the sessions of the engineering section which were held Dec. 30 and 31 in the Engineering Building of the university. Seventy-five papers and addresses were presented on various subjects of industrial, hydraulic and civil engineering, the latter including 30 papers on highway construction and pavements.

The next regular meeting of the association will be held at San Francisco, Calif., Aug. 2 to 7, 1915. As this will be during the Panama-Pacific Exposition, it is expected that the meeting will be largely attended.

Testing Liquid Flow Meters*

By W. S. Giele

SYNOPSIS—Description of a laboratory for testing and calibrating liquid flow meters by means of direct comparison of like quantities, such as volumes, inches of water head, and rates per unit time.

The laboratory herein described was designed and built to facilitate the investigation and testing of liquid flow meters, with special reference to those of the V-notch weir type. This type consists essentially of a rectangular chamber containing a vertical dividing wall with a V-notch weir plate attached to the upper part. On one side is the "approach" chamber provided with suitable baffles, and on the other, the "outflow" chamber which receives the discharge of the notch, and from which water passes to boiler feed pumps or other places of delivery. This meter is provided with an autographic recording device, giving a continuous record from which the instantaneous rate of flow may be read, while also permitting a continuous integration of quantity.

The indicating, recording and integrating instruments will be best understood by reference to Fig. 1. A float in either

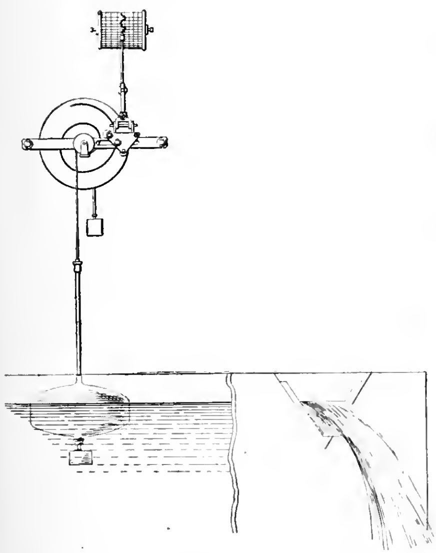


Fig. 1. Recording Devices

the approach chamber or a chamber in communication therewith, bears a vertical stem, actuating (by means of a cable and drum) a revolvable cam, which is adapted to displace a pen carriage or integrating train equal distances for equal increments in the rate of flow. For convenience in manufacture and use, it is desirable that one standard height of chart be employed for all capacities, and that this chart be subdivided decimally. With arbitrarily selected weir-notch angles this might be attained by cutting a different cam for each capacity, but it is much easier to use one standard cam, embodying the relation between the rate of flow and the head of water on the notch, and to accomplish the adaptation to different rates of flow by varying the diameter of the cable drum and the angle of the notch itself; thus making it necessary to establish accurately the relation between the coefficient of the notch and the angle.

The method decided upon was to construct a master flow meter so arranged that the rate of flow could be maintained accurately at any desired value for long periods; and after having determined with precision the performance of this standard, to use it as a means of measuring the flow through the meters which it is desired to investigate.

By this means of direct comparison, a degree of accuracy can be secured in the meter under test practically equal to that of the standard. Such a standard having once been accurately calibrated, disturbing influences arising from the effects of proportions of the channel of approach, conditions

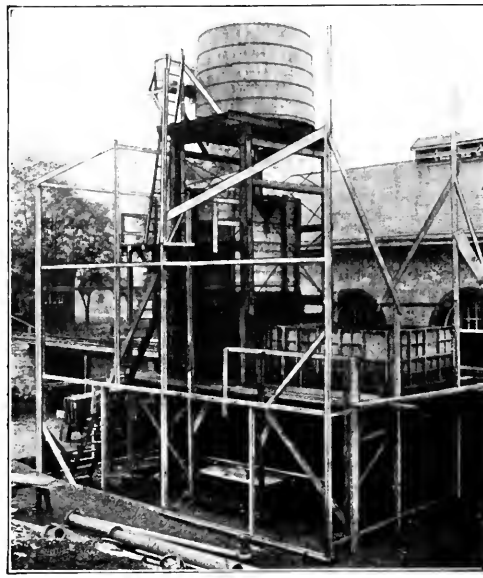

Fig. 2. General View of Meter-Testing Plant

of surfaces, form and material of notch, directions and interference of currents of flow in the channel of approach, etc., can be ignored.

It is estimated that by this method greater accuracy can be obtained in a run of one-half hour at a low head than would be possible in a run of fifteen hours at the same head, using either volumetric or gravimetric methods.

Description of Apparatus

As shown in Figs. 2 and 3, the testing plant has a large storage tank from which the water is drawn by a pump and elevated to a supply or constant-head tank at the highest level, its purpose being to supply water to a discharge orifice at a constant head so that the rate of flow through the standard notch may be maintained invariable at any desired capacity.

From the constant-head tank the water passes to the standard-notch tank, thence flows over the calibrated notch into the meter under test, whence it is discharged to the storage tank to circulate again.

During the preliminary work on the calibration of the standard notch, instead of passing from the standard notch to the meter under test, the water flowed alternately to either of two volumetric measuring tanks, from which it discharged into the storage tank to resume its course.

In view of the necessity for permanent maintenance of conditions under all circumstances, the entire plant was constructed with the utmost regard to permanency and rigidity. The foundation consists of a concrete slab approximately 24 ft. long by 10 ft. wide, carried to solid clay soil and reinforced in all directions by 1-in. rods.

The storage tank rests directly on the concrete foundation and holds a little over 1000 cu.ft. of water. The supply to the pump is through an 8-in. opening located with its center

*Excerpts from a paper before the American Society of Mechanical Engineers, at New York, Dec. 4, 1914.

about 8 in. above the bottom of the tank (to eliminate sludge which might accumulate on the bottom), and 12 in. from the vertical center line of the end of the tank. It is also supplied with a 3-in. drain at its lowest point and with a system of steam pipes whereby the water may be heated to the desired temperature.

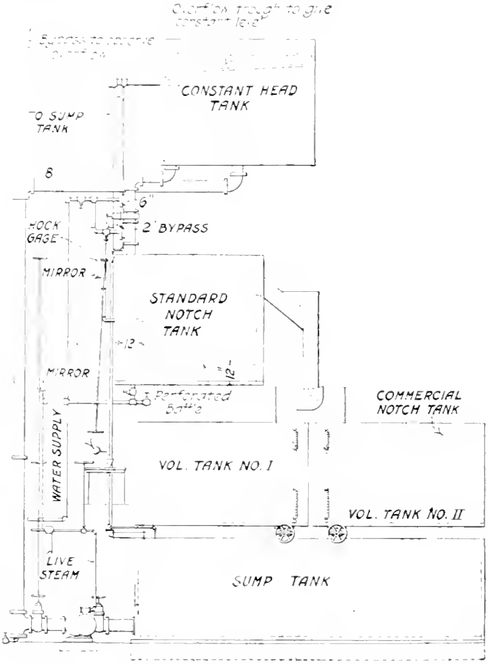

Fig. 3. Elevation of Testing Plant

The pumping unit is an 8-in. single-stage, centrifugal pump about 4 ft. from the end of the storage tank. It is gear-driven by a single-stage steam turbine, and has a capacity of about 120 cu.ft. per min. against the head of the highest tank, which corresponds to a flow of about 450,000 lb. per hr.

The outlet from the constant-head tank is a 6-in. line taken from the bottom and as close to the side as possible. This arrangement was adopted after experiments looking toward the prevention of a swirling motion within the tank.

The maintenance of a practically constant head in this tank is essential to a constant flow through the system. This is accomplished by the installation of an overflow weir consisting of a rectangular trough 8 ft. 8 in. long, having inflow edges or weirs on both sides. These edges are constructed of metal and were carefully brought into a horizontal plane so that the discharge would be uniform throughout their length. The overflow at these edges is carried by a 4-in pipe line back to the storage tank, this line being provided with a ½-in. bypass discharging into open funnels on both the standard notch level and the observation room level so that the observer may constantly watch the overflow and thereby judge of the constancy of the head.

The approximate amount of water in the constant-head tank is indicated by a float to which is attached a chain passing over sheaves and extending to the pump room with pointers at each level.

The outlet pipe for the constant-head tank into the standard-notch tank contains a 6-in. valve for roughly setting the larger flows and a 2-in. valve in a bypass carried around the 6-in. valve for fine adjustment. The stem of this 2-in. valve is carried down to the observation station so that the flow may be accurately controlled from that point.

Every precaution has been taken to prevent change in shape or position of the standard notch. It rests on a structural steel platform supported by heavy, rigidly braced columns carried outside the volumetric measuring and storage tanks directly to the foundations, the column loads being distributed on the foundation by two 15-in. I-beams, grouted in. The standard V-notch is approximately 22½ in. high by 11¼ in. wide at the top, and its full capacity at 18¼ in. head is roughly 110 cu.ft. per min.

The standard-notch tank is divided into two compartments by a rigid partition 1 ft. from the end opposite the notch and ending 1 ft. above the bottom. The supply line discharges behind this partition 2 ft. below the surface of the water, and the water finds its way under the partition, spreads out over the bottom of the tank and rises through a perforated baffle having approximately 2000 holes ¾ in. square. This arrangement has resulted in a quiet surface of approach, even at the highest rates of flow.

It was not necessary to find the apex or zero level of the standard notch with extreme precision, it being necessary only to provide a reference point from which measurements could always be taken, and which would be immovable with respect to the notch itself. This reference point consists of a hook gage securely soldered to the notch with its point in a plane normal to the plane of the notch through its vertical center line and ½ in. away from it. The level of the water above the zero level is read by a second adjustable hook gage attached to the opposite end of the tank.

As any tilting of the tank would not only change the cross-section of the stream issuing from the notch, but also the relation between the hook gage by which the level is read and the notch, the care in supporting the tank is further checked by means of special gages to indicate any deflection in the tank or supports. These special gages consist of four glass tubes with three reference lines, spaced 9 in. apart, etched entirely around each. The four gage glasses are firmly attached at the four corners of the standard-notch tank.

The level of the water flowing through the standard-notch is obtained by means of a specially designed hook gage connecting with the still-water chamber. The special and unusual construction of this hook gage arises chiefly from the extreme range of height which it must cover and the consequent possibilities of error resulting from differences in temperature between the various parts of the gage itself at various times, and also between the water column within the gage tube and the temperature of the water in the still-water chamber. To eliminate the effect of temperature changes in the gage itself, the elements were so constructed that expansions due to increased temperature would tend to compensate each other. To eliminate the effect of differences of temperature between the two water columns, the hook gage tube was jacketed by flowing water taken from the same source of supply as that to the still-water chamber. The hook itself has a 60-deg. point and is constructed as shown in Fig. 4.

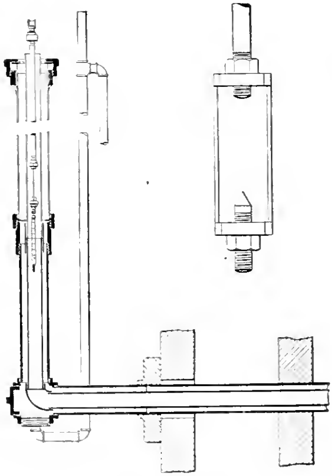

Fig. 4. Showing Arrangement of Hook Gage

The register of the point of the hook with the surface of the water is observed from below the water surface, in which position it is possible to see both the hook itself and the reflected image on the surface of the water. The hook is at the water surface when the point of the reflected image coincides with the point of the hook. Any deviation from this position is observed as double the distance between the point of the hook and the water surface, thus permitting exactness in this observation, which is further promoted by the fact that the reading is taken through a magnifying lens and reflected downward and horizontally by a mirror to the observation station, at which point a four-power binocular is rigidly supported for observation. The hook is illuminated by means of a frosted incandescent bulb.

Owing to the number of readings to be taken and the space covered by the plant, special means were necessary to bring all observations and controls to a central observation station. Fig. 5 is an interior view of the observation room showing the desk from which observations are taken.

When running tests, it is necessary only to observe that the water level remains at the point of the hook and it is not necessary to read the height of the hook gage on the standard-notch tank during the progress of an experiment. A similar hook gage is applied to the meter under test with the addition of an extended shaft bringing the graduated scale to the observation room where the operator can read the height of water passing over the weir under test. This reading is taken immediately above the eye pieces of the binoculars through which is observed the coincidence of the water surface and the hook.

It was determined after several experiments that the hook and hook rod must be relieved of all strains and left free to align themselves by gravity. While with the jacketed

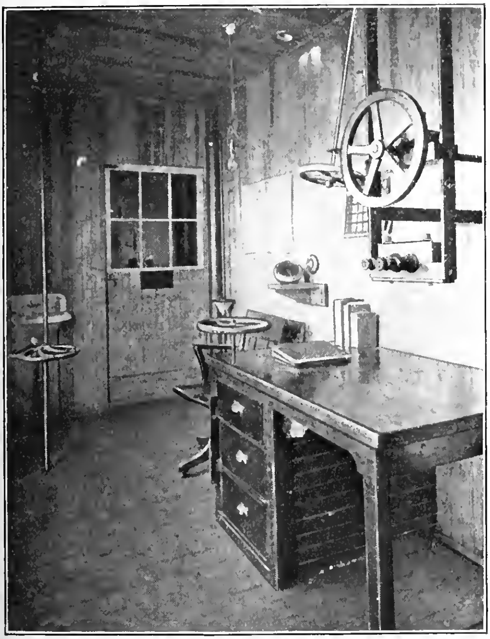

Fig. 5. Observation Room

arrangement it was never possible to detect a difference in temperature between the water in the hook gage tube and in the still-water chamber exceeding ½ deg. F. during the course of a whole day, it is interesting to note the results which might be obtained from an unjacketed gage. Without the jacket water it was found that a difference of 20 deg. F. (from 50 to 70 deg.) was entirely possible and effected a vertical head of 30 in. of water. The reading of the gage under such conditions would be 0.018 in. in error.

In investigating the effects of temperature changes on the parts of the gage it is to be noted that the vertical sheave support in its expansion will compensate for the elongation of the cable due to temperature, and that the expansion of the drum will tend to compensate for the elongation of the hook rod between the point of the hook and the attachment of the cable.

In preparing for the calibration of the standard notch, a curve was plotted, indicating the ideal conditions of flow, which the experiments would approximate. This curve was then divided into sections so that these could be separately plotted from the empirical data obtained to a much larger scale. After having mapped out the points it was desired to plot on the curve it was necessary only to set the hook gage at heads corresponding to these points and start the circulation of water through the system. After bringing the flow up to the desired head by manipulation of the control valves, readings were taken at regular and frequent intervals, until a sufficient number had been obtained showing uniform conditions, to furnish data for the necessary computations with assurance of reliability.

Municipal Plant Not to Extend Service

A recent bill passed by the city council of Seattle to permit the municipal lighting plant to extend its service beyond the city limits to serve rural districts has been vetoed by the mayor. The council refused to pass the bill over the mayor's veto. In refusing to adopt the plan of extending the city lighting system to outlying communities, Mayor Gill said in part:

"To say that the Seattle lighting plant is a money-making concern in the sense that it earns money for the general purpose of reducing taxation is wrong. From its inception the lighting plant has controlled the rates of this city. It has saved our business men, taxpayers and residents many millions of dollars and will continue to do so unless it is brought into disrepute and made a political plaything.

"Under this theory of outside extensions there is no reason why the city of Seattle should not engage in any other commercial business and conduct grocery stores, drygoods stores and other profit-making concerns. All there is embodied in this bill is pure socialism and opportunity given to settle the grudges of certain persons arising from real or imaginary grievances against a private corporation.

"The financial condition of our lighting plant at the present time is due to gross financial mismanagement by the council for the past three years. The councilmen refused to comply with the recommendations of former Chief of Police Griffiths and myself, and light downtown alleys, giving as an excuse that they had no money, although they are now preparing to become 'wet nurse' for the suburban districts outside the city limits, and are far worse off financially now than then. I have always maintained that the plant should seek a fair return on the money invested and the amount so earned be expended within the limits of the city to the end that all our people should have light at the lowest cost consistent with good business management.

"The tax rate of the city during the past few years has increased at a highly unprecedented rate, and we have nothing to show therefor except a street car line which was not intended to accommodate the public and which did not even accomplish the purpose of is principal promotors. As a matter of fact, there is no money in the light fund."

Research Fellowships at Illinois University

To extend and strengthen the field of its graduate work in engineering, the University of Illinois has since 1907 maintained ten research fellowships in the engineering experiment station. These fellowships, for each of which there is an annual stipend of $500, are open to graduates of approved American and foreign universities and technical schools. Appointments are made and must be accepted for two consecutive collegiate years, at the expiration of which period, if all requirements have been met, the master's degree will be granted. Not more than half of the time of the research fellows is required in connection with the work of the department to which they are assigned, the remainder of the time being available for graduate study.

Nominations to fellowships, accompanied by assignments to special departments of the engineering experiment station, are made from applications received by the director of the station each year not later than the first day of February. These nominations are made within the month of February by the station staff, subject to the approval of the faculty of the graduate school and the president of the university. Appointments are made in March, and they take effect the first day of the following September.

Nominations are based upon the character, scholastic attainments, and promise of success in the principal line of study or research to which the candidate proposes to devote himself. Preference is given those applicants who have had some practical engineering experience following their undergraduate work. Research work may be undertaken in architecture architectural engineering, chemistry, civil engineering, electrical engineering, mechanical engineering, mining engineering, municipal and sanitary engineering, physics, railway engineering, and in theoretical and applied mechanics. The work of the station is closely related to that of the college of engineering, and the heads of departments in the college constitute the administrative station staff. Investigations are carried on by the members of the staff and other members of the instructional force of the college of engineering, by special investigators employed by the station, and by the research fellows. Four vacancies are to be filled at the close of the current academic year. Additional information may be obtained by addressing the director of the engineering experiment station, University of Illinois, Urbana, Ill.

3000-Volt Direct-Current Electrification

Plans for the electrification of the Puget Sound lines of the Chicago, Milwaukee & St. Paul Ry. have now been completed and contracts let to the General Electric Co. for the electric locomotives, substation apparatus and line material, and to the Montana Power Co. for the construction of the transmission and trolley lines. This initial electrification of 113 miles of main line between Three Forks and Deer Lodge is the first step toward the electrification of four engine divisions extending from Harlowton, Mont., to Avery, Idaho, a total distance of approximately 440 miles. Later on, it is understood, the electrification will extend to the coast.

The Montana Power Co. covers a large section of Montana and part of Idaho with its network of transmission lines, which are fed from a number of sources of which the principal ones are:

Madison River	11,000 kw.
Cañon Ferry	7,500 kw.
Hauser Lake	14,000 kw.
Big Hole	3,000 kw.
Butte (steam turbine)	5,000 kw.
Rainbow Falls	21,000 kw.
Small powers aggregating	7,390 kw.
Total developed	68,890 kw.

Further developments, part of which are under construction, are:

Great Falls	85,000 kw.
Holter	30,000 kw.
Thompson Falls	30,000 kw.
Snake River	20,000 kw.
Missoula River	10,000 kw.
Total	175,000 kw

Total capacity developed and undeveloped 244,000 kw

The several power sites are interconnected by transmission lines, operating at 50,000 volts for the earlier installations and at 100,000 volts for later installations.

The railway company will purchase power at a contract rate of $0.00536 per kw.-hr., based on a 60 per cent. load factor. It is expected under these conditions that the cost of power for operating the locomotives will be considerably less than is now expended for coal.

In order to connect the substations with the several feeding-in points of the Montana Power transmission lines, a tie-in transmission line is being built by the railway company that will permit feeding each substation from two directions and from two or more sources of power. This transmission line will operate at 100,000 volts.

The immediate electrification will include four substations containing step-down transformers and motor-generator sets with necessary switchboard apparatus to convert 100,000-volt, 60-cycle, three-phase current to 3000 volts direct current. This is the first direct-current installation using such a high potential as 3000 volts, and this system was adopted in preference to all others after a careful investigation extending over two years.

SUBSTATIONS

The substation sites of the electrified zone provide for an average intervening distance of approximately 35 miles.

The substations will be of the indoor type, with three-phase, oil-cooled transformers reducing from 100,000 to 2300 volts, at which potential the synchronous motors will operate. The transformers will be rated 1900 and 2500 kv.-a. and will be provided with four 2½ per cent. taps in the primary and 50 per cent starting taps in the secondary.

The motor-generator sets will each comprise a 60-cycle synchronous motor driving two 1500-volt direct-current generators connected permanently in series for 3000 volts. The fields of both the synchronous motor and direct-current generators will be separately excited by small generators direct-connected to each end of the motor-generator shaft. The generators will be compound wound, will maintain constant potential up to 150 per cent. load and will have a capacity for momentary overloads of 300 per cent. normal rating. To insure good commutation on these overloads, the generators will be equipped with commutating poles and compensating pole-face windings. The synchronous motors will also be utilized as synchronous condensers, and it is expected that the transmission line voltage can be so regulated thereby as to eliminate any effect of the fluctuating railway load.

Water-Power Bills before Congress

There were two bills introduced during the session of Congress just closed, each of which is of considerable importance and will have a controlling influence over future water-power projects if enacted into law. On careful reading, there seems to be no conflict of purpose at present or likely to arise from the enaction of both bills.

The Adamson bill deals exclusively with navigable waters, consequently with projects of considerable magnitude, while the Ferris bill deals with water-power development within the public lands and reservations of the United States. The Adamson bill, the first introduced, is an act to amend "An act to regulate the construction of dams across navigable waters," approved June, 1906, amended June, 1910, and is in general terms as follows: Authority is vested in the Secretary of War and the chief of engineers of the War Department to grant persons of proper status the right to construct and maintain a dam across or in any of the navigable waters of the United States, after obtaining approval of the plans, on condition that such persons shall maintain without expense to the United States such locks, booms, sluices or other structures which may then be deemed necessary. Also in case of future necessity, the grantee must furnish free water power or power generated from water power for the use of the United States for such construction. Provision is made for certain reimbursement to the United States for expenses incurred with reference to the project and also for funds to restore conditions whenever it shall be determined that navigation has been injured. It specifically states that the interests of navigation shall be paramount to the use of such dam for power purposes and that the grantee at his own expense shall maintain necessary lights and signals to aid navigation and such fishways as shall be prescribed by the Secretary of Commerce.

That persons constructing or maintaining any dam, etc., shall be liable for damage to private property by overflow or otherwise.

It shall be a misdemeanor punishable by a fine not exceeding $1000 a month to fail or refuse to comply with the lawful order of the Secretary of War, and if such failure or refusal is continued, all rights shall be revoked by a decree of the court. If such dam be declared an unreasonable obstruction to navigation its removal may be ordered at the expense of the grantee. The rights granted under this act shall continue for a period of 50 years after the completion of the dam, and after the expiration of that time such rights shall continue until compensation has been made for a fair value of the property as Congress may deem wise, unless revoked for cause.

After the expiration of 50 years, and on giving notice of one year, the United States may take over all of the property upon paying the fair value, together with the cost to the grantee of the locks or other aids to navigation and all other capital expenditures. The fair values shall be determined by an agreement between the Secretary of War and the owners, or by legal proceedings instituted by the United States, but no claim for the franchise, good will or pending contracts shall be made.

Provision is made to regulate the charges for service to the customers which shall be just and reasonable, and discriminatory charge is specifically prohibited and declared to be illegal. The Secretary of War is empowered to prescribe what shall be the just and reasonable rates in certain states, and in case of violation, certain provisions relative to forfeiture are applied. The valuation for rate-making purposes is to be based on all capital and expenditures required. The jurisdiction of the Secretary of War is provided only for states not provided with adequate laws for the regulation of rates, etc.

Another provision is that no works constructed under the provision of this act may form a part of or in any manner affect a combination or an unlawful trust, but it shall be lawful for different grantees to exchange and interchange current, to assist one another whenever necessary under regulations prescribed by the Secretary of War, but in no case to raise the price or operate in restraint of trade.

This act shall not apply to irrigation or power dams or other projects under the jurisdiction of the Secretary of the Interior or the Secretary of Agriculture upon public lands of the United States.

The Ferris bill vests in the Secretary of the Interior authority to lease to citizens of the United States, or those who have declared their intention to become such, for a period not longer than 50 years, the right to construct and maintain dams, etc., for the generation and distribution of hydro-electric power when the project will not injure a forest or national reservation. It gives preference to developments by states, counties, etc., for municipal uses and purposes, and also specifies that the lessee shall at no time, without the consent of the Secretary of the Interior, contract for the delivery to any one customer of electric energy in excess of 50 percentum of the total output. The physical combination of plants may be permitted in the discretion of the Secretary, but combinations to limit the output of electrical energy, to restrain trade or increase prices are forbidden, and, except upon written consent of the Secretary of the Interior, no sale or delivery of power shall be made to a distributing company, except in case of emergency, and then only for a period not exceeding 30 days.

Upon not less than three years' notice prior to the expiration of the lease, the United States may take over the properties upon condition that it shall pay the actual cost of the various items and the reasonable value of all property taken over, the value to be determined by mutual agreement between the Secretary of the Interior and the lessee. Such value shall not include the franchise, good will or other intangible elements. In the event the United States does not take over the properties a new lease may be granted.

For the occupancy of public lands, the Secretary of the Interior is authorized to collect charges or rentals, the proceeds to be paid into the reclamation fund under the Reclamation act, and upon the return to the reclamation fund of such moneys, 50 percentum shall be paid by the Secretary of the Treasury to the state within the boundaries of which the hydro-electric power is generated, said moneys to be used by the state for the support of public schools or for public improvements. Leases by municipal corporations solely for municipal use shall be issued without rental charges, and leases for development not in excess of 25 hp. may be issued to individuals or associations for domestic, mining or irrigation use without charge.

In states not provided with a commission to regulate rates, the Secretary of the Interior shall be vested with power to regulate such rates until such a time as the state shall provide a commission.

Where the Secretary of the Interior determines that land values will not be materially injured, power projects will be permitted, where rights now granted for the use of public lands for the purpose of irrigation or mining alone are not abridged.

The Secretary of the Interior is authorized to examine the books and accounts of lessees and require reports upon oath, and making false statements is subject to punishment as for perjury.

The final provision is made for the transfer of permits under the provision of any previous law to the present one.

Boiler and Stoker Test from Banked Fire

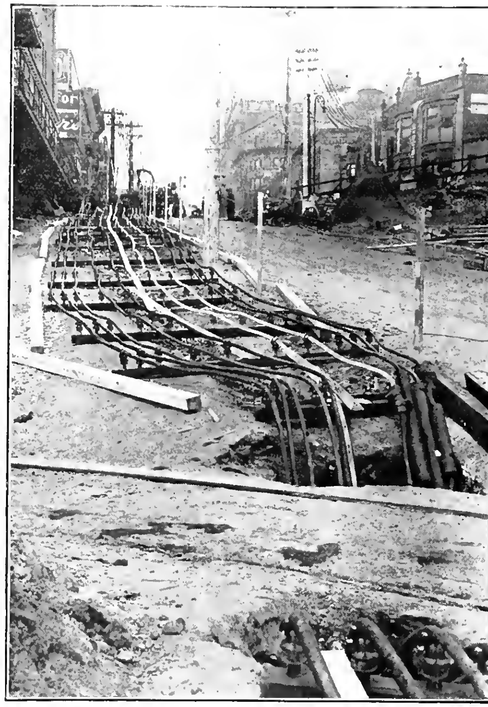
In a test made recently at the Scott Street steam station of the Toronto Electric Light Co., Ltd., Toronto, Canada, a 554-hp. Babcock & Wilcox boiler equipped with a Riley stoker was brought up to 354 per cent. of its rating in seven minutes. This performance was made possible by the moving grates of this type of underfeed stoker. The fire at once becomes active, because when starting up the stoker the moving grates also start, breaking up the fuel bed so that the air enters quickly for active combustion.

Before starting this test the boiler pressure was just below the normal pressure of 150 lb., and sufficient coal was being fed to maintain this condition. The signal to start the stoker fan was given when the steam pressure had dropped 5 lb. below normal, and this was taken as the time of starting the test. The load on the boilers was figured from switchboard kilowatt reading, figuring back through the turbine water rate, corrected for radiation losses. The turbine water rate was checked by a hot-water meter in the feed line. The turbine was called in at 9:36 a.m.; reported ready for load 3¾ minutes later. It was synchronized 41½ minutes past 9, but the stoker fan had started at 9:39. At 9:44 the load was 900 kw., equivalent to 95 per cent. of the boiler rating. Then the load went to 1700 kw., which was equivalent to 201 per cent. of the boiler rating, and at 9.46, seven minutes after the stoker and fan started, the load was 3000 kw., or 354 per cent. of the boiler rating.

This plant is used as a standby for the hydroelectric power generated at Niagara Falls. It is maintained with live banked fires in readiness to pick up the load in case of interruption to the hydro-electric power supply. This steam station contains four 554-hp. water-tube boilers, each equipped with a six-retort Riley self-dumping underfeed stoker. Forced draft for the stokers is supplied by a blower directly connected to a 125-hp. direct-current motor.

Temporary Repair Work at Cleveland

Following the fire in the three manholes and 150 ft. of feeder ducts, which temporarily paralyzed electric service in Cleveland's business district, as reported in the Dec. 29 issue, the Cleveland Electric Illuminating Co. took vigorous measures to restore service. The photograph shows the temporary cables with cross-arm spacers laid on the ground over Vinegar Hill. The cross-arms were later raised 30 in. above the ground. These temporary cables follow the line of the burned out ducts, which were immediately below, and were spliced onto the undamaged ends of the power-house feeders, it



TEMPORARY FEEDERS

being necessary to tear out a part of the duct line to get at these as the nearest manhole was badly damaged.

In addition to these a temporary overhead line of 10 cables was strung from the terminal pole, over Ontario St., and down to a manhole where connection was made with undamaged underground feeders.

The trouble occurred at 2 a.m., Wednesday (Dec. 16), and partial service was restored to some sections by noon, but it was not until Friday night that full service was restored.

"Made in the U. S. A." Exposition

The "Made in the U. S. A." Industrial Exposition, to be held in the Grand Central Palace, New York, from Mar. 6 to 13, will be national in its scope and will embrace an extensive and comprehensive exhibition of important American manufactures in all lines of trade and industry. Its dates have been selected to show distinctly American products in New

York at a time when the city is the Mecca of buyers from all sections of the country in many different lines of trade, and special efforts are being made by leading export and other associations to bring South American and other foreign buyers to the city at this time.

This exposition is the outgrowth of the work of the committee organized by Joseph Hartigan, commissioner of weights and measures of the City of New York, and the organization of the exposition, which means so much to American trade, is in the hands of Harry A. Cochrane, one of the most successful organizers and managers of American trade shows and industrial expositions. The exposition is designed to answer a twofold purpose—to stimulate and increase the sales of American-made goods to our own and foreign buyers and also to educate the American public to the resources and productions of our manufacturers and show them the goods they can obtain in this country that they have heretofore purchased from abroad.

High-Tension Feeders Cause Subway Accident

The most disastrous accident in the history of the New York subway system occurred during the rush hour Wednesday morning, when twenty 11,000-volt feeders let go in two manholes adjacent to the tracks at Fifty-third Street.

Practically the entire system was tied up and several thousand people held in the trains. The smoke and fumes from the burning insulation pervaded the subway for considerable distance, resulting in the death of one person and rendering over two hundred people unconscious. Quick response was made by the hospitals and the fire department and all the available pulmotors were put into service. The firemen ripped off the sheet-iron pans and gratings, normally used for ventilation, and rescued many through these openings to the street.

A thorough investigation is under way by both the company and the Public Service Commission as to the initial cause of the disaster, and the report will be awaited with interest; for this is the second time within a month that feeders have failed with disastrous consequences, the other being in Cleveland as reported in our Dec. 29 issue.

OBITUARY

WALLACE W. MANNING

Wallace W. Manning, chief inspector for the New York branch of the Hartford Steam Boiler Inspection & Insurance Co., died of pneumonia, Sunday, Dec. 27, 1914, after an illness of about a week, at his home, 66 87th St., Brooklyn, N. Y., aged 34 years. He was born in Cincinnati, and had lived in Brooklyn for about 20 years, 16 of which were spent with the Hartford company. He was chief inspector for six years.

Mr. Manning was the son of Mr. and Mrs. John Howard Manning, who survive him, as does his widow, Margaret Manning, two children, Howard and Ward, and a sister.

Funeral services were held at 8 o'clock Wednesday night at his late residence, and the interment took place Dec. 31.

WILLIAM N. SMITH

William N. Smith died at his home, 380 Fifth St., Brooklyn, N. Y., on Jan. 3. Mr. Smith was born in Scotland 63 years ago and had made his home in Brooklyn for 43 years. He was the engineer at the Brooklyn Bridge power house for nearly 40 years, and was transferred only when that station was abandoned. He was well known in engineering association circles and had a host of friends. He was a past-vice-president of Brooklyn Association No. 8, N. A. S. E., past-president of the Modern Science Club, chairman of the Combined Associations of Engineers of Brooklyn for five years, a member of Melville Council No. 9, Universal Craftsmen, and the International Union of Steam and Operating Engineers. Mr. Smith was also past-master of Lexington Lodge No. 319, F. and A. M., and a member of the Masonic Veterans' Association, and Bridge Council No. 49, New York Civil Service Association. He leaves a widow, two sons and seven daughters. The funeral services were held at his late residence on Tuesday evening, Jan. 5, and were attended by delegations from the several organizations above mentioned. Interment was at Greenwood Cemetery on Wednesday at 2 p.m.

PERSONALS

Heinrich J. Freyn has resigned as third vice-president of H. Koppers Co., Chicago, effective December 1, 1914.

Paul H. Brangs has been elected a director of the Heine Safety Boiler Co. to fill the vacancy caused by the death of Colonel E. D. Meier. Mr. Brangs is manager of the New York office.

Prof. John J. Flather, head of the department of mechanical engineering of the College of Engineering of the University of Minnesota, is spending a year's leave of absence in Scotland.

Prof. W. H. Kavanaugh, head of the experimental department of the College of Engineering of the University of Minnesota, has been elected chairman of the Minnesota section of the American Society of Mechanical Engineers.

Arthur G. McKee announces that Robert E. Baker and Donald D. Herr, his business associates during a number of years past, have joined with him in the incorporation of his engineering and contracting business under the name of Arthur G. McKee & Co.

Maxwell Carson Maxwell, for the past seven years head of the Department of Applied Mechanics, Pratt Institute, Brooklyn, New York City, is now superintendent of power and plant of the Yale & Towne Manufacturing Co., Stamford, Conn. He is responsible for the power generation and distribution, building maintenance, new building construction, general repairs and maintenance of machinery, shafting, etc., and also has charge of the tool department.

ENGINEERING AFFAIRS

Washington University's Lectures on Public Utilities

The appointment of James E. Allison, some time chief engineer of the St. Louis Public Service Commission, as lecturer in economics in Washington University, is of particular interest to the students of engineering in the University. During the second semester of the current year, Mr. Allison will deliver a course of lectures, under the general direction of the department of economics, which will deal with the economic principles underlying the regulation of public utilities. Some of the specific problems to be studied are the organization and operation of public utility corporations, their securities and the methods of financing them, and especially the method of valuing public utility properties for taxation and rate regulation. Seniors in the School of Engineering will now be required to take this new course which will replace in part the second semester's work in general economics. It is believed that this course presents an unusual opportunity, both because of the importance of the subject and the high standing of the lecturer.

In order to further encourage the study of economics by students of engineering of Washington University, Mr. Allison has established a fund, to be known as "The Allison Fund," the annual income of which is to be used either for awarding cash prizes or in such manner as in the opinion of the dean of the School of Engineering and the head of the department of economics will best promote the object of the fund. When a prize is offered, competition will be open to the students of engineering who undertake a special investigation of the field of public utilities under the direction of the department of economics, with such restrictions as to eligibility as may be specified from time to time.

POWER

Vol. 41 NEW YORK, JANUARY 19, 1915 No. 3

A New Year Letter

Written by the supervising engineer of a public utility-company in the Middle West to engineers of different power plants under his direction.

○ ○ ○

Dear Sir—With the beginning of the new year it might be well for all of us to investigate every point about our power plant with a view to getting higher economy, if possible, in our future operation and maintenance. Below are a few questions we should ask ourselves, answering them in our own minds, not allowing the matter to drop until we are satisfied everything possible has been done and a report made out stating why certain results cannot be attained:

Are our boilers clean; is the brickwork in good condition, and are all cracks and unnecessary openings airtight?

Is the feed-water heater clean and working efficiently, and is the water as hot as possible?

In water-tube boilers, do we know that the baffling is tight and that the gases are not short-circuited directly to the stack?

Are we sure all blowoff valves are tight and that we are not blowing down too much?

Are our dampers working, and do we use them instead of closing the front doors on hand-fired boilers, allowing cold air to filter through the brickwork, etc., or, on stokers, allowing the fires to burn off the back of the grate?

Are we carrying a steady maximum steam pressure?

Are all our grates, gages, flue cleaners and other boiler auxiliaries in perfect condition?

Have the soot and ashes been cleaned out of the bases of the stacks?

Do we know that the breeching is not partially stopped up with soot?

Do we know that our draft is the maximum possible under the existing conditions?

Are we using the minimum amount of labor to properly perform the work in both the engine room and the boiler room?

Are our engines operating as economically as possible under their present conditions?

Do the pistons leak?

Do the valves leak, and are they properly set?

Is there undue drop of pressure between the boilers and the engines?

Is the steam reasonably dry?

Is the back-pressure on the exhaust a minimum?

If we are using superheaters, do we know that we have the maximum superheat?

If not, are the superheaters stopped up or dirty?

Are all steam traps in good condition, or are valve seats cut, floats collapsed or other parts defective?

Are all exposed heating surfaces properly covered?

Do we know that all valves on steam lines and all drain valves are tight?

Are all drains from oil separators, heaters, piping, etc., clear?

In plants running condensing, are we using the proper auxiliaries to keep our feed-water temperature a maximum and our motor-driven auxiliaries operating at maximum efficiency due to low temperature of the condensing water?

Are we trying to get a maximum hotwell temperature by controlling the amount of condensing water to the condensers?

Have we the maximum vacuum possible with the present temperatures, barometer and load?

Do we keep a maximum load factor on the apparatus in use?

Do we try to keep down the cost of supplies, such as lamps, oil and waste?

Do we know that our apparatus and our station light and power wiring are in safe condition?

Have we fire extinguishers on hand, and any fire hose we may have properly connected?

Have we taken all precautions to prevent accidents by protecting all openings by railings, inspecting all ladders to see that they are safe, looking after all weights or other heavy parts that may be suspended from above, and seeing to it that all pulley blocks, tackle chains and other tools are in perfect order; that there are no oily or slippery places in or around buildings; that piping or any part of apparatus in use is not showing signs of strain; that proper guards are placed around wiring, switchboards and high-tension apparatus, and that danger signs are placed where necessary?

Have we prepared for extreme weather conditions in the way of ice, floods, lightning, etc.?

Have we taken care of the effects of high winds and rains on our stacks, windows, roofs, etc.?

The whole thought of this letter is to bring out any suggestions or ideas you can put forward to improve our economy and service. If you will put in writing anything of this nature we will be glad to make every effort to get the matter attended to.

[*Written by F. W. Laas, Cedar Rapids, Ia.*]

Baltimore Sewage-Pumping Plant

By Warren O. Rogers

SYNOPSIS—This sewage-pumping plant has three 400-hp., 27,500,000-gal. pumping engines and three 260-hp. water-tube boilers. Sewage is pumped against a head of 72 ft. through 42-in. discharge pipes. Drainage water is used in the condensers of the pumping engines and is handled by engine-driven centrifugal pumps. Sewage from the Back River disposal plant is utilized to operate two 150-hp. waterwheels, each driving a 110-kw. alternating-current generator the electrical output of which is used for lighting and motor circuits at the disposal plant.

What is regarded by engineers as the most scientific system in the world for handling sewage is the twenty-one-million-dollar sewage system now under construction at Baltimore, Md. Prior to the great fire in 1904, the city, with a population of nearly 600,000, was without a sewage system, depending on cesspools and private sewers.

Owing to the contamination by sewage of the waters of the Chesapeake Bay and the injury done the oyster industry, the legislature passed laws requiring a sewerage system and the purification of the sewage before discharging into the bay. A sewerage commission was appointed, with Calvin W. Hendrick as chief engineer, under whose direction this system was constructed and is now nearing completion.

By a series of intercepting sewers, about two-thirds of the city's sewage is carried to Back River by gravity; the rest is intercepted along the river and harbor front. Upon reaching the new pumping station near the center of the city, it is pumped against a head of 72 ft. through 42-in. iron mains for about a mile, from which point it flows by gravity to the disposal plant at Back River, some six miles east of the city.

Pumping Plant

The pumping station (Fig. 1) is constructed of brick and stone on a concrete foundation. Below the main floor the walls are of granite, and above they are of light-brown brick with terra cotta moldings. The roof is of slate, supported by steel trusses carried by steel columns built into the walls.

The building is fireproof, has an outside dimension of 188 ft. by 156 ft. 7 in., and is 59 ft. high from the ground to the top of the walls. The engine room is 180 ft. long, 51 ft. wide and 68 ft. high from the basement floor to the tie beams of the trusses. It is lined with enameled brick for 23 ft. above the basement floor.

At present there are three triple-expansion, crank and flywheel, condensing pumping engines (Fig. 2) having 22, 42 and 62 by 60-in. steam cylinders. These units run at 20 r.p.m., each having at this speed a capacity of 27,500,000 gal. of sewage every 24 hr., or a total of 82,500,000. The horsepower of the engine is 400 at normal speed, with 175 lb. steam pressure, and operating with a 28-in. vacuum. The first receiver pressure is 32 lb. and the second receiver has a pressure of 2 lb. gage. These pumping engines rest on concrete foundations separated from the building so as to absorb any vibration.

The boiler room is separated from the engine room by a screen chamber below the main floor level and a machine shop and storeroom on the main floor level. The boiler room is 94 ft. long by 50 ft. wide, with space for five 260-hp. water-tube boilers set separately; at present there are but three 260-hp. boilers (Fig. 3). Each has two steam drums 23 ft. 3⅝ in. long and 36 in. diameter, made of $\frac{7}{16}$-in. plate. The tubes are 18 ft. long and 4 in. diameter. The heating surface of the drums is 193 sq.ft. and that of the tubes 2473, a total of 2666 sq.ft.

Two of these boilers are estimated as having sufficient capacity to supply steam for the three pumps. One boiler only is under pressure now, and it supplies steam for the pump that handles the sewage at the present time. The spare boiler is held to take care of fluctuations in the sewage. Each boiler is capable of supplying steam for one pumping engine and all auxiliary machinery.

The boilers are hand fired and have a grate area to heating surface of 1 to 44.4. The furnace gases pass to an economizer above the boilers having 1550 sq.ft. of heating surface; it heats the water from the main pump feed-water heater from about 90 to 160 deg.

All the boilers are connected to a single brick chimney 200 ft. high above the boiler-room floor; it has an inside diameter of 10 ft. at the top. It is lined with firebrick for half its height and rests on a concrete foundation. The draft is controlled by a damper regulator which operates a main damper between the boiler and the stack. Each boiler has a connection to a CO_2 recorder. One boiler is equipped with a superheater.

The boiler feed water is metered, each boiler having a separate meter and a differential draft gage. Feed water is handled by either of two 6 and 3¼ by 6-in. pot-valve outside packed duplex pumps back of the boilers. Coal is delivered to the plant in barges and unloaded by a grab bucket into a hopper which delivers the coal to a bucket conveyor, and then into any one of the five 200-ton bins above the boilers. The conveyor also carries the ashes from the basement to an ash bunker at the top of the boiler room, where they are loaded into wagons for removal. Fig. 4 shows the bucket conveyor in the basement.

At one end of the pump room are two 40-hp. centrifugal pumps driven by 7 and 14 by 8-in. compound condensing engines. Each pump has a capacity of 3000 gal. per min. and draws water from underdrains below the interceptors, and discharges either through the condensers of the main pumping engines or to the harbor direct. These engines (Fig. 5) each drive an air pump by a noiseless chain drive. At the same end of the building there is a 35-kw. 7 and 13 by 8-in. compound engine-driven generator set delivering current at 250 volts, at 300 r.p.m., for station lighting and motor circuits. There is also a smaller generator driven by an 8x7-in. vertical engine, and a small motor-driven air compressor, used to supply air for operating the exhaust valves on the low-pressure cylinder, at from 28 to 30 lb. pressure.

Screen Chamber

In the basement, between the pump and boiler rooms, is the screen chamber, and below its main floor is a reservoir into which the sewage is discharged from the interceptors and then drawn by the pumps. All sewage is screened twice, first through a set of movable screens at the entrance to the screen chamber and then through a fixed screen over the suction pipes of the pumps. The

Above the screen chamber, level with the pump-room floor, are toilets for the engineer and firemen, a machine shop large enough to do ordinary repairs, and a storeroom. Above these is a header room (Fig. 6). The steam piping between the boilers and pumping engines

movable screens catch the coarser materials, which are hoisted out, the water with which they are saturated is removed in a steam press, and the screenings are then burned in a special furnace in the boiler-room basement.

is so arranged that no single accident can put more than one boiler or pumping unit out of service. On the boiler-room side of the header room is an 8-in. main header which reduces to 4 in. at the ends. This header is held in place by brackets secured to the side wall about 12 ft. above the floor. On the opposite side of the room, near the floor, a duplicate 8-in. header is piped to the opposite header by three 5-in. long-radius bent pipes. The pipe connections between the second header and the pumping engines are 5 in. in diameter. A duplicate set of auxiliary pipes runs from the headers to the auxiliary units in the pump-room basement. Both headers are dripped to a separate drip line and the water of condensation returned to the boilers. The plant is operated by F. H. Cronin, chief engineer.

Sewage from the pumping plant is discharged into the main sewer at a point where it will flow by gravity to the disposal plant at Back River. Here there are three hydrolytic tanks, three sludge-digesting tanks and 18 acre of broken-stone sprinkler filters, together with two settling basins. There are in process of construction 28 Imhoff tank units, 16 sludge-digesting tank units, with accompanying sludge beds, and 12 additional acres of broken-stone sprinkling filters.

As the sprinklers are 15 ft. below the hydrolytic tanks, a head is obtained sufficient to spray the sewage over the stone beds through nozzles spaced 15 ft. apart. The hydraulic head is controlled by butterfly valves which cause the sprays to rise and fall, varying from close to the nozzles out to the limit of 15 ft., thus utilizing uniformly all of the surface of the stone bed as the nozzles throw a square spray.

All spray falls on the beds and trickles down through 8½ ft. of broken stone, coating the stone with a gelatin-like film in which certain bacteria multiply by millions and attack and kill the injurious bacteria in the sewage. When the sewage reaches the bottom of the filtering beds it is practically pure. It then finds its way to a central passage under the beds and is delivered to the settling chambers, requiring three hours for its passage. The sewage then drops 18 ft. through either of the two 150-hp. waterwheels in the power house.

The power thus obtained is used to operate two 110-kw., 60-cycle, three-phase, 2300-volt alternating-current generators (Fig. 7), at 276 r.p.m. The two 7½-kw., 125-volt exciters are each driven by a noiseless chain belt at 1000 r.p.m.; the speed of the generators is regulated by two belt-operated hydraulic governors. The output of these two generators is utilized for illuminating the disposal plant and for operating small motors. To insure against interruption of service, an 85-hp. gas engine is coupled by a clutch to one of the generators so that if there is not enough water to operate the unit the engine can supply the power. It runs at 276 r.p.m. and has three 10½x16-in. cylinders.

At one side of the room is a motor-driven centrifugal pump with a capacity of 600 gal. per min. against a head of 157 ft., at 1750 r.p.m. This pump forces water into a tank and is used for washing out the hydrolytic tanks and for general flushing purposes.

The Hot-Bulb Oil Engine

By Edwin Lundgren

SYNOPSIS—Description of the important details and points which the designer has to consider, with data gained from practical experience.

The oil engine with hot-bulb ignition is a type that has been developed widely during the past ten years, and which has gained a large field of application in Europe, particularly for marine and for agricultural purposes. Of course, the main condition for commercial success is rational management and good shop methods, but the design of the product is just as important. The paramount requirement is a reliable engine, as nearly foolproof as possible, and of simple construction. The two-stroke-cycle type appears to have proved simpler and more economical than the four-stroke-cycle engine with hot-bulb ignition; therefore, this type will be selected for discussion.

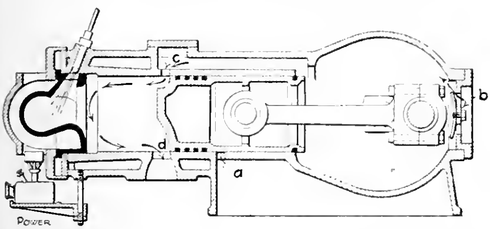

Fig. 1. Typical Two-Stroke-Cycle Hot-Bulb Engine

Reference to Fig. 1 will make clear the principle of this engine. Air is sucked into the crank chamber by the piston, either through ports *a* in the cylinder wall or through a simple air valve *b*; it is then compressed in the crank chamber and led through a bypass and ports *c* into the cylinder, where it is deflected by the piston and expels the exhaust gases through the ports *d*. The cylinder is now filled with air; not pure air, of course, as the quantity admitted is not large enough to scavenge perfectly and as the nature of the process makes perfect cleaning of the cylinder impossible. This mixture of pure air and burnt gases is compressed by the piston on its return stroke, and at 50 to 85 per cent. of its travel, the fuel—kerosene, fuel oil or crude oil—is injected through a fine spray nozzle directly into the heated vaporizer or hot-bulb head. At about dead-center spontaneous ignition takes place, an explosion and combustion follow, and the piston is driven forward on its working stroke until it uncovers ports *d* and then *c*, whereupon the cycle is repeated.

The typical indicator diagram of Fig. 2 illustrates the process within the cylinder, showing the compression to be fairly high, varying in different designs from 90 to 110 lb. per sq.in. The explosion pressure may reach 300 to 350 lb. per sq.in.

Considering the relative merits of three-port and two-port engines, it may seem at first that the three-port is the simpler and better, but the reverse is true, as the two-port engine requires a simpler casting. Also, for lubricating, it is better to avoid the third port, and the two-port engine gives a little more power. For smaller sizes it is advisable to cast the cylinder and frame in one piece, and the saving in machinery will offset the higher cost of casting. One of the most important parts is the cylinder head and vaporizer or bulb. Figs. 3 to 6 show different types which have been used successfully. The clearance volume is $\frac{1}{1.5}$ to $\frac{1}{5.5}$ of the stroke volume according to the compression desired. The walls of the vaporizer, which are usually cast iron but sometimes cast steel, have to be made fairly thin, otherwise too much time will be required to heat it for starting.

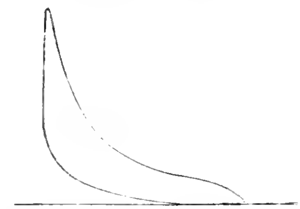

Fig. 2. Indicator Diagram from Two-Stroke-Cycle Hot-Bulb Engine

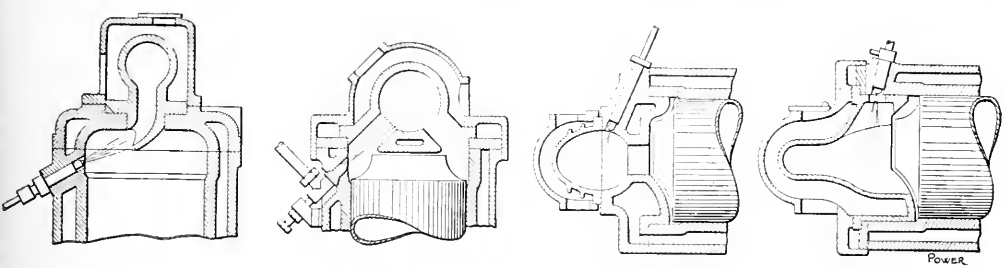

Fig. 3 Fig. 4 Fig. 5 Fig. 6

Different Arrangements of Hot-Bulb Ignition

Against the walls of this heated vaporizer the fuel is sprayed in a fine mist. The proper formation of this spray, however, requires experience. If it is too fine, preignition will occur, whereas if it is too coarse, combustion will not be good, and high fuel consumption will result.

A good nozzle construction is shown in Fig. 7. After passing through one or two check valves the oil is led through the spiral grooves and the fine hole at the point of the nozzle, the size of the hole and the depth of the grooves exercising a decided influence upon the formation of the spray.

Of course, the action of the fuel pump is also important. It must have a quick, short stroke, and as the fuel for each revolution has to be forced through a fine hole within a fraction of a second, the pressure must be very high; the writer has measured it to 800 lb.

A typical construction of fuel pump and governor is shown in Fig. 8, the design being simple and self-explanatory. The steel plunger is ground in the brass body of the pump. Sometimes a packing is not provided, although it is to be preferred. If used, it should not be tightened enough to hamper the return stroke of the plunger, which is produced by the spiral spring. The stroke can be varied by shifting the block *a*, and the pump

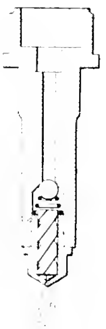

Fig. 7. Fuel Nozzle

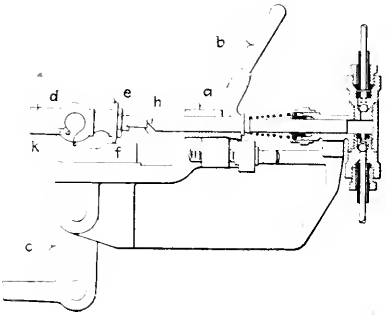

Fig. 8. Fuel Pump and Governor

can also be actuated by hand through the lever *b*, which is necessary when starting.

The simplest governor is the "hit-and-miss" type and for most purposes it is sufficient. In Fig. 8, the lever *c* receives its motion from a cam or an eccentric. To it is attached a lever *d*, which carries a square fiber disk *e*, and by means of a spring *k* is pressed down on block *f*. Usually the disk *e* just slides back and forth on the block, but if the speed increases, the lever with the fiber disk, due to inertia, jumps too high when it leaves the little incline shown, and thus its edge *g* misses the edge *h* of the push-rod. In this manner the speed can be kept within narrow limits when changing from full load to no load, and it can be adjusted by changing the tension of the spring *k* or by shifting the block *f*.

The speed also can be controlled by a flywheel governor, which changes the stroke of the fuel pump or keeps the suction valve open during part of the pressure stroke. As an alternative, an ordinary centrifugal governor may be employed which acts in a similar manner, or which shifts a cam that in turn gives the pump a different stroke.

A weak point with many engines of this type is the injection of water into the cylinder. This is necessary for heavy loads as otherwise preignitions will occur. On the other hand, water should not be admitted when the engine is running idle or at light loads, for it will misfire and possibly shut down. The water retards combustion and effects cooling. The effect of water injection is shown in the indicator diagram, Fig. 9, where purposely a little too much water was admitted. Usually, the water

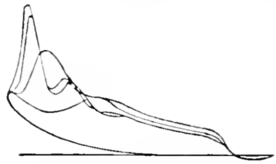

Fig. 9. Showing Effect of Water Injection

is admitted in a rather crude way, through a needle valve into the bypass, from which it enters the cylinder with the air. In this case continuous attention has to be paid to the needle valve to regulate the amount of water. If the load is fairly steady, no attention is required, but with a varying load it is inconvenient. Therefore, in several designs the water is injected by a small pump under the influence of the governor, thus giving more or less water to suit the load.

With a view to eliminating the necessity for water injection, the writer once built an engine having a flywheel governor that turned the pump-actuating eccentric so that with light loads the injection took place at the usual time, but at heavy loads so late that no preignition could occur. The engine worked all right, but experience has shown that even here water injection proved advantageous, as it increased the power.

Of prime importance also are the dimensions of the ports for the air inlet and the exhaust, which depend largely on the size and speed of the engine; the greater the speed, the larger the ports, although in larger engines the ports can be made relatively smaller. On an average, the length of the exhaust ports is 20 to 22 per cent. of the stroke, and that of the inlet ports 9 to 13 per cent., while they occupy about 90 deg. on the circumference. The exhaust ports should be uncovered so early that the pressure in the cylinder is almost nil when the

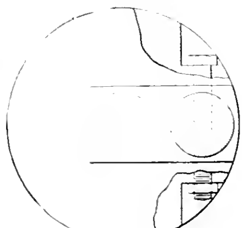

Fig. 10

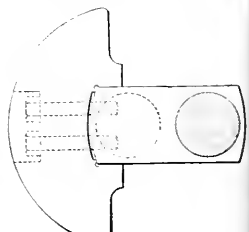

Fig. 11

Wrong and Proper Designs for Counterweights

inlet ports open, for only in that case can effective scavenging be obtained.

The pressure of the scavenging air is not high, about 4 to 5 lb. per sq.in., but it is enough to blow the air and oil out of the crank case through every possible opening, particularly around the shaft. In small engines this does not amount to much, for the bearing is usually a straight cylindrical bushing, and if sufficiently oiled, does not let any air escape. Sometimes a steel disk is placed on the shaft, the idea being that the side of this disk, in contact with the bearing, will keep tight enough even if the bearing wears down a little. In other cases disks are employed which do not rotate but which are pressed by springs against the crankshaft, making a good joint. In still another arrangement a cast-iron ring is sprung into the bearing.

In order to make the pressure in the crank case as high as possible and render the crank case efficient as an air pump, the clearance must be kept as small as possible. A long stroke is therefore not advisable. The importance of the clearance is, however, often overrated as it does not pay to make a counterweight such as that in Fig. 10; Fig. 11 is a better design. The writer once tried several engines with and without counterweights and marked difference in power was not noticeable.

In a horizontal engine the counterweight is necessary, for otherwise too strong vibrations will occur. While a counterweight like that in Fig. 11 is best, it is cheaper

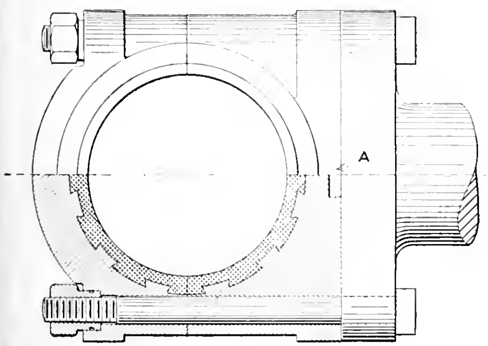

FIG. 12. CONNECTING-ROD END

to cast one in the flywheel. However, it is not to be forgotten that such a weight revolving at high speed will cause additional stress on the main shaft. The main parts of the crank mechanism offer no extraordinary features, and are usually computed, assuming an explosion pressure of 300 lb. per sq.in. For determining bearing surfaces a lower value can be used—about 250 lb.

The connecting-rod should be so designed that an adjustment of its length can easily be made, the marine head, as shown in Fig. 12, being recommended. The head should be as small as possible, so as not to make the crank chamber too large. Often the dimension *A*, Fig. 12, is too small, for it must be remembered that sometimes rather violent knocks occur which are hard on the material. Ample clearance (3/8 to 1/2 in.) should be provided where rough cast-iron surfaces are concerned.

For lubricating the main bearings ring oilers are preferable. A system of force feed is really the best, but it is more expensive and requires more attention. With forced feed the castings are simpler than for ring oiling. Although the performance of this type of engine is not as good as the high-compression or Diesel type, the high economy of the latter is offset by the many complicated parts, which make the small sizes prohibitively expensive. For these small sizes (2 to 50 hp.) the type described has proved reliable and economical.

Safety-Valve Specifications

BY A. B. CARHART

The specifications concerning safety valves in the proposed boiler code, as recently revised by the committee of the American Society of Mechanical Engineers, are of special importance because they express briefly and clearly all of the details concerning safety valves that were discussed and unanimously agreed upon at a conference held in Boston a few weeks ago, at which nearly all the safety-valve manufacturers of this country were represented. These specifications, therefore, may be regarded as representing the best modern practice, for they embody the combined experience and judgment of those who have had the best opportunities for the study of the subject; and as nothing at that conference was adopted without unanimous assent, the provisions must be regarded as safely conservative and proper.

The paragraphs concerning common lever valves are of little present importance, in view of the recommendation that all other than modern pop safety valves should be replaced as soon as possible.

An item of special interest in paragraph 19 is the requirement that each boiler carrying a pressure over 15 lb. and requiring a valve larger than 3 in. must have at least two safety valves. This does not mean duplicates, but that the total requirements shall be divided into smaller units. It insures greater safety and better operation of the valves and boiler. It is not likely that both valves would ever be inoperative at the same time. Safety valves are calculated to discharge the maximum steaming capacity of the boiler under extreme conditions, and each time a single large valve opens it will discharge steam at a rate much greater than generated under normal conditions. This sudden discharge is wasteful, and the pressure will drop more than necessary before closure. To avoid this, safety valves are often adjusted to blow down only one or two pounds and operate with unreasonable violence, causing destructive hammering in the valve and a considerable shock to the boiler when the large outflow of steam is suddenly checked, which in effect produces a miniature explosion every time the valve opens.

Under ordinary conditions a small valve, operating very gently, would afford adequate relief and it requires much less attention than a larger one. The second and third valves would not open unless the pressure should continue to rise, but would be in reserve as emergency protection two or three times greater than required under normal conditions.

Under paragraph 20, additional safety-valve protection is required on low-pressure boilers, because the rate of flow through the same orifice is less at the lower pressure.

In paragraph 21, an entirely new maximum evaporation calculation has been adopted. Modern conditions, with stokers and forced draft, show fuel consumption much greater for a given grate area than formerly, therefore the new formula and table proposed by the A. S. M. E. seem much more logical.

Paragraph 24 requires that valves shall be of the direct spring-loaded "pop" type. Prior to 1875, all valves, and since then some valves, have been made that are spring loaded, but do not have the pop feature.

For low steam pressure such valves serve fairly well, but their chief defect is that they open only slightly when the steam pressure reaches the set limit, and do not lift higher as the pressure increases except by some special device. This consists of an addition to the disk excluded from the pressure of the steam when the valve is closed, but when the valve opens, the steam acts upon the additional area also and causes the valve disk to suddenly rise more than it would by the pressure upon the original area only.

The table on page 36, paragraph 21, fixes the normal steam discharge to be expected of each commercial size of safety valve at the several pressures given. It is required in paragraph 22 that all valves must show lifts and discharges at least equal to the values given in the table, when the blowdown in boiler pressure is regulated to the amounts specified in paragraph 30. It is further provided that the discharge rating of a safety valve, for the purposes of calculating the number and size of valves necessary for a boiler, shall not be greater than the values given in the table. This embodies the unanimous agreement of all manufacturers at their recent conference, following a long discussion of this special topic.

The requirement in paragraph 27 that safety valves must be attached directly to the boiler without intervening pipe or fitting or internal dry pipe, and upon a separate outlet independent of any other steam connection, has perhaps aroused more comment and criticism than any other in these specifications; yet in the judgment of those having the greatest experience and special knowledge of the subject, this is probably the most important requirement. All of the valve manufacturers were unanimously for this provision in its present form.

The provision in paragraph 25 that the several valves on the boiler should be set to open at pressures at least 3 lb. or 5 lb. apart seems proper. To set several valves on the boiler to open at nearly the same pressure is a mistake, because ordinarily the amount of steam to be discharged is much less than any one of the valves alone could properly take care of. Two or three valves opening intermittently will involve much damage to themselves and harm to the boiler.

Paragraph 30, as to the proper amount of blowdown in pressure for which the valves should be adjusted to close, is the result of the experience of all of the safety-valve manufacturers. Close regulation is harmful, generally resulting in sharp and violent action of the valve in opening and closing, shortening its useful life and unduly straining the boiler.

The purpose of the lifting gear specified in paragraph 31 is simply to afford some means of insuring that the valve disk is free and that its action is not interfered with by deposits of boiler scale or lime in the valve guides.

Paragraph 36 specifies that safety-valve springs shall withstand a cold compression test without showing any permanent set. This is to avoid dangerous consequences if the spring is screwed down to hold the valve closed during a boiler test. That such practice is entirely wrong is recognized in paragraph 10, which specifies that a test clamp or gage shall be used to hold the valve disk upon its seat during such a test.

There is also a provision that a spring shall not be used for any pressure more than 10 per cent. above or below the working pressure for which it was designed. That valves will not operate properly and will not give normal lift or blowdown when the springs are either too weak or too stiff is not always recognized.

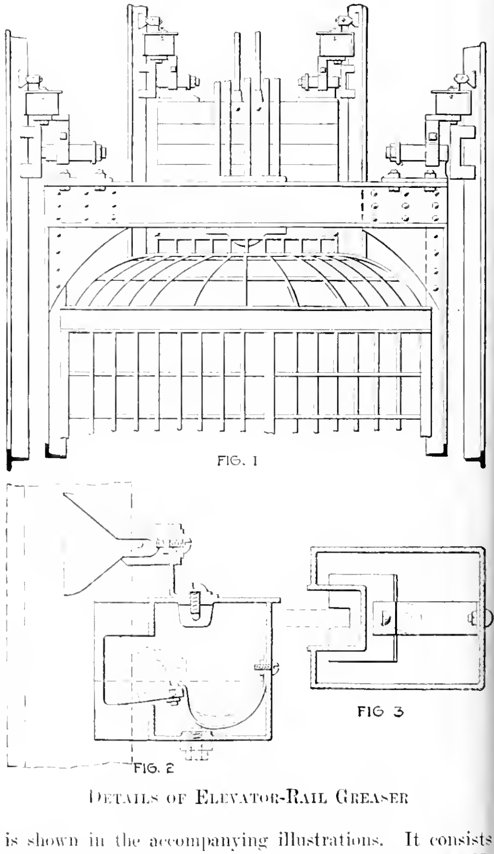
Paragraph 39 provides that at least one safety valve shall be connected near the outlet of a superheater to insure a circulation of steam through the superheater, to protect it from harmful rise of temperature in case the normal demand for steam is suspended for any reason. Valves smaller than the 3-in. size are recommended for this service, as they are more easily maintained and kept tight. Paragraph 41 provides for standard flanges for each valve size.

The following joint letter was forwarded to the Council of the A. S. M. E., on Nov. 11, 1914:

We, the following safety-valve manufacturers, have carefully examined the third edition of the preliminary report of the Special Committee on the Construction of Steam Boilers, with particular reference to the specifications applying to pop safety valves, and are all agreed that these embody just what was unanimously accepted by the valve manufacturers who were in conference on Oct. 2, 1914. We therefore respectfully urge that your body accept and approve of same without modification, aside from such typographical errors as may be found therein.

Elevator-Rail Greaser

A device which will lubricate continuously and automatically the guide rails of the car and counterweight of an elevator has recently been perfected. The apparatus



Details of Elevator-Rail Greaser

is shown in the accompanying illustrations. It consists primarily of a box to hold the grease, which has a U-shaped recess so that it may straddle the web of the rail.

Through an opening in this recess a double-ply leather wiper projects. It is notched to fit the rail and, being attached to the wall of the box by a flexible spring, is free to move vertically. When the car is going up, the leather wiper is in the position shown by the full lines in Fig. 2. The dotted lines show its position for a downward movement of the car. The spring also tends to push the leather forward against the rail.

The box is filled with an even mixture of grease and graphite of the proper consistency to flow to the rail when it is agitated by the movement of the leather and spring. The greaser is attached to the top beam of the car or counterweight (Fig. 1). The feed of the grease is varied by moving the box toward or away from the rail. To remove any excess grease from the rail and drop it back onto the leather a double-bladed scraper straddling the rail is mounted on top of the box. The blades are adjustable for varying widths of guide, and in or out adjustment is permissible as they are secured to the top of the box by a screw passing through a slot.

When supplied, the box is filled with grease. At the end of six months the level of the grease is usually lowered to a point from which it cannot reach the rail. About half a pound of grease is needed to refill the box, and it is claimed that the device is then ready for another six months' service. The cover may be removed by loosening three screws which pass through the casing of the box into lugs projecting down from the cover. With this arrangement it is not necessary to remove the screws entirely and thus run the risk of dropping them into the elevator well.

Results of tests conducted on electric elevators equipped with these rail greasers show a reduction in starting torque of from 10 to 25 per cent. over dry and hand-lubricated guides. Other advantages claimed are savings in shoe and rail, the elimination of jars and jerks common to an elevator guided by dry rails, noiseless operation and no dropping of oil or grease to the floor of the well. The upkeep is small as the only part subject to wear is the leather wiper. This lasts for a long period and may be renewed at a cost of a few cents. The leather is made in sizes to conform with rails having face measurements from ½ to 9 in. W. A. Garvens, 708 South Ashland Blvd., Chicago, is supplying this device.

An American Engineer in Cuba

By Frank E. Small

SYNOPSIS—Impressions of an American operating engineer sent to Cuba to put some run-down plants in safe and economical condition.

The writer hopes that none will construe the substance of the following to be a slap at all engineers in care of Cuban plants.

On going to Cuba as a trouble man one feels that the island has grown in plants faster than it has in engineers competent to care for them. There are many good men, to be sure, but many are unfit. This condition among engineers is aggravated by the unfavorable attitude of the owners or employers toward skilled labor. Cuba is of course warm, and ice and refrigeration plants become more numerous as industry grows. Some business houses have failed owing to unnecessarily high operating costs. Some of these plants are quite old, five to ten years, and the equipment has greatly deteriorated or become obsolete. To convince the owners that they should first hire a good engineer at double or triple the usual local salary, and should immediately spend money for new equipment when they are already losing money, is difficult.

The writer has found plants which, when new, produced six tons of ice for one ton of coal, although at the time of his visits they were getting but one to two tons per ton of coal. Some plants in other industries are just as bad.

At one plant a locomotive-type boiler was set in brickwork. This seemed new and led to an inquiry as to why the brick setting was used. The engineer informed us that the firebox had been patched so many times that it was deemed advisable to set the boiler in brick, putting the furnace under the back of the boiler to reduce the temperature in the firebox.

The first look into the furnace of a horizontal return-tubular boiler in this plant showed water running from around the edges of a 24x48-in. patch, the second one to be put on that crown-sheet. The writer threatened to leave if permission was not given to reduce the pressure to 80 lb. (it was 100 lb.). This seemed to create considerable laughter in the office, but when the manager was shown that that patch was carrying a load of over 115,000 lb. he began to congratulate himself on being alive.

For some reasons the boilers here had their gage-cocks removed, gage-glasses being depended upon for showing the levels. The differences between the readings of any two steam gages was so great that for safety's sake it was necessary to immediately learn the correct pressure.

A steam hose had been used to clear the tubes of soot, and although the front ends were clear enough, the back ends contained soot that had accumulated and baked on. A brush could not be pushed through the tubes.

On the way to one plant the first day, the engines could be heard pounding before the writer was within a block of the plant. Notwithstanding this condition, the engineer was as contented as could be. This plant was but four years old, although one would take it for fifteen were it not for the modern equipment.

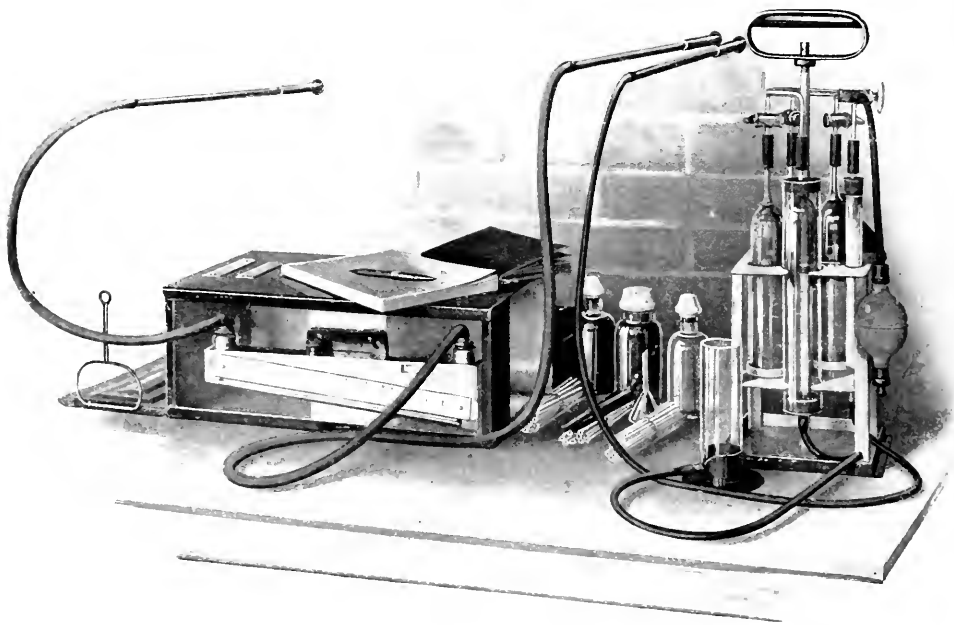
The writer's experience leads him to believe that owners should, for a time at least, receive more support from builders. Equipment is installed and operated until accepted, but in many cases it is necessary to "break in" the purchasers' engineers, and this is by no means done thoroughly. There are few competent men available, and consequently it is but a short time until the equipment is giving poor service and the builder's reputation with the local owners is injured. The builder would do well to try to get a good man to care for the plant.

At present plants here are not so much in need of men who can obtain economical results, although these must follow, as of men who can keep equipment running well.

Boiler Efficiency Kit

In checking up boiler efficiency it is essential to analyze the flue gases and take temperature readings as they leave the boiler. It is also desirable to note the draft at the fire and the drop in draft between the furnace and the damper, as these factors determine the air supply. When these data are known it is possible to calculate the combustion efficiency.

A convenient and complete kit of apparatus for obtaining the above mentioned data is being supplied by the Precision Instrument Co., Detroit, Mich. The equipment is neatly arranged in a case. The illustration shows the various devices in position for testing a boiler. The case is divided into three compartments, but by an ingenious arrangement the covers to all three compartments are locked by a small padlock within the handle of the case. A differential draft gage is contained in one compartment, the middle chamber contains an Orsat apparatus of special design and the third space a high-temperature thermometer, a special printed report pad for recording the various test data, some rubber tubing, etc.



Kit Unslung and Ready for Use

As indicated, the draft gage is arranged so that both the draft in the furnace and the drop in draft between furnace and damper may be conveniently taken. For this purpose rubber tubing of suitable length and sectional iron pipes of the fishpole variety are provided. The draft gage is graduated in hundredths of an inch. For compactness the three pipettes and the burette of the Orsat are arranged in a circle. The analyzer is graduated to read in tenths of one per cent. The necessary rubber tubing for the analyzer is furnished.

The high-temperature thermometer is encased in a brass tube to prevent breakage and is provided with sectional extension pieces so that it may be inserted through any ordinary wall of a boiler setting. In the compartment containing the thermometer there is space for storing tubing, data pads and bottles containing the chemical mixtures.

The kit is also provided with a book of instructions and manual of testing methods, a pad of standard test-report blanks, proper chemicals for absorbing CO_2, O and CO, already mixed for use, a funnel, and in short, all the necessary parts and materials required to conduct a boiler-furnace efficiency test. That all of this equipment can be kept in a small, compact case ready to be carried to the point of immediate use is an advantage.

Some Original Ideas

An operator complained of the rapidity with which the brushes of his engine-driven generator were consumed, although the load was comparatively small and there was no evidence of sparking. All brush-contact surfaces appeared to have been recently sandpapered, but he stated that they had not been touched since their installation about ten days before. It developed that the engine had been shipped from one place and the generator from another and that they had been connected on the ground.

As the commutator showed some eccentricity, a local machinist was engaged to turn the commutator in its own bearings. He had used a diamond-pointed tool, which was all right, but had also used a coarse feed and a comparatively deep cut, thereby converting the commutator surface into a milling cutter, so far as the brushes were concerned. On being recalled to finish the job, he explained that he had made that kind of surface on purpose, so as to make the brushes "bite better."

In another case, complaint was made that a machine would not generate, but by the time the inspector arrived it was generating all right. The operator stated that, as far as he knew, he had not done anything to help matters, but had let the machine run to "work in the bearings." It seems that he was particular how the machine looked and had been touching up bolt-heads and nuts with gold paint, and while doing this had concluded to give the commutator a coat, with the result that the machine would not pick up until the brush friction had removed the gold paint.

In another case a plain shunt-wound generator and an interpole generator were being operated in parallel. When the attendant wished to withdraw the interpole machine from parallel operation, he found it difficult to reduce its current to a low value. He had observed the practice of oiling commutators occasionally and at such times had noticed the current decrease on the machine. Being in the habit of applying the results of his observations, he adopted the practice of oiling the commutator of the interpole generator whenever he wished to take it out of service. The result was that the commutator absorbed so much oil that it eventually broke down.

Kingsford Double-Flow Pump

Among the line of Kingsford centrifugal pumps is that known as the double-flow type, Fig. 1, which in the illustration is motor driven. It is manufactured by the Kingsford Foundry & Machine Works, Oswego, N. Y.

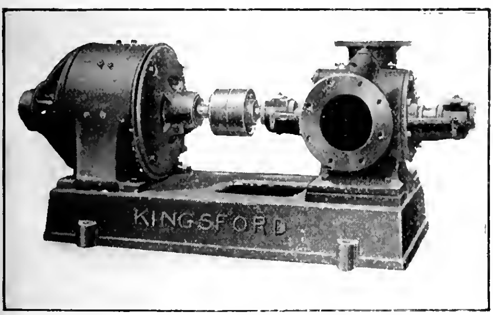


Fig. 1. Kingsford Double-Flow Pump

A sectional view of the pump is shown in Fig. 2. In this design the water-ways are liberal, the stuffing-boxes are of ample depth and the span between the oil-ring bearings is small. As the water seals are internal, the leakage is collected in the bearing buckets, and from there piped into a common waste-pipe.

The pump is so designed that with one head removed and the setscrews in the coupling loosened, the shaft and impeller may be removed from the casing without disturbing the suction or the discharge pipe connections. As the joints between the heads and shell are metal to metal, set gaskets are eliminated and alignment is insured. The impellers are made of single castings integral with the balance ring, which under ordinary conditions will wear until the impeller requires renewing. Fig. 3 shows an impeller with staggered veins; this design is used in pumps of large capacity.

Theoretically, the double-suction pump is hydraulically balanced and free from end-thrust, but in practice unequal leakage through packing fissures, inaccuracies in casting or unequal wear, supplemented by lodgment of foreign matter, all tend to disturb the theoretical balance, and the result is that end-thrust is present. In this design of pump this difficulty is overcome by automatic water balance, with which it is claimed neither wear nor foreign matter will disturb the equilibrium of the impeller. Therefore, stationary and positive thrust bearings are eliminated.

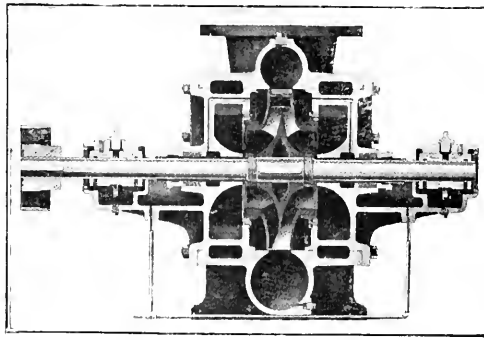

Fig. 2. Sectional View of the Kingsford Double-Flow Pump

Leakage from the pressure to the suction side of the impeller is reduced to a minimum by bronze packing rings. They are attached to the heads and in connection with rotating rings on the impeller form part of the automatic water-balance device.

Although the shells or main casings are made split horizontally, when conditions warrant, the pump is generally made with the shell of a single casting with integral sections and discharge openings. The volute surrounding the impeller permits of omitting diffusion veins for low and moderate heads. The design of this pump makes it possible to locate suction and discharge openings at various positions, as for instance a pump with a horizontal or vertical discharge is sometimes found convenient, and frequently the suction and discharge openings are desired on the same side.

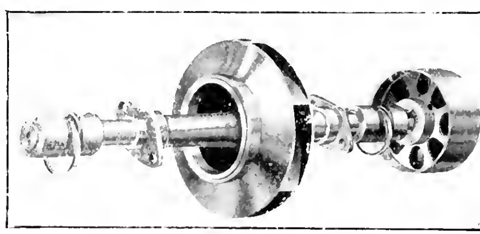

Fig. 3. Pump Shaft and Impeller

The head and bearing housings, secured to the main casting by studs, come metal to metal, and a water-tight joint is secured by a rubber cord placed in a triangular-shaped space formed in joining the heads and shell. The head forms a part of the suction chamber and guides the water into the impeller opening.

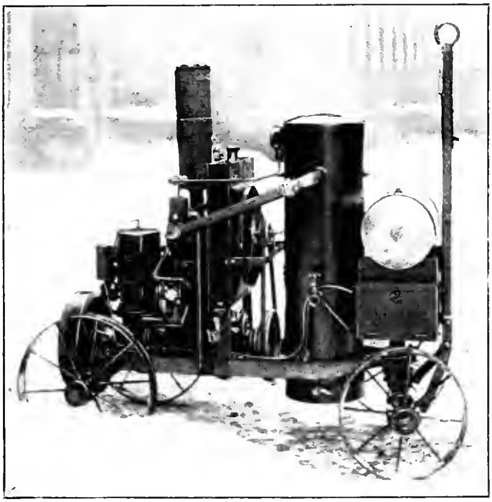
Ordinarily, the pump shaft is of machinery steel, made exceptionally large and stiff to prevent bending and to carry the impeller without vibration. When liquids which affect iron and steel are to be pumped, the shaft is covered by a sleeve of composition metal. This sleeve is provided with threaded ends and fits snugly on the shaft. It is easily removed by a special kind of wrench

In other than belt-driven pumps, a flexible coupling is used between the pumps and prime mover which allows for any slight inaccuracies in alignment. This coupling consists of cast-iron halves, one of which is fitted with steel bolts extending into corresponding holes in the other coupling half, the driving force being transmitted through the medium of rubber cushions mounted on the sleeves.

Imperial Portable Air Compressor

The small portable gasoline-engine-driven air compressor, illustrated herewith, has been developed by the Ingersoll-Rand Co., 11 Broadway, New York City.

The compressor is self-contained and is operated by a simple single-cylinder gasoline engine coupled directly to the compressor, both pistons working on the same



PORTABLE AIR COMPRESSOR

crank-shaft. The engine is of the single-acting, two-cycle type. This standard air compressor has a capacity of 45 cu.ft. per min. at a pressure of 90 lb., and is fitted with an air unloader. The engine speed is controlled by a centrifugal governor.

Cooling is provided for by a gear-driven pump and an automobile-type radiator with large tank capacity, serving both the compressor and the engine. The radiator is assisted by a large fan.

An air receiver tested to 300 lb. water pressure and fitted with a safety valve, pressure gage, the necessary piping, outlets, etc., is hung at one end of the frame and a 15-gal. capacity gasoline tank is supported on a large tool box. The outfit complete weighs 1600 lb., and is designed for hand transportation, but it can be fitted with tongue and singletrees if desired.

Efficiency Test on a Large Alternator

BY J. H. MCDOUGAL

Some time ago the writer had occasion to test a large alternator to determine its efficiency and segregate the losses. The plant was situated in the mountains, at a very inaccessible point; on which account, together with the fact that the test had to be made on short notice, it was necessary to depart from the common methods of testing.

The machine was a three-phase, 2300-volt, 60-cycle, 5500-kw. alternator direct-connected to two tangential waterwheels and operated in parallel with a number of other plants. The waterwheels were equipped with needle nozzles, the needles being operated by hand and the governing done by deflecting the nozzles. One governor controlled both nozzles.

In order to improve the accuracy of the test, two current transformers were installed of such a size that the losses of the machine, run as a motor, would give full-scale deflection on the indicating wattmeters. The regular two-wattmeter method of measuring three-phase power was used. Both nozzles were disconnected from the governor. It was also deemed advisable to install short-circuiting switches on the current transformers, as in synchronizing practically full load was sometimes thrown on the machine, which it was feared would burn up the small-capacity current transformers. As no regular short-circuiting switches were available, two blades of an old 250-volt quick-break switch were mounted on separate boards and served very well.

In making the test one nozzle, No. 1, was completely closed, and the other, No. 2, was gradually opened until the machine with its field circuit open was brought up to normal speed. After noting the position of the handwheel and the number of turns, the nozzle on this wheel was closed. Nozzle No. 1 was then opened and the machine brought up to speed and synchronized with the system. By adjusting this nozzle the load was brought to zero. Nozzle No. 2 was now opened to the point where it stood in the first part of the test and the amount of power furnished to the system was noted. It will be seen that this power plus that lost in the armature by resistance will equal the power consumed by friction and windage. This is evident, as the water that was used to deliver this power was equal to that used in overcoming friction and windage in bringing the machine up to speed. A very small error would be introduced due to neglecting the load losses, but as this would be but a fraction of one per cent., it may be neglected.

In order to determine the core loss, nozzle No. 1 was closed and No. 2 was used to bring the machine up to speed, and the field current was brought up to the normal full-load running point. The position of nozzle No. 2 was noted and it was then closed. Nozzle No. 1 was now opened and the machine brought up to speed and synchronized. After bringing the load to zero, nozzle No. 2 was opened to its position at the beginning of the core-loss test and the amount of power delivered to the system noted. This power plus the resistance loss in the armature minus the friction and windage losses gave the core loss.

To check this last reading, all water was taken off the wheels and the generator allowed to run as a motor. This reading checked very closely, although to get satisfactory readings, it was necessary to somewhat change the excitation, which of course changed the core loss to a slight extent.

In the matter of load losses, the recommendations contained in the Standardization Rules of the American Institute of Electrical Engineers were followed. One-third of the short-circuit core loss was, as an approximation and in the absence of more accurate information, assumed as the load loss.

The machine was short-circuited and brought up to speed by nozzle No. 2, and the field current increased until full-load current flowed in the armature windings. The short-circuit was then removed and nozzle No. 2 closed. The machine was synchronized by nozzle No. 1, and No. 2 was opened to the point at which it stood at the beginning of the load-loss test, and the amount of power delivered to the line was noted. The core loss for the excitation used on short-circuit was determined as for the full-load voltage. Therefore, the power shown in the load-loss test plus the armature resistance loss, minus the friction and core loss at the excitation used, divided by three, gave the core loss as nearly as it could be determined.

The armature resistance was measured with an ammeter and a low-reading voltmeter. Thus the armature resistance losses could be calculated. The field resistance was also measured and full-load excitation noted so that the resistance losses in the field could be computed. These completed the list of losses and the efficiency could therefore be computed by dividing the output by the output plus losses. The mechanical losses of the waterwheels were, of course, included in the mechanical losses obtained, but as the guarantee included these, no effort was made to segregate them.

"World's Best" Feed-Water Regulator

The "World's Best" automatic feed-water regulator, manufactured by the McDonough Automatic Regulator Co., Detroit, Mich., is of the thermostatically controlled type. The main purpose of its design is not only to secure a continuous feed, but a positive automatic control of a continuous feed to vary with the boiler load and to maintain a water level within limits best suited for constant maximum boiler capacity, efficiency and uniformity of operating conditions.

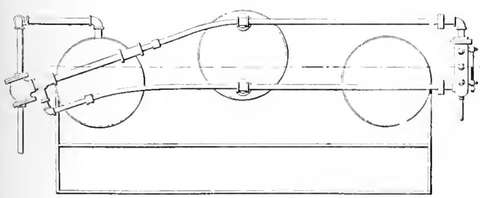


Fig. 1. Position of Regulator When Connected to a Boiler

This regulator, Fig. 2, maintains a continuous feed proportional to the evaporation and for light and uniformly varying loads a constant water level. For sudden increase in load and the resulting rapid drop in the water level, the regulator valve does not open suddenly to admit a large quantity of water into the boiler, but there is a time element in the expansion of the tubes operating the valve which uniformly increases the feed, permitting the immediate furnace heat to be used for evaporating and not for heating cold feed water.

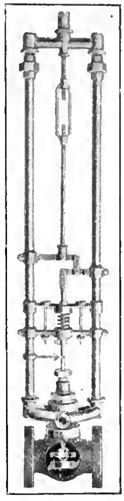

Fig. 2. Regulator

This regulator consists of a special feed valve, two headers and two expansion tubes connected in parallel through a rigid linkage to the feed-valve stem. The use of two tubes doubles the power of expansion and contraction, and the levers transmit the motion to the feed valve in a ratio of 5 to 1. A turnbuckle and pointer indicator permit of accurate adjustment of the valve, and the pointer indicator shows the position of the valve while the regulator is in operation.

The regulator is installed in an inclined position, Fig. 1, wholly supported by the feed piping with the connections made to the water column, as shown. In operation, the lower ends of the tubes are filled with water and the upper with steam. As the water falls or rises in the boiler, it correspondingly falls or rises in the regulator tubes, presenting a greater or lesser area of the tube surface to the steam, causing them to expand or contract accordingly. The inclined position of the regulator gives the greatest variation in exposed tube surface for a given variation in water level and the greatest sensitiveness to variations in load.

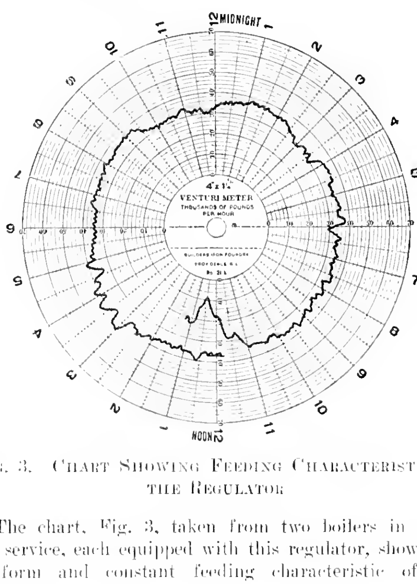

Fig. 3. Chart Showing Feeding Characteristic of the Regulator

The chart, Fig. 3, taken from two boilers in regular service, each equipped with this regulator, shows the uniform and constant feeding characteristic of the device.

Pipes for Steam Engines

By Frederick W. Salmon

SYNOPSIS—In the literature on the proper size of steam and exhaust pipes for steam engines there is little in practical shape for ready use; therefore, data of sizes of a large number of successful plants have been plotted and tables given of values obtained by plotting smooth curves representing fair averages of good practice.

There are two methods of determining pipe sizes—one is by a long and elaborate computation of pipe friction, with the use of coefficients based on a limited number of experiments; the other is what some people would call a rule-of-thumb, in which the pipe size is determined as a fraction of the cylinder diameter. The first of these is commonly based on a steam velocity in feet per minute or per second.

For the modern steam plant in a factory or the municipal plant of a small city, designed according to conventional practice and having a fair grade of reciprocating engines set close to the boilers, it is much more convenient to calculate pipe sizes from the gross pounds of steam per hour required by the engine at the best rated load and make use of a formula based on the most suitable pipe size as established by several decades of good commercial practice.

The old rule-of-thumb would answer but for the fact that during the past few years some of the engine builders have increased the rated speeds of their engines—and therefore the rated horsepower and steam consumption—without apparently increasing the pipe sizes, and in some cases wire drawing results; whereas, if these simple formulas were used for the pounds per hour and the pipe sizes chosen accordingly, the wire drawing would not be higher than that heretofore established as good practice.

The curves and constants given in the chart are from the mean curves found by plotting the results of data obtained of sizes of engine pipes used in a large number of successful power plants. The maximum and minimum curves were quite irregular, but they appeared to vary up to about 10 per cent. of the mean values.

As illustrating the use of the table, take the case of a 14x36-in. noncondensing Corliss engine under 100-lb. steam pressure by gage, and running 100 r.p.m., which is rated by the builders at about 135 i.hp. at 1/4 cutoff (the rating of different builders varies somewhat), and assume such an engine at that load to take 26 lb. of steam per hour, which is about what many engine builders guarantee in their contracts for such a size under these conditions. There is then 135 i.hp. × 26 lb., or about 3500 lb. of steam per hour, and looking on the chart the nearest sizes are found to be 4-in. steam pipe and 5-in. exhaust, which sizes are as small as one should like to make them for ordinary conditions of plant arrangement.

In special cases of very large plants or long steam mains, the drop in pressure from pipe friction should be calculated. Perhaps that method of choosing pipe sizes should be followed, but the table will be found useful for a large percentage of the cases arising in practice.

Capacity and Power of Hydraulic Pumps

By R. A. Lachmann

The accompanying tables provide a ready means of ascertaining the power and capacity of a plunger pump. Although computed for single-acting pumps with a slip of 5 per cent., and working against a pressure of 1000 lb. per sq.in., they may, by a few simple calculations, be made to apply to any direct-acting pump. A couple of examples will make this clear.

TABLE 1—CAPACITY AND POWER OF SMALL SINGLE-ACTING HYDRAULIC PUMPS

No. of Plungers	Diameter of Plungers, Inches	Stroke in Inches	*Capacity in Cu.In. per Min.	*Capacity in Gal. per Min.	Revolutions per Min.	Speed of Plunger in Ft. per Min.	Pressure, Lb. per Sq.In.	†Horsepower Required to Run Pump

1¾		1373	5.94				4.35

*Figures given are 5% less than the theoretical capacity, on account of loss due to slippage.
†Figures given are 25% more than the theoretical horsepower, allowing for friction.

Assume a two-plunger pump with ¾-in. plungers, a 2½-in. stroke (the movement of the plunger in one direction) and a speed of 100 r.p.m. when working against a pressure of 1000 lb. per sq.in. Under these conditions the capacity and necessary horsepower can be read directly from Table 1.

First, look for 2½ in. under the heading "stroke;" then the number 2 in the column headed "number of plungers," and opposite this for the plunger diameter of ¾ in. Following this line to the right, there will be found the desired information under the respective columns: that is, the capacity in cubic inches per minute will be 210, the capacity in gallons per minute will be 0.9, and the horsepower required to drive the pump will be 0.66. A 1-hp. motor would probably be selected.

TABLE 3—CAPACITY AND POWER OF LARGE SINGLE-ACTING HYDRAULIC PUMPS, SINGLE PLUNGER—1⅞-IN. TO 4½-IN. DIAMETER

Diameter of Plunger, Inches	Stroke in Inches	*Capacity in Cu.In. per Min.	*Capacity in Gal. per Min.	Revolutions per Min.	Speed of Plunger in Ft. per Min.	Pressure, Lb. per Sq.In.	†Horsepower Required to Run Pump

*Figures given are 5% less than the theoretical capacity, on account of loss due to slippage.
†Figures given are 25% more than the theoretical horsepower, allowing for friction.

Now assume the following conditions: Stroke, 2½ in.; diameter of plungers, ¾ in.; number of plungers, 4; speed, 150 r.p.m.; pressure, 1700 lb. per sq.in. Find the capacity and the horsepower required.

As the quantities and sizes involved are directly proportional to those in the table, first double the quantities given for two ¾-in. plungers; this gives the first multiplier, namely 2. Then since 150 r.p.m. is 1.5 times 100 r.p.m., shown in the table, the second multiplier will be 1.5. The third multiplier is 1.7, since 1700 lb. is 1.7 times 1000 lb. The product of these three multipliers is:

$$2 \times 1.5 \times 1.7 = 5.1$$

which is the common multiplier. Then the capacity is

$$5.1 \times 210 \textit{ cu.in.} = 1071 \textit{ cu.in. per min.}$$

$$5.1 \times 0.9 \textit{ gal.} = 4.59 \textit{ gal. per. min.}$$

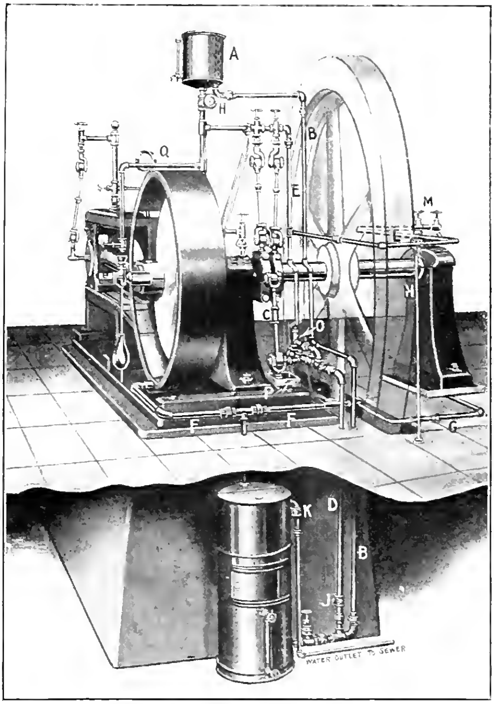
and

$$5.1 \times 0.66 \textit{ hp.} = 3.366 \textit{ hp.}$$

or about 3½ hp. would be required.

Nugent Pressure Return Oiling System

From time to time in these columns the various Nugent lubricating devices, such as the pendulum crankpin oiler, the antipacked telescopic oiler for crossheads and eccentrics and the illuminated oil filter with the automatic water separator, have been described. For about a year, however, the company has been combining these various devices into a complete pressure system for individual units, such as is shown in the accompanying illustration.



Nugent Oiling System

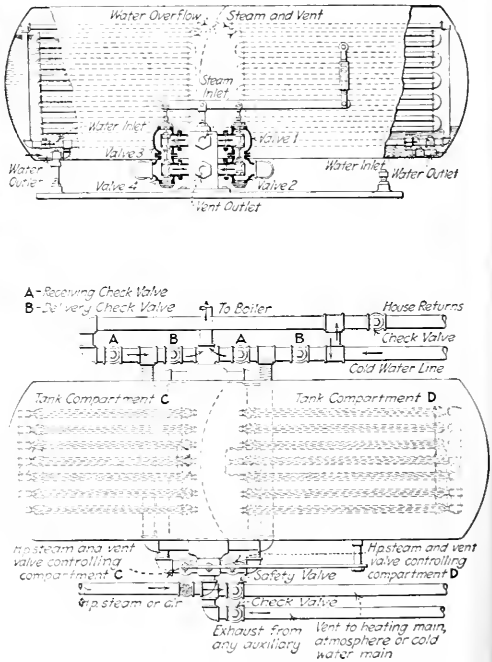
A simple plunger pump actuated by the engine eccentric draws the oil through the pipe *D* from the storage space of the filter. The oil is forced to the system on the engine and to the reservoir *A*, which is provided with a gage glass and an overflow leading from the top of the tank. The oil flows back to the filter through the pipe *B*. By manipulating the valve *H* any pressure up to 25 lb. can be maintained on the system. A check valve *J* prevents oil returning to the filter through the suction. Open-sight feeds supply the oil to the various points of service, and drains *F*, *F* and *G* from the crankpit, eccentric pan and outboard pillow block return the oil to the water separator and oil filter shown under the floor. If any of the openings in the sight-feeds should become clogged, it is an easy matter to force up the pressure to the limit previously given and blow out the obstacle. The safety valve *O*, set at 25 lb., protects the system.

Pipes *L* and *M* convey the oil to the outboard bearing, *N* is a support for pipe *L*, *K* is a sight-feed in the water-outlet pipe leading to the sewer. *Q* is a gage to show the pressure on the system, and *P* is a drip pan for the oil pump. The system is thus complete in itself and is actuated by the unit it serves. If any trouble should develop it is localized to the one unit. Additional information may be obtained from W. W. Nugent & Co., Chicago, Ill.

Farnsworth Tilting Traps

A combined feed-water trap, heater and weigher is being marketed by the F. C. Farnsworth Co., Bush Terminal, Brooklyn, N. Y. The illustration shows a section of this tilting type of apparatus.

The tank has two compartments which fill and empty alternately. Instead of trunnions, flexible copper hose is used. Water is carried to the top of each compartment and distributed over the copper heating coil through a perforated pipe. First, the coil is heated by exhaust steam fed in through the vent valve. When the compartment fills with water its weight tilts the tank, interchanging the valve, venting the opposite side and simultaneously admitting steam at boiler pressure in the coil and



The Farnsworth Tilting Trap

out onto the surface of the water to force the latter into the boiler.

The trap may be furnished with or without the heater. A counter may be made to register the number of oscillations and the weight of water delivered calculated from the reading.

Traps acting on the same principle, but with modification of the inlets, outlets and partitions, are adapted to services such as those of a blowoff or condensate weighing tank and trap, and of sewage or water lifts using steam or compressed air.

Special Reconstruction Jobs*

By Osborn Monnett†

SYNOPSIS—Limited headroom and floor space call for unusual designs of setting not recommended for standard practice. Some interesting cases are presented.

Installing new boilers in old office buildings offers one of the most difficult problems the designer will encounter if smokelessness is one of the prime considerations. Fig. 1 shows how it was done in a plant requiring additional boiler capacity with limited floor space and headroom in which to install it. It was necessary to provide 100 boiler-hp. in a floor space of 7 ft. 5 in. by 8 ft. 5 in. and a headroom of 10 ft. and to find room for a smokeless setting. The solution was a Worthington boiler of spe-

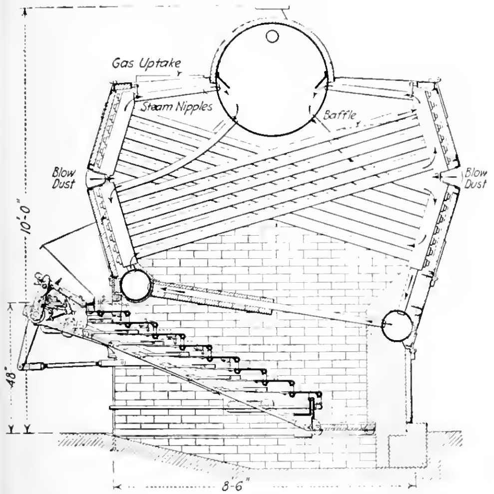


Fig. 1. Worthington Boiler, 100 Hp., and Moore Stoker

cial design in which the rear mud drum extended some 18 in. below the normal position and connected with the front mud drum by 2½-in. tubes, spaced 4 in. on centers. It gave 48 in. of free space between the bottom of the front mud drum and the floor line and provided opportunity for a tile roof on the tubes connecting the mud drums. Strong ignition for a Moore stoker installed directly under the boiler was thus obtained. This unit has met every requirement of floor space and headroom and is running smokelessly on loads up to 40 per cent. above rating. The same combination in almost any capacity can be supplied by simply adding to the width of the setting without increasing the headroom or floor space in a lengthwise direction.

Fig. 2 is another application of the Worthington boiler to limited floor space. The floor space occupied by the boiler is 10 ft. 2 in. wide by 11 ft. long, while the stoker adds 3 ft. 3 in. to the length. The headroom to the steam nozzle of the boiler is 16 ft. This unit is of 300 boiler-hp. capacity. The ignition arch is 6 ft. long, with a low-pressure water-back furnishing a permanent support for the built-up bridge-wall. Between the two, good throat action is obtained, insuring complete combustion and good economy. The arch is supported by another low-

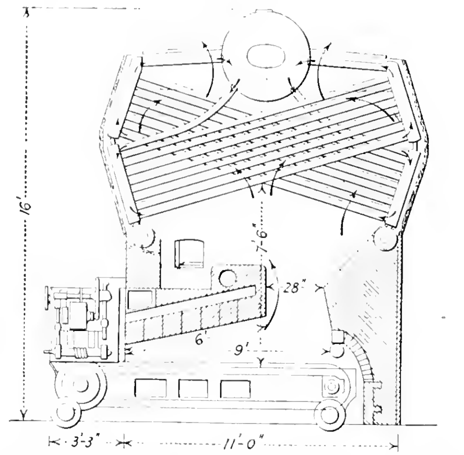

Fig. 2. A 300-Hp. Worthington Boiler and Chain Grate on Limited Floor Space

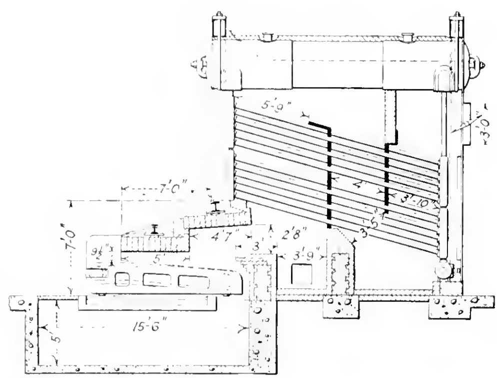

Fig. 3. A 390-Hp. B. & W. Boiler and Laclede-Christy Chain Grate; 7-Ft. Headroom and 7-Ft. Extension

pressure water-back and provision is made for ventilation over the arch to insure satisfactory life.

The horizontal water-tube boiler, vertically baffled, equipped with a chain grate, short ignition arch and short flame travel, is frequently encountered. This type of setting is a constant smoker. It is true that the smoke may not at all times be dense enough to be a violation, but there is hardly a moment in the twenty-four hours during which No. 1 or No. 2 smoke on the Ringelmann chart

†Smoke inspector, City of Chicago.

is not emitted. This is due to the volatile matter being chilled by the nest of tubes before combustion can be completed. Frequently the setting is erected with only 6-ft. space from the floor line to the front header, so that considerable remodeling is necessary before good results may be expected.

The best method of cleaning up these settings is by raising the boiler or lowering the floor, and putting in horizontal baffles. A good illustration of this is given in Figs. 1 and 3 on pages 532-3 of the Oct. 13 issue. Sometimes the boiler is set high enough so that only the combustion-chamber floor need be lowered when the horizontal baffle is put in. In any case, liberal space must be provided in the combustion chamber to avoid "bottling" the hea , and therefore burning up the arches and tiling. Occasionally, when floor space is to be had in front of the boiler, it has been possible to pull out the stoker and get enough flame travel to clean up the setting.

A case of this kind, Fig. 3, consists of a B. & W. boiler with a Laclede-Christy chain grate in 7 ft. of headroom, built out 7 ft. from the gate to the flue caps and having a 5-ft. flat ignition arch, followed with a 4-ft. 7-in. secondary arch. This unit operates smokelessly and may be considered satisfactory up to rated capacity. Of course, such a setting cannot be considered good for capacities above rating, but it can be taken as a reconstruction possibility where conditions permit.

Results of Changes in Boiler Furnace

By Morgan B. Smith*

SYNOPSIS—A specific instance where the efficiency of two 500-hp. Stirling boilers, each fitted with two Roney stokers, was greatly increased by enlarging the combustion chamber or furnace.

At the instance of E. J. Burdick, superintendent of power, Detroit United Railway Co., the writer in conjunction with F. L. Fisher, Chief Engineer of the Rochester, Mich., power station, carried out at the company's laboratory an extensive investigation of the rate at which combustion progresses in Stirling boilers, each having two Roney stokers.

This investigation showed that completion of combustion is delayed at a point too far back in the gas travel when such boilers are fitted with Roney stokers and restricted combustion chambers, as is the case when each stoker is housed in a separate furnace and long combustion arches are used. Combustion was never complete short of the bottom of the second pass and at times not even half-way up the last or third pass. This was manifestly bad practice, resulting in the production of dense smoke and relatively low efficiency.

It is obvious that the cure for this condition lay in so designing the furnaces as to assure quicker completion of combustion before the gases turned downward into the second pass. It was believed that less restriction of the gases would give this result and that less smoke would be produced; higher efficiency ought also to be attained. With a less restricted combustion chamber the volatile constituents in the fuel would be distilled less rapidly, owing to lower furnace temperatures, and less smoke would result as these products would have time for complete ignition before impinging on the relatively cool tube surfaces.

We determined to gradually cut away the long arches and note the results after prolonged operation. In this we were disappointed, for the division wall in one of these boiler furnaces, already weakened, gave way and let both arches down. There was nothing to do but to clear away the mass of firebrick and get the boiler back on the line as soon as possible. Advantage was taken of this new state of affairs by making a thorough study of the boiler operation without arches, comparing this to the old operation with the arched furnaces.

The division wall was trimmed down to follow the line of the grates (inclined) and made 6 in. higher. We now had one large high furnace with no division wall to break up the flow of the furnace gases. We found that we must protect the front wall of the setting, so we extended the coking arch 10 in. inside this wall, battering it back against the wall, at the same time protecting the structural-steel frame at the front of the boiler. This gave 22 in. of coking arch, the only arch in the furnace. We also increased the height of the first or front baffle one foot, giving 13 sq.ft. more baffling surface, a longer gas-travel, and a reduction of the breeching temperature.

These boilers have been in operation six months and as a result of the efficiency attained we are similarly modifying all of these furnaces. It is expected to have a Stirling boiler fitted with Murphy stokers in satisfactory operation without any arch in a short time.

In all our power stations we reduce the results to a basis of kilowatt-hours obtained per million heat units supplied to the furnaces. The data given below show the results obtained since taking out the long arches as against results with long arches—i.e., large, unrestricted combustion spaces against small, confined spaces.

COMPARATIVE OPERATION

SHOWING THE OLD AND THE NEW ARCHES

The turbine water-rate is approximately 14 lb. under operating conditions. To handle the load requires that the two boilers shall run at an average of from 160 to 175 per cent. of rating.

Points noted in the operation of these boilers with modified furnaces are:

1. Virtually no smoke is produced, a mere haze being visible most of the time. No soot of a black, oily nature is made, the accumulation on the tubes and around the clean-out doors being more like fire-clay than soot.

2. More even heat absorption in the three banks of tubes is attained. The front bank is greatly relieved of the high heating effect of the gases as they travel over the old arch. Both the second and third banks of tubes do more work. The front bank will show longer life than with the arched construction.

3. Deterioration of the grates is less, due to lower furnace temperatures.

4. Better quality flue gases are obtained, no CO being found until the CO_2 reaches 16 per cent. The average CO_2 figures given are somewhat lower than the true maximum because of the loss of from 1 to 1.5 per cent CO_2 in air of infiltration through the boiler settings.

5. Less coal and ashes are handled, also less soot.

6. Cost of firebrick arches is eliminated.

7. Peak loads are carried more easily because we can burn more coal in a given time than before.

8. The water level in the boilers does not surge as before because the front bank of tubes is heated almost uniformly throughout its length.

9. There seems to be no need of a fourth pass in the gas travel, although this might improve the efficiency if it did not unduly cut down the draft available (natural draft; chimney 200x10 ft.).

10. Combustion is now completed before the gases turn downward into the second pass, except when the boiler is being pushed above 175 per cent. of rating, at which times combustion is carried further into the passes, being completed at the middle of the second pass. As these boilers seldom exceed 160 per cent. of rating, the object of these experiments may be said to have been accomplished. The slower rate of distillation of the volatile matter in the fuel together with better mixing conditions (volatile matter with oxygen) is the secret of the elimination of smoke.

We believe that these boilers should be set 1 ft. higher than at present, in which case even better results should be attained with the given fuel. Choice of fuel has much to do with furnace and boiler-setting design; too little attention is given to such items. With higher boiler settings the brickwork is increased and the danger of leaky settings is augmented, but with settings properly incased this should not cause alarm.

Tension on Brushes should be set by the aid of a small spring balance, so that all the brushes will bear with an equal pressure. This refers especially to high-speed machines; the pressure will vary from about 8 to 10 oz. per sq.in. of brush surface in slow-speed machines up to 1¼ lb. in the high-speed types.

Concrete Filling for Engine Beds and Machine Frames

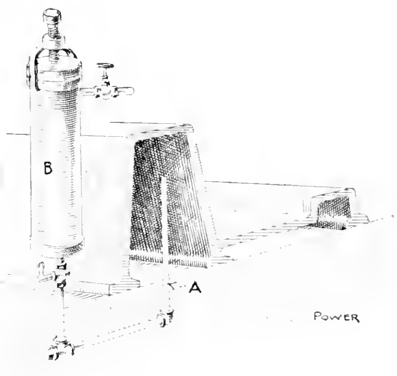
By F. W. Salmon

Should the bed of a large engine or generator be filled solid with concrete? A concrete filling will tend to absorb the vibration, reduce the noise from pounding and give the bedplate a larger and better bearing upon the foundation.

I have had bedplates filled with concrete, and it has always proved advantageous. Some of these have been filled before erection by turning the bedplate bottom-side up and filling the space with a mixture of one part of portland cement to three or four of clean sharp sand, and allowing it to set.

If the engine or machine is already erected and loose on the foundation, or acts like a piano sounding-board, it can be easily filled in the manner shown in the illustration. A small air vent, ¼-in. pipe size, is tapped at the highest point of each compartment or space. The old grouting is channeled out and pipe *A* put in and well grouted in place with equal parts of portland cement and sand.

The charging cylinder *B* can then be screwed on and connected to a supply of compressed air. Grout is put in, the cylinder quickly closed, and a light pressure of air—say 10 to 30 lb.—is turned on to drive the grout into the space to be filled. Do not allow any grout to stand in the pipes or the cylinder, as it will set. Blow the grout out clean each time as soon after filling as possible and at night take down cylinder *B* and wash it clean with water.



Means of Filling Hollow Bedplates

In many cases this work is done gradually, a little put in one day, more the next, and so on. The pipe *A* should extend nearly to the top of the inside of the frame in every case, so that the grouting cannot run back into it, while refilling the cylinder *B*.

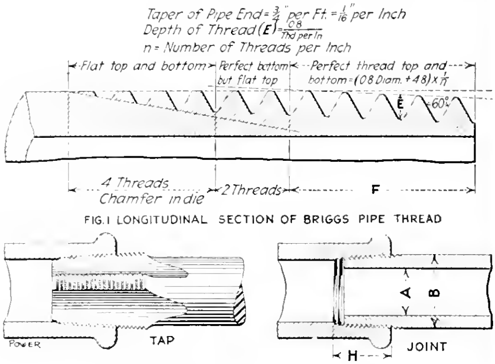
In a few cases, I have had a little air pressure kept on the top of the concrete during the time it was setting, thus insuring the concrete being in good contact with the inside of the bedplate at all points, but care must be exercised to avoid springing the bedplate.

Sand, of course, may be used after a small layer of concrete has been introduced and has hardened, but solid concrete is more desirable in every case as it reduces the vibration and noise much better than sand and gives the bed greater support.

My experience is that filling an engine or heavy machine bedplate with concrete costs but little and is a good thing to do.

Standard Pipe Threads

The illustration under the above heading in the issue of Nov. 3, p. 646, is not correct in that threads *F* should



Briggs' Standard Pipe Thread

be perfect at top and bottom to agree with the text, and the decimal point is missing in one formula. The new illustration herewith is corrected in these particulars.

The Sediment in a Boiler will accumulate in the portion of the bottom near to the region of the bridge-wall in the furnace; and if you have no such thing as a bridge-wall it will accumulate where the fire is hottest. This is a result of heat movements that send the hot water upward from highly heated spots while the cooler water surrounding sweeps in below, carrying with it sediment that builds a little mound, if there is some one spot that is materially hotter than the rest of the surface exposed to the fire.

In a Refrigerating Plant, if one wishes to obtain the best results, the machinery should be run regularly and evenly; otherwise things will go wrong. When excessive quantities of liquid come back to the compressor, the compressor piston-rod stuffing-box will start to leak. It is bad practice to tighten up on the stuffing-box glands because the rod contracts when cold, but when the frost disappears it becomes hot and expands again so that the leak will disappear; otherwise the packing will burn when the rod expands. When the frost comes back to the machine on account of low steam pressure, which causes the machine to slow down, the best thing to do is to shut the main liquid valve for a while or stop the machine, after having pumped the low-pressure side down to zero pressure, until the steam pressure rises again.

Often, when the frost comes from one room very strongly, it may back up into all the other returns and then it is hard to tell by looking at them which is the one that is doing the damage, or if there are several returns giving trouble, which one freezes back the most. By wetting the finger tips and touching each return, the one that sticks to the fingers most readily is the one that should be turned off some. It is good practice to have marks of some kind on each expansion valve so placed that one can tell exactly how much was turned on or off.

If a refrigerating machine is to be stopped for a little while only, and the valves in the compressors are in good order, the discharge stop valves may be left open, but never the suction stop valve. This should be an engine-room rule.

Editorials

Driving Boilers and Burning Tubes

The author of the "Mechanical Engineers' Pocketbook" favors our correspondence columns with some observations upon our recent remark that "scale or oil which will cause no serious overheating of the metal when three pounds are evaporated per hour per square foot of heating surface is very likely to make trouble when the evaporation goes up to six or ten pounds." He points out that with an average evaporation of three pounds per square foot per hour there may be times, as just before firing a fresh supply of coal, when the rate of transmission of heat may be equivalent to an evaporation greatly in excess of this figure. That is, one must not assume, because his boiler averages three pounds per square foot per hour, that it may not be working some of the time at the higher and more dangerous rate. His observation that the temperature of the fire is almost independent of the rate of driving seems to be irrelevant if it is the driving of the fire which is meant, but it is difficult to see, notwithstanding the reference to driving the boiler which follows shortly, how a hotter fire can be maintained without a corresponding increase in the rate of evaporation.

New York City's Proposed License Bill

It seems to be a never-ending duty of ours to remind engineers and legislators that some folks in this land are guaranteed a right to a livelihood by the Constitution of the United States, if not by the exercise of that sense of justice which civilized beings should manifest. If it were not so easy for those of the medical, pharmaceutical and other professions to kill the children of men, their possible victims would not require that they be certified by a license of competency. If steam boilers and engines were not veritable infernal machines in the hands of the unskilled, if they had not caused an appalling loss of life and property, the public would not seek to protect itself by inquiring into the correctness of their structure or the fitness of their operators.

Safety is the object, the end, the all, of such laws. But unfortunately, some engineers want to corner their local markets for engineers and to do it under the guise of public safety. They want to say to their fellow engineers: "Here, this territory is ours. No matter how badly you need a job, or how good the job is that you are after, or how competent you are to fill it, you cannot have it because you have not lived here one, three or a dozen years." It seems almost incredible that men should attempt to legalize and statutize their selfishness, yet they do. The laws of Buffalo and New York City are well known examples, but any law that denies the right of aliens to follow their trade or profession in any state, on the same footing as any citizen of that state, is unconstitutional and would be nullified the first time it was taken to court. Some engineers of New York City do not know this and have proposed a bill for the creation of a separate bureau in the department of licenses for the inspection of certain steam boilers and the examination and licensing of engineers and firemen. First, they wish to create the offices of superintendent of inspection, two general inspectors, two examiners, nine boiler inspectors, and other subordinates, and make all jobs appointive by the commissioner of licenses. It is not deemed advisable to examine into the competency of these appointees.

Applicants must be subjected to a physical and practical test of their fitness. The practical part is all right, but the physical test is nonsense.

A man must be twenty-one years old to get a fireman's license. Candidly now, how many of those who participated in the making of this bill were firing boilers before they were twenty-one? And do those who were believe now that they were not men enough for their jobs? Certainly not. That section of the bill is also ridiculous.

Worst of all is the section which states that "No such applicant (engineer) shall receive a license as engineer unless he is able to keep accurate data of the cost of operation and maintenance of boilers and steam machinery."

Much as we urge engineers to acquire such ability, we would not include its possession as a license-law requirement, for law is for safety, not to confer special privileges on certain classes, and safety does not depend on the knowledge above mentioned. Some men can operate plants safely who would make a poor showing before examiners as power-plant economists.

Surely, the engineers of New York City will kill this bill before its gets into Albany. Is it any wonder New York State cannot enact a state license law?

Specifying Unit Station Costs

In comparing the cost of generating plants it is always interesting to reduce the figures to the unit basis, but in many cases insufficient care is taken to specify just what units are in mind. In a typical instance the cost of an electric plant was found to vary from $45 to $125 per kilowatt, according to the selection of the factor divided into the total outlay in money. It is important in making such calculations to state whether one means cost per kilowatt of existing total rated capacity, cost on the basis of maximum sustained output for a protracted period of specified length, cost per kilowatt of plant completed to the ultimate capacity of the existing building, or whatever the factor of selection may be. Engineers are often a bit careless in this, with the result that figures do not always afford accurate deductions.

Sometimes, for example, a coal-handling equipment suitable for the proposed ultimate capacity of a given plant is provided long before all the engine or turbo units planned for have been installed. If the full cost of this equipment is included in the unit determination for the station on the basis of perhaps a half of the ultimate number of generators and boiler batteries, one gets a different result from that obtained by making an allowance for that portion of the coal-handling plant required by present service and making a note to that effect on the estimate sheet.

Similarly, when a few units are housed in a building large enough for a substantial increase in capacity, one gets a relatively high building charge if a cost determination is made on the basis of the existing generating units. Figures of this kind are instructive and well worth assembling, but where they are prepared for an installation not yet complete according to the full plans, the fact should be made known in presenting unit cost data, so that a reasonable allowance can be made by those to whom the data are submitted.

It is often needless to attempt to separate that part of the cost of buildings or auxiliary apparatus such as stacks and condensing water tunnels chargeable to present plant from the ultimate station capacity cost, for in very large stations the boiler batteries and main units cost so much more than the auxiliaries that a considerable variation in the outlay for the latter produces but a comparatively small change in the unit result. That is, a building with sufficient house room to accommodate four 15,000-kw. turbo units and their necessary boilers will probably not cost enough more for the fourth unit to render valueless figures of unit outlay based on the total building space, even where only three machines are at first put in.

To return to the starting point, one may figure unit cost on any basis he pleases, and with profit, but unless that basis is definitely specified along with the figures deduced, misinterpretations and wrong comparisons are likely to spring up and cause trouble all around.

Concerning Expense Accounts

On the rare occasions when operating engineers are sent on business trips, they should realize the importance of their expense accounts. The way in which such accounts are rendered makes or mars the engineer's business reputation, and probably will affect his future advancement. Artists, scientists and even practical engineers are popularly considered as constitutionally unbusinesslike, and the more one studies the reasons for personal advancement, the more convincing is the evidence that clear-cut thinking and writing, methodical ways of doing things and an appreciation of the monetary side of affairs are powerful factors in the advancement of technical men to positions of executive responsibility.

The expense account is practically as important in the impression it makes upon the employer or superior officer as is the report of the engineer's trip. A man may go to a distant city, obtain the desired data, embody it in a valuable report and return home feeling that he has "made good" at the task in hand, but unless he turns in an expense account which can be roughly checked or audited by the man who "O. K.'s" the bill, he misses a real opportunity. A slovenly penciled memorandum of funds expended or a carelessly compiled group of items which yield no definite information as to the cost of main outlays, like transportation, hotel fare, cab or horse hire, telephone and telegraph expenses or important incidental disbursements made necessary by the trip, does the engineer positive harm.

The "boss" may not think anything about the matter, and then, again, he may. He may say to himself some time, "Johnson has gone over to Erie and got just the figures I wanted; he has put them down in the way I like; that fellow's got a clear head and his expense account shows that he has some business horse sense besides knowing a lot about steam engines and generators. I'm going to keep my eye on him and see if I can't work him up to take some of these details off my mind, and maybe make him assistant superintendent some day." There is nothing impossible about such a train of thought as this, and while it does not run through the individual employer's mind often, it is mighty important when it does—to the fellow who is striving to get ahead.

Needless to say, the right kind of a man will be as careful about squandering his employer's money as his own. This does not mean stopping at the cheapest hotels, for a first-class concern will wish its representatives to travel in reasonable comfort.

As one of the auxiliary matters, the proper handling of which will contribute to the sum total of impressions which lead to good repute, the engineer's expense account when away from home deserves thoughtful consideration.

Just for Fun

Send us the story of any piece of rank stupidity on the part of a power-plant employee that to your mind beats those in "Some Original Ideas," page 81. Just at present the fellow who gilded the commutator holds the palm. We do not wish to give much space to accounts of foolishness, but a limited number of the best letters received will be used. They will amuse all and instruct some perhaps.

Engineers' Study Course

The section on Power-Plant Design concluded with last issue. Four individual lessons not classified as a section, as were most of the previous ones, will appear, beginning with this issue, and these will end the Study Course, for the present at least. These last four lessons will be: "The Conversion of Energy" (page 103), "The Efficiency of Heat Engines," "Heat-Engine Cycles," and "Steam-Engine Cycles."

Those who bind their volumes of POWER, or who desire an index to facilitate reference to the filed copies, can have such an index by simply signifying their desire to the Subscription Department of POWER. An index is printed upon the completion of each half year, and is furnished free to all who care to have it.

Out in Ohio the following is what they require in an engineer-janitor:

ENGINEER-JANITOR for large building; must be a man of good habits and willing to work, otherwise we cannot use you. State age, size of family, experience; give names and addresses of four responsible parties as references.

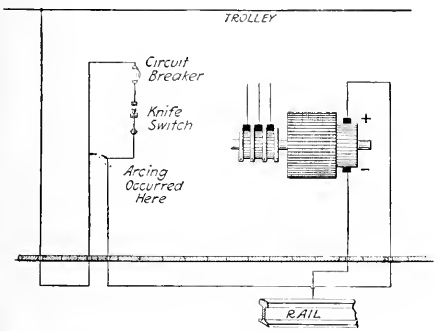
If this is a movement against race suicide we could suggest further qualifications with perhaps a little more emphasis on the "experience," for anyone in charge of a steam boiler has it in his power to reduce population.

Correspondence

Unusual Experience with Rotary Converter

During a severe electrical storm in northwestern Ohio an unusual phenomenon was produced by lightning on a rotary converter. The machine is part of a portable substation located in a box-car and which may be operated in parallel with the permanent substations on any desired section of the line.

No lightning protection was provided either on the 13,000-volt, alternating-current side or the 600-volt direct-current trolley side, the operator having instructions to shut down during lightning storms and pull all the switches.



Diagram, Showing Where Arcing Occurred

At the beginning of this particular storm, the operator pulled all the switches, consisting of the high-tension alternating-current switch, low-voltage starting and running alternating-current switches, the direct-current circuit-breaker and switches, the field breakup switch and the shunt-field switch.

Following an intense flash of lightning, the converter started to run, the direction of rotation being reversed, and the speed increasing at an enormous rate. The insulation on the wiring back of the switchboard was afire and produced a dense smoke which cut off a view of the leads and connections. As the machine had acquired such a high speed that it was likely to go to pieces, due to the centrifugal force on the armature, the operator telephoned the power station and ordered the power off the lines. This was immediately done, whereupon the converter came to rest, after a long period. The fire back of the switchboard was then put out.

An inspection of the rear of the switchboard revealed the fact that the lightning had struck the trolley at some point in the near vicinity and the heavy rush of current accompanying it had punctured the insulation and arced across two leads which were close together on the back of the switchboard. One of these leads was from the trolley to the direct-current busbar and the other was from the direct-current side of the converter to the bottom point of the direct-current switch. The trolley-to-rail current maintained this arc and flowed to the direct-current end of the converter which started as a series motor with no load. The sketch will make this clear. The only damage inflicted was upon the insulation at the rear of the switchboard, the converter not being injured in any way.

Simplifying Reports of Boiler Tests

Mr. Morrison's letter in the Nov. 10 issue certainly touches upon a matter that requires to be put into clearer meaning than is usual at present. To simplify boiler reports, and make them of value to both directors and himself, the writer employs the following form:

Actual weight of water evaporated per pound of fuel (name of fuel).
Pounds of water evaporated for one cent.
Total cost to evaporate 1000 lb. of water, including labor.

Underneath for the writer's own information are:

Average percentage of CO_2.
Average temperature of feed water.
Average temperature of gases to chimney.
B.t.u. value of coal.
Amount of ash for given weight of coal.

With the first three items the directors can understand easily what the boiler plant is doing, and the remaining figures give the engineer all the particulars he really wants to know. If there are any peculiarities observed during the test, these are added in a footnote.

E. R. Pearce.

Rochdale, Eng.

Suggested Use of Terms Vapor, Steam and Gas

The terms vapor, steam and gas as applied to the gas-like condition of water expanded by heat, although meaning the same thing, are, unfortunately, often used as though referring to things that differ in their properties. We read of steam pressure and vapor pressure; that water flashed into steam or vapor. Often in books the words vapor and steam are both used; perhaps to avoid the too frequent use of either word.

To one familiar with the definitions there is no mental effort required to connect the two with a single meaning, but to the beginners this practice is more or less confusing, and still more so by steam being sometimes called a gas.

I have recently asked a number of engineers what they understood by these terms. The majority had the correct idea, but some had a hazy impression of some difference. One said that he understood vapor to be that which was given off the surface of water at ordinary temperatures, or below 212 deg., and that steam was given off at above 212 deg. This man knew that the composition of both was the same as water, but thought the two terms were used as a convenience to distinguish the difference in temperature. He understood the term gas to mean superheated steam.

Now, if we must use the words vapor, steam and gas as applied to the expanded condition of water, it seems to me that the ideas of the engineer quoted would be more logical than mixing or using the terms interchangeably. We would then have vapor at temperatures below 212 deg., steam at above 212 deg. and gas as superheated steam.

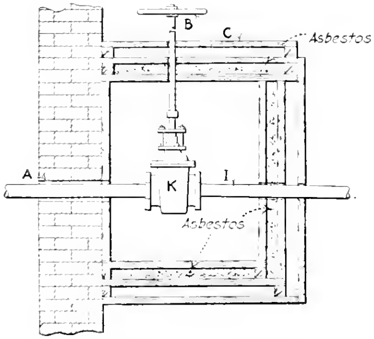
Kansas City, Mo.

Keeping Blowoff from Freezing

I overcame a difficulty similar to that described by A. T. Rowe, page 788, Dec. 1, at a place where the



Box around a Blowoff Valve

temperature often drops to 30 deg. below zero. I built a double-walled box around the blowoff valve and filled the space between the walls with asbestos. The cover was inclined to allow the rain or snow to run off and was removable to give access to the valve when necessary.

A handle *B* is used to open and close the blowoff valve *K* without removing the cover. A space where the pipe passes through the wall at *A* admits a small amount of heat to the box. The pipe *I* has a slight slant so that no water can remain in it, and it has never frozen up during several years' use.

Forcing Boilers and Bursting Tubes

In the illustrated article on "Burst Boiler Tube" in your issue of December 8, page 805, the statement is made that "scale or oil, which will cause no serious overheating of the metal when three pounds are evaporated per hour per square foot of heating surface, is very likely to make trouble when the evaporation goes up to six or ten." This statement is apt to give an unwarranted sense of security to owners of boilers which are usually not driven at a rate of over three pounds evaporation per hour per square foot of heating surface. The fact is that when the rate of driving of a boiler averages this figure, there are times, when the fire is at its brightest, just before firing a fresh supply of coal, when the rate of transmission of heat may be equivalent to an evaporation greatly in excess of this figure.

Also, the rate of transmission of heat through the surface of the bottom half of the lower row of tubes, immediately above the fire, depends on the temperature of the fire, the temperature of the water in the tube, and the resistance to transmission of heat of any layer of scale or oil which may be on the surface of the tube. The temperature of the fire is almost independent of the rate of driving. It depends chiefly on the dryness of the coal, the completeness of the combustion, and the amount of excess air over that necessary to insure complete combustion. It is quite possible with either anthracite or semi-bituminous coal to have a temperature of 3000 deg. F. in the furnace, whether the boiler is driven at a moderate or at a high rate. Given a condition of firing which produces such a temperature, the rate of driving per square foot of heating surface depends upon the amount of heating surface that is provided for the absorption of the heat, and as this surface, or nearly all of it, is beyond the lower row of tubes immediately over the fire, it can have nothing to do with the establishing of a condition which would cause the burning out of a tube in the lower row.

If statistics of burst boiler tubes should show that bursting is more frequent at high rates of evaporation, it does not follow that the high rate of evaporation in itself is the cause of the more frequent burstings. It is more probable that the greater frequency is due to the greater quantity of scale that is deposited in a given time when the boiler is driven at a high rate, and the conclusion to be drawn from this is that with high rates of evaporation it becomes necessary to use feed water that is purified before entering the boiler.

Water-Hammer in Vacuum Pump

We had considerable trouble by vapor being carried over from the surface condenser to the vacuum pump and causing water-hammer. It was necessary to stop the pump

Reservoir for Condensate

and relieve the vacuum before the water would drain out, and as this usually occurred during the heavy-load period it called for fast work.

The quickest way was to slack off the valve-chest cover, but as the water accumulated to a dangerous extent, four or five times on a watch, it became a serious matter. To overcome this, I connected a 6-ft. length of 4-in. pipe, with a reducing elbow and a 1-in. globe valve at each end, to the bottom of the valve chest. Valve *A* at the end next to the pump should be left open and *B* at the other end closed until water accumulates in the pipe; then *A* is closed and *B* opened to drain the water into the sewer. Pet-cock *C* is opened to admit air during the draining process. With a reservoir of this capacity, it is only necessary to drain out once in twenty-four hours.

F. O'DONNELL.

Coscob, Conn.

Correction for Twisted Valve Stem

The diagram shown was taken from the high-pressure cylinder of a Corliss cross-compound condensing engine connected to a centrifugal pump. One valve stem was so twisted that the valve had a late admission, as shown, and the speed of the engine was reduced from 135 to 128 r.p.m.

After the key was taken out, the valve was turned until

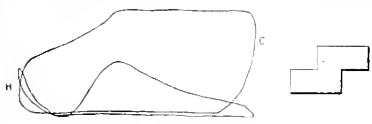

DIAGRAM WHEN STEM WAS TWISTED; NEW KEY

it was in the right position and an offset key was made to suit the new position instead of turning the stem over and cutting a new keyway. The valve required no further adjustment.

LAWRENCE KJERUIFF

Kansas City, Mo.

Improperly Finished Pumps

Referring to the letter on p. 892, Dec. 22 issue, under the above caption, I agree that stuffing-boxes are generally too shallow, but find that better results can be obtained with the bottom of the stuffing-box and the face of the gland square than at an angle. The packing should touch the rod from one end of the stuffing-box to the other with a moderate pressure over a large area rather than a concentrated pressure on a small area at the two ends, causing excessive local friction and wear.

I have designed and used many stuffing-boxes for steam, water and vacuum and have never had any difficulty with square faces. The operating engineer is quick to see the advantage of having each piece of packing in the box doing something like its share of the work. I have packed ½-in. reciprocating valve stems against 150-lb. pressure with soft packing in a stuffing-box 2½ in. deep. The glands were held by two ⅜-in. studs screwed up snugly with a small wrench, causing very little friction.

Good results have been obtained with a shallow stuffing-box having 30 deg. beveled bottom and gland face in packing a stationary pipe extending through a jacket against a steam pressure of 150 lb. In this case the stuffing-box was only 1 in. deep for ½-in. pipe, the object of the bevel being to obtain a tight joint in a small space regardless of friction.

Baltimore, Md.

Large Saving in Hotel La Salle Plant

To anyone not acquainted with the facts, the attempt on page 63 of Jan. 12 to refute the article appearing in the Nov. 3 issue of POWER might appear like an able defense of the former high cost of operation, but as a matter of fact it is misleading, to say the least. In the following reply it is the writer's intention to take each paragraph in turn and to give the facts in each case. Before doing this, I wish to state that the figures in Mr. Wilson's article are correct, and this statement is verified by the accompanying letter from the auditor of the hotel, who has held that position since February, 1910. The deductions made and the reasons given for the savings are also true in every respect. I know personally that it was not the author's intention to find fault in any way with my predecessor or his method of running the plant. There had been a difference in operating cost of $45,000 per year, and to tell how such an enormous saving had been made was the sole purpose of the article. This was done accurately. I do not take any glory unto myself for the saving, as in my opinion any engineer worthy of the name could have effected the same results by keeping on the job and by winning the full confidence of his men and his employer. Following is my reply, in which the numbered paragraphs refer to those of similar sequence in the preceding letter.

1. Mr. Lawrence admits that he was on the job 18 months before the hotel was opened. He had to pass on all the mechanical equipment before it was contracted for and also to O.K. the same before it was accepted. It was all contract work and all changes were up to the contractor. Certainly hotel help was not used to make contractor's changes. After the hotel opened all material and any labor done by the plant force which did not apply to the engineering department was charged to "Improvement and Betterments." The department was given credit and to the full amount specified by the engineer. Although Mr. Lawrence does not actually say that it was charged to his department, he infers that it was and overlooks the fact that the data given in the article do not go back of 1910. It will be seen in Table 2 of the article that the labor charges are practically the same for the four years given. The maintenance and supply items for 1910 and 1911 are excessive, due to lax operating methods, but the items are made up of legitimate power-plant charges.

2. By the present management it is also required that the house be thoroughly ventilated at all times, but as there were certain ventilating fans performing certain functions at different times, it was possible, by making a few changes, to arrange a schedule of fan operation which permitted shutting down some of the fans part of the time and the saving of considerable power. Under former conditions it was impossible to properly ventilate and cool one of the dining rooms until the air ducts had been enlarged and an additional fan installed, having a capacity of 6000 cu.ft. per min. During the summer months this room had been closed as it was so hot nobody could stay in it. For the past two years it has been open every day. Besides, a complete ventilating system has been installed in the laundry, where formerly there was no ventilation at all. All other fans are being run the same as ever, but only when needed and not haphazard as before. Instead of shutting down motors, except as before stated where they are run on schedule, three additional motors

have been installed in the laundry, two in the nineteenth-floor kitchen, one in the eighteenth-floor kitchen, and two in the sub-basement. Regarding cooling and refrigeration, a more even and lower temperature is maintained in the different rooms than ever before, and an additional 6000 cu.ft. of air per min. is supplied. This is not cutting down on service. The figures in the article also show that considerably more ice was made. The machines are now operated on exhaust steam and not on live steam, as in former days. This is an item of saving. It is true that 25-watt tungsten lamps have been substituted in part for 16-cp. carbon lights. Any intelligent engineer would do the same, and it is inconceivable that any manager would refuse a better light costing less for maintenance and current providing he was properly informed of the facts.

3. The steam traps certainly did have an elaborate system of piping and must have been put in on the time and material basis. There were 15 on the high-pressure lines in the engine and boiler rooms. On the discharge line of each trap was a valve and between this valve and the trap a 1/4-in. valve for detecting leakage of steam. Upon taking charge, I went to each trap, closed the valve in the discharge line and opened the try-valve. Without any exception, not water but steam under boiler pressure blew out. An investigation showed that the seats and valves of the traps were badly worn, and in some cases the valve was completely eaten away, giving a direct passage for the steam. The traps discharged to an open heater with cast-iron sections, and this in turn was connected with the expansion tank, from which risers to the heating system and the atmospheric exhaust were taken off. An employee who has been under both managements reports that on one occasion a repair was to be made to the heater. The valve between the expansion tank and the heater had been closed. Shortly afterward the latter exploded, and the cause was live steam from the traps.

4. It is common knowledge that as a hotel or any building gets older it requires more attention and especially more sweeping. This is true in the present case, and the hotel is noted for its cleanliness. As stated, there are three vacuum machines of the inspirator type which use steam at boiler pressure and carry a vacuum of 12 in. On each machine is a control valve to automatically shut off the steam when the proper vacuum is reached. When the writer took charge all three machines were in operation and blowing continually without a sign of cut-off. The machines were overhauled, and it was found that one would do the work and still cut off intermittently. The same number of sweepers are in operation, and, as the hotel is getting older, more sweeping is necessary. One machine does the work very efficiently.

5. These lights were installed during the summer before the writer took charge, for illumination during the roof-garden season. The same number of lights are still there and are burning every night of the season. There is no change in the schedule. Instead of reducing the lighting it has been increased. An addition of 825 twenty-five-watt tungsten border lights has been made at the fourth floor, also 1350 ten-watt lamps in a large roof sign, and numerous table fixtures, each containing three 10-watt tungstens.

6. Changes are continually being made, and more now than when I first took charge. The nineteenth-floor kitchen has been entirely remodeled and several additional steam-using appliances installed. A new kitchen has also gone in on the eighteenth floor, with coffee urns, soup heaters, steam tables, etc. Besides, a number of steam-using appliances have been added to the laundry. All of this work was done by the engineering department. Contrary to the inference made by Mr. Lawrence, the work was charged to "Improvement and Betterments" and the power plant was allowed a credit.

7. All engineers in Chicago know what it was to get coal in 1910, but that was only during the months of June, July and August. At that time I was in charge of a hotel plant three times the size of this plant and made a better showing than in the previous years. In Table 2 in the article the difference in the coal bills for 1910 and 1911 is $3500, which, divided by the tonnage for the year, amounts to only a few cents. Under conditions as I found them here, it was impossible to burn anything but a good grade of washed coal, as with inferior coal the combustible matter in the ash would be excessive. As to records, the boiler-room foreman who was on the job then and is still in the same capacity states that no records of coal were kept other than the amount of coal coming into the building; also that the water meter was out of repair continuously and was inaccurate, and before it could be used on the tests cited it had to be completely overhauled. Readings from it could not have been "absolutely correct," and it is rather difficult to see how the daily coal consumption could even be estimated with any degree of accuracy. Steam coming from the exhaust head on the La Salle, even on the coldest days, was a matter of comment among engineers of the city. Besides it is difficult to see how evaporation could be "kept up to the highest possible point at all times" with a CO_2 reading of 1½ to 2 per cent., which is all that could be obtained by the writer until the furnace conditions were changed.

8. To operate the electrical units at the best load factor, the same means were at the disposal of my predecessor. Even with the larger load he was carrying, due to inefficiency in more ways than one, it would not have been necessary to operate more than one unit at a time. In the very tests to which he refers a change of schedule was recommended, which would have effected a saving estimated at $15 per day, or $5475 per year. The two methods of operation were outlined in the article. I have followed the plan of operating the second unit from 7 a.m. to 5 p.m., the largest unit from 5 p.m. to 1 a.m., and the smallest the balance of the night. This allows each unit to operate at its highest efficiency and has proved a very flexible arrangement. All of the rooms are still cooled in the summer, as previously stated. Furthermore, hourly temperature readings are taken. By supplying an additional 6000 cu.ft. of air per min., it was possible to reopen the German restaurant during the hot months. This does not look like a discontinuance of service. The various services required have been maintained, but much more efficiently than in the past. As to the plant speaking for itself, I am willing to have it. I do not consider an engine room served by fluttering arc lamps well lighted. It now has clusters of 25-watt tungstens. All pipe joints and valve stems are kept packed and steam tight. When the writer took charge, there were leaks in the headers, stop valves, auxiliary valves, etc. In fact, on top of the boilers conversation was impossible, and in any part of the plant it could only be carried on under difficulties. The boiler tubes were in bad condition and a large number had

to be replaced. Water leaking at the ends of the fire tubes had mixed with soot and formed a hard deposit, half filling the tubes for a considerable portion of their length. The remodeling of the furnaces was accurately described in the article. Due to this it was possible to use an inferior coal costing less per ton. As to the condition of the engines, the following sentence of a letter from the builders to the writer will be illuminating: "I want to congratulate you on the nice running of your engines, which have undoubtedly taken time and great care to bring into line, as they have been fearfully abused."

9. Mr. Lawrence could not be expected to know that reliable tests have been conducted by the writer so that he knows exactly what he is doing in the plant and furthermore that accurate daily records are kept of coal and water. As to the tests mentioned by Mr. Lawrence and printed in part in his letter, I have nothing to say. There is no occasion to bring another party into the controversy, and for that matter it is not necessary, as the results obtained speak for themselves. These were given accurately in the article by Mr. Wilson, as well as a careful analysis of how the saving was effected.

10. In the article appearing in the Nov. 3 issue, the size of the new elevator pump was given, but no special reference was made to it as it was not installed until last August. The latest records given in the article were for the year 1913. As to the necessity of installing this pump, it may be stated that the three pumps originally installed had to be maintained in service from 6 a.m. to 12 midnight, and at times under the former management they were so hard pressed that it was a common occurrence for the accumulator to hit the bottom, nearly wrecking the duplex pumps before the attendants could reach the throttle. Apart from better elevator service, the new pump has effected a saving in coal, as the coal costs for corresponding months in 1913 and 1914 will show:

COAL COST PER MONTH

	1913	1914
August	$3159.09	$3059.10
September	3198.62	3046.52
October	3471.41	3128.93
November	3229.66	2898.28

In August the pump was only run two weeks, as the builders still had some work to do on it. In September and October, it was run three weeks each month and in November nearly four weeks.

The new hot-water heater was badly needed. Before it was installed, it was necessary to carry 3 to 4 lb. back pressure on the entire system to furnish enough hot water for bathing, and even then there were many complaints over the low temperature of the water. The new heater has done away with this trouble, and the building can be heated by steam under a pressure of 1 lb.

The above covers all points brought up by Mr. Lawrence. Numerous other items might be mentioned to show how the saving given in the article was effected, and if desired the writer can go into fuller detail at a future date. It will be of interest to notice in the auditor's letter that the saving last year was even greater than in 1913, and more work has been done than ever before.

W. W. Bird,
Chief Engineer, Hotel La Salle.

Chicago, Ill.

I have served the Hotel La Salle Co. in the capacity of auditor since February, 1910, and to the best of my knowledge the charges made to the engineer's department during the periods shown in Table 2 of the Nov. 3 issue of Power were all legitimate charges to that department.

When the services of the engineer's department have been required for changes or additions to construction, full credit has been given on the company's books for time and materials used.

It should be noted that your correspondent particularly refers to the period of September to December, 1909, whereas the Nov. 3 issue of Power gives no figures whatever for that period. It may be that he has some specific item in mind, and if such is the case, I would be glad to investigate and report on it after hearing from him.

It might interest your readers to know that further economies effected in the engineer's department during the year 1914 make a still more favorable comparison with previous years' operations, especially in view of the continued increase in the hotel's business.

W. H. Peterken,
Auditor, Hotel La Salle.

Chicago, Ill.

Detecting Ammonia Leaks

In the Dec. 15 issue, Mr. Anderson takes exception to my method (see Nov. 3 issue, p. 656, under Robert G. Thurston) of detecting ammonia leaks in brine tanks. His method is to empty the tank, get inside it and test the coils with a sulphur stick while the pressure is on the coils. This is the best method, but how many engineers are going to take the trouble to pump out the tank, crawl inside of it while it is cold and slimy and conscientiously apply the sulphur stick to every joint? There are few. I agree with Mr. Anderson that there will be a few pounds of ammonia lost by using my method, also that the sulphur stick will locate ammonia leaks more readily than litmus paper or Nessler's solution, but when he claims that he can detect ammonia in brine by smell before it can be detected with litmus paper or the solution, I must say I am skeptical.

Mr. Anderson states that to test the brine-tank coils properly one should reduce the pressure to 5 lb. before testing. The higher the pressure the more prominent the leak and the more readily it may be detected.

The use of the words "discharge tanks" in my article is wrong. The manuscript read "discharge lines."

Mr. Anderson claims that some losses are due to the disintegration of the ammonia. This is questionable.

Water should not be present in the ammonia in a properly managed compression plant. In an absorption plant it is of course different. Many operators claim that running with cold rods draws moisture into the cylinder with each stroke of the machine, due to the moisture clinging to the cold rod and being drawn in with it. I have seen considerable water get into the system with the oil by using the oil over again and not having it properly filtered. Moisture will also get into the system when the expansion coil or suction line is opened and left open; the moisture precipitates on the cold surfaces and accumulates in the pipes and when the system is put in operation again is swept along with the ammonia.

If steam is used to clean the oil out of the system and it is not thoroughly blown out with air afterward, the condensation will remain in the pipes.

Thomas G. Thurston.

Chicago, Ill.

Inquiries of General Interest

Inspection of Storage Batteries—How often should storage batteries be inspected?

C. E. C.

It is well to thoroughly inspect them at least once a week, using a special lamp for the purpose.

Bar-to-Bar Test of Armature—When making a bar-to-bar test of a dynamo or motor, what would a sudden drop of milli-volt reading indicate?

Z. H.

A sudden drop in the reading would indicate a short circuit, either between the bars themselves or between the windings connected to the respective bars.

Pitting Due to Presence of Fatty Acids—What would cause oily feed water returned from an exhaust steam-heating system to pit boiler tubes?

R. M. C.

Pitting might be due to fatty acids contained in animal or vegetable oil used as an adulterant of the engine cylinder oil.

Anchor Ice—What is anchor ice and how is it formed?

R. C. M.

Anchor ice or ground ice consists of needles and thin scales of ice which form in moving water and sometimes on the bottom of still water. They usually cease to form after the body of water has become frozen over. On coming in contact with submerged objects these particles of ice adhere and soon form large masses difficult to dislodge.

Quality of Steam Gathered near the Surface of the Water—What would be the quality of steam gathered in a petticoat pipe near the surface of the water in a boiler as compared with steam taken from the top of the boiler?

J. E. N.

In the process of ebullition the globules of steam, in rising from the body of water to the surface, entrain water which is unevaporated and which is projected above the surface of the main body of water. Unless the steam is superheated there will generally be some water thus entrained that will be carried to every part of the steam space of the boiler. It is usually the case that the nearer the disengaging surface of the water, the larger will be the proportion of water thus entrained by the steam, hence steam gathered near the surface of the water by a petticoat pipe would be much wetter than steam taken from the top of the boiler.

Changing Governor Pulley—A belt-driven governor regulates the speed of an engine to 80 r.p.m. The governor driving pulley on the main shaft is 12 in. diameter and the receiving pulley on the governor is 7 in. diameter. To what size should the governor receiving pulley be increased to regulate the engine to 90 r.p.m.?

With 80 r.p.m. of the engine the speed of the governor pulley is $\frac{80 \times 12}{7}$ r.p.m., and as practically the same speed of governor would be required, then for regulation at 90 r.p.m. of the engine shaft, the governor receiving pulley should be

$$(90 \times 12) \div \left(\frac{80 \times 12}{7}\right) \text{ or } 7\tfrac{7}{8} \text{ in. diameter.}$$

Original Babbitt Metal—What was the original recipe for babbitt metal?

L. J.

The original recipe proposed by the inventor, Isaac Babbitt, a brass founder, of Boston, Mass., was 4 lb. of copper, 8 lb. of antimony and 24 lb. of tin = 36 lb. of mixture called hardening, and to every pound of hardening 2 lb. of tin was added, so that the completed mixture was in the proportions: 4 lb. of copper, 8 lb. of antimony and 96 lb. of Banca tin or 1 : 2 : 24. For making the alloy the melting must be gradual or the antimony and tin will largely separate from the copper and form oxides or dross on the surface. Thus 4 lb. of copper is melted first, then 12 lb. of tin and 8 lb. regulus of antimony are added slowly to the molten copper, to which 12 lb. more of tin is added to form the hardening. Then for use with each pound of this, 2 lb. of Banca tin is melted. The surface should be covered with pulverized charcoal and a small portion of sal ammoniac. Previous to pouring the mixture it should be well stirred.

Evaporation per Pound of Fuel Oil—What would be the rate of evaporation per pound of fuel oil having a calorific value of 18,500 B.t.u. per pound with a boiler efficiency of 75 per cent., a steam pressure of 50 lb. gage and a feed-water temperature of 135 deg. F.?

S. F.

With 75 per cent. boiler efficiency there would be

$$0.75 \times 18{,}500 = 13{,}875 \text{ B.t.u.}$$

realized per pound of fuel. As each pound of feed water raised to 50 lb. gage pressure, or about 65 lb. abs., would contain 1178.5 B.t.u. above 32 deg. F., and as with feed water at 135 deg. F., or 135 — 32 = 103 deg. F. above 32 deg. F., each pound would receive 1178.5 — 103 = 1075.5 B.t.u., then $\frac{13{,}875}{1075.5}$ or 12.9 lb. of water would be evaporated per pound of fuel.

Effect of Temperature on Wire Resistance—If the resistance of 1000 ft. of copper wire at 75 deg. F. is 100 ohms, what would be the resistance per foot at 90 deg. F.?

R. J.

The resistance of copper wire increases with an increased temperature. The formula to be employed is:

$$R_2 = R_1 + C \times R_1 (T_2 - T_1),$$

where

R_2 = The resistance, hot;
R_1 = The resistance, cold;
C = The temperature coefficient, depending upon the metal, which in the case of annealed copper averages about 0.00223;
T_1 = Temperature, cold;
T_2 = Temperature, hot.

Hence, where the resistance of 1000 ft. of copper wire at 75 deg. is 100 ohms, the resistance per foot at 90 deg. F. would be

$$R_2 = 100 + 0.00223 \times 100 \ (90 - 75)$$
$$= 100 + 0.223 \times 15$$
$$= 103.345 \text{ per 1000 ft. or 0.103345 ohms per ft.}$$

Connecting Ground Circuit of Generator—At what point in the armature of a three-phase generator would it be proper to connect the ground circuit for the generator to operate on a grounded neutral system?

A. R. P.

If the generator is star connected, ground the neutral as in Fig. 1, in which case the maximum potential to ground will be 58 per cent. of the line voltage. If delta-connected,

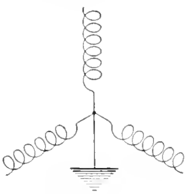

Fig. 1

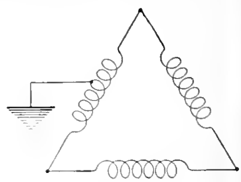

Fig. 2

Methods of Grounding Generator

one side may be grounded as in Fig. 2, in which case the maximum potential to ground is 87 per cent. of the line voltage. The ground may be direct, or through resistance or reactance, the latter limiting the flow of current.

Engineers' Study Course

The Conversion of Energy

All the activities of power plants depend upon the general fact or law of nature that the different kinds of energy can be converted one into another. In these activities four kinds of energy are involved: Chemical, thermal, mechanical and electrical. Selection by twos gives the following combinations, as illustrated by one or more practical examples:

Chemical energy to heat: Combustion in boiler furnace or in engine cylinder (a).

Chemical to mechanical: No direct conversion, heat energy coming between.

Chemical to electrical: Electric battery, particularly the storage battery (b).

Heat to chemical energy: Dissociation of water or carbon dioxide in boiler furnace or gas producer, also operations of reducing metals from their ores (b) or (c).

Heat to mechanical work: All kinds of heat engines (c).

Heat to electricity: Only such feeble activity as that of the thermocouple.

Mechanical work to chemical energy: None.

Mechanical to heat: Compression, friction, impact, etc. (a).

Mechanical to electrical: The electric generator (b).

Electrical to chemical: Electrolysis, as in charging storage batteries (b).

Electrical to heat: Electric lighting and heating; use of a rheostat as load for a generator, when testing (a).

Electrical to mechanical: The electric motor (b).

Three of these combinations, namely, chemical to mechanical, mechanical to chemical, heat to electrical, are either absolutely or practically impossible except through some intermediate transformation. The other nine are divided into three classes, indicated by the letters (a), (b), (c).

Class (a) comprises the transformations which are or can be complete, every one having heat as its final state. The fact that the whole of the fuel may not be burned in a furnace or engine does not qualify the completeness of energy conversion for what is burned, and under special conditions, as in the fuel calorimeter, complete combustion is surely obtained. In the conversion of other forms of energy into heat an efficiency of unity is, therefore, attainable.

The transformations in class (b) have unit efficiency as an ideal limit, which may be approached but never quite attained. To these interchanges between chemical and electrical and between mechanical and electrical energies should be added the transmission of mechanical work and its change in form by machinery. The efficiency of most machines lies within the range of from 70 to 95 per cent. A large generator or motor will go a little above 95 per cent. The perfect generator, motor or storage battery cannot be realized, but it is easily imaginable and can be quite closely approximated.

Notice particularly that all the energy not usefully converted in the operations of class (b) is changed into heat and thus wasted.

Last comes class (c)—the conversion of heat into some other form of energy, and especially into mechanical work; in other words, the question of heat-engine operation and efficiency. The outstanding fact in this field is the impossibility of anything approaching complete conversion. Within the limits imposed by natural physical conditions, there is no known or imaginable method or scheme of working by which a heat engine can change into work the whole of a given amount of heat supplied to it. Necessarily, such an engine converts but a portion of the heat received and gives up the remainder as heat in an inconvertible state. Its limit of efficiency is not 100 per cent., but some fraction which, with varying conditions, ranges from perhaps 15 to 65 per cent. To reason out the character of this limit and establish its value is one of the important tasks of the science of thermodynamics.

After the descriptive statements which have just been made, and keeping in mind the power-plant point of view, the following summary will appear rational:

Chemical, mechanical and electrical energies may be put in one class, and are sometimes called the higher energies. Heat is a class by itself and is a lower form of energy, especially when it has sunk into a state of low temperature or intensity.

Then the different types of conversion classified as (a), (b) and (c) may be briefly defined as follows:

The higher energies can be completely converted into heat. They also have certain interconvertibilities, in which the efficiency may approach, but can never attain to, unit value. And what is not usefully converted is lost as heat.

By certain processes heat can be converted into the higher energies, but only in part, since there is always a large remainder of energy left in thermal form.

Finally, the tendency in nature is for all kinds of energy to sink into the form of heat of low temperature.

Relative Efficiency of Steam, Gas and Oil Engines—Roughly stated, a first-class modern steam engine utilizes about 12 per cent. of the available heat in the coal, resulting in, say 1.6 to 1.7 lb. of fuel per b.hp.hr. during a week's work of 55 hr. If the boilers are to be fired by producer gas, for which purpose slack and dust can be used, then each brake horsepower will require about 2 to 2.2 lb. of coal. Internally fired gas and oil engines are approximately twice as efficient as steam engines, which means that they utilize about 25 per cent. of the available heat. Crude oil being 37 per cent. better than good ordinary coal, oil engines should use only about three-eights as much oil as the coal mentioned above, say about 0.6 lb. per b.hp.-hr. Then, however, as there are no boiler radiation losses over night, a material saving results and the oil consumption per week of 55 hr. may be about 0.5 lb. per b.hp.-hr. Petrol and similar internal combustion engines would require about 0.4 lb. per b.hp.-hr. Gas engines have also about the same efficiency as oil engines; but as there is a loss of about 20 per cent. in the producers, if these work day and night, and another loss of quite 10 per cent. if they have to stand idle over night, the efficiency of gas engines is only about 40 per cent. better than that of first-class steam engines.

Design and Operation of the Cleveland Municipal Electric Light Plant*

By Frederick W. Ballard

The new Cleveland, Ohio, municipal lighting plant, known as the East 53d Street Station, went into operation July 20, 1914. It is the largest central station in this country built by a municipality, and is intended not only to supply electric current for street and commercial lighting, but also for power users. The rates charged for the service range from $0.03 per kw.-hr. maximum to $0.01 per kw.-hr. minimum. This station has a capacity of 25,000 kw. and is at present loaded to one-fifth of its capacity.

The estimated results which will be secured from the new 25,000-kw. station, which has just been placed in operation, are based upon an annual output of 60,000,000 kw-hr. and with fixed charges founded upon a total plant investment of $3,000,000. Fixed charges amounting to 9 per cent. on this investment would equal $0.0045 per kw.-hr. Cost for coal is estimated at $0.002 per kw.-hr.; station costs exclusive of coal at $0.0015; distribution costs exclusive of fixed charges at $0.004; administration charges at $0.005, and profits at 8 per cent. on the investment at $0.004. This makes an average price to be secured per kilowatt-hour generated of $0.0165. From the three months' operation of this station, together with tests that have been conducted, the indications are that these estimated results will be secured.

The plant was built from the proceeds of a $2,000,000 bond issue by the City of Cleveland, about one-half of this amount being invested in the station itself. The other half is to be invested in the substations and in the distribution system, including overhead and underground lines. In addition to the $2,000,000 derived from this bond issue, there are also available the proceeds of a $500,000 bond issue voted by the City Council to supplement the original bond issue, making a total amount of $1,500,000 to be invested in the distribution system. The value of the present distribution systems connected with the Brooklyn and the Collinwood stations is about $500,000, making the total value of the East 53d Street Station, together with its distribution system, about $3,000,000.

The results which have already been obtained in the operation of the Brooklyn lighting station and the East 53d Street Station during the first eight months of the year 1914 tend to substantiate the original estimates of what will eventually be secured in connection with the operation of the East 53d Street Station. A statement of revenue and expense connected with the operation of these two stations for the first eight months of the year is as follows:

TABLE 1—REVENUE AND EXPENSE STATEMENT FOR FIRST EIGHT MONTHS, 1914

Revenue from sale of current for first eight months of 1914	$153,363.65
Kw.-hr. generated, 7,863,610; average sale price, $0.0195.	
Kw.-hr. sold, 6,270,726; average sale price, $0.0244.	
Operating and maintenance for first eight months	97,044.60
Kw.-hr. generated, 7,863,610; average cost price, $0.0123.	
Kw.-hr sold, 6,270,726; average cost price, $0.0154.	
Net earnings for eight months	$56,319.05

The total kilowatt-hours generated for eight months is greater than the output for the year 1913. The average cost price per kilowatt-hour generated is $0.0123, as compared with $0.0149 for the previous year. The results secured in the way of operation and maintenance costs in the power station itself for the months of August and September are shown in Table 2:

TABLE 2—EAST 53D STREET POWER STATION REPORT, AUGUST AND SEPTEMBER, 1914

	Aug.	Unit Cost	Sept.	Unit Cost
Operation				
Labor	$1498.48	$0.0018	$1573.00	$0.0017
Switchboard attendance	352.80	0.0004	380.00	0.00042
Oil, packing and waste	....	.....	66.89	0.00008
Sundry expense	....	.....	10.46	
Coal	2686.50	0.0033	2415.69	0.0026
Maintenance—				
Condensers, piping, etc.	5.48	.....	.....	.....
Total operation and maintenance	$4543.26	$0.0056	$4446.04	$0.0048
Total kw.-hr. generated	809,120	.....	914,850	.....

*Excerpts from paper read at the annual meeting, December, 1914, in New York City, of the American Society of Mechanical Engineers.

The East 53d Street Station during these two months has been operating at less than one-fifth of its total capacity. The figures representing unit costs for the various items of labor, maintenance, fuel, etc., are considerably higher than should obtain when the station is running up to its capacity, when it will be operating at a much higher efficiency in regard to coal consumption per kilowatt-hour, and also the labor and other charges will be less per unit cost by reason of the larger output. During the month of August, the output of the Brooklyn and East 53d Street Stations amounted to 1,117,920 kw.-hr., of which 936,467 kw.-hr. was sold to customers, giving a loss in transmission of only 16¼ per cent. The average sale price for the kilowatt-hour generated was $0.0174, while the average sale price of what was sold was $0.0207, the revenue for the month being $19,405.38.

That an average load factor of 40 per cent. will be secured on this station when the load is built up to its ultimate capacity seems to be assured, and the indications are that a better load factor will be obtained. A typical load curve is only 2700 kw., but with a load factor of 80 per cent. based on the peak load there is a total output on the generating station of 51,925 kw.-hr. If these conditions can be maintained or even approximated when the load on the station has been built up to its ultimate capacity, the load factor will be considerably greater than 40 per cent. The location of the station was determined mainly by the convenient and economical facilities for delivering coal and also by the possibility of securing the cheapest and best water for condensing purposes. The Water-Works Department has a 9-ft. tunnel extending five miles into Lake Erie and draws water at this point from 125 ft. below the surface. This water, after passing through the surface condensers in the power plant, passes on to the suction chambers of the water-works pumping engines. The increase in temperature of the water going into the city mains, it is estimated, will not exceed 1 deg. F. In this way the lighting plant has not only secured the cleanest and coldest water for condensing purposes possible, but has also made use of a plant calculated to obviate any possibility of interruption by clogging of the inlet with ice or débris floating in the lake.

The coal question was considered as of next if not of equal importance to that of water. As the Lake Shore & Michigan Southern Ry. tracks run along the southern line of the property, with an elevation of about 60 ft. above the lake level, a method of handling the coal almost entirely by gravity has been worked out. Fig. 1 is a cross-section of the station in detail, wherein the coal is delivered overhead by the railway cars and is discharged by gravity into 3400-ton capacity bunkers, from which it is drawn through gates under pneumatic control into an electric telpher, which moves back and forth from under the bunkers on the track leading out over the stoker hoppers. The coal hopper on this telpher is carried on scale beams, and the weight of the coal and the time of delivery are recorded.

The special features in connection with the design of this station different from standard practice are as follows: The use of motor-driven auxiliaries throughout the plant; large boiler units with high steam pressure; economizers of greater capacity than ordinarily installed; a new arrangement of coal-handling apparatus; the use of both forced and induced draft with practically atmospheric pressure in the combustion chamber; automatic control of furnace conditions; simplicity of the piping layout, due to motor-driven auxiliaries; and the use of an auxiliary steam turbine for driving the auxiliary motors. This turbine is supplied with a jet condenser, the cooling water for which is used as boiler feed water after being passed through the economizers.

The practice of using motor-driven auxiliaries has not been adopted in this country principally for two reasons—(a) the use of exhaust steam from the steam-driven auxiliaries for feed-water heaters has been considered advisable as giving sufficient economy to warrant the use of steam, rather than motor-driven auxiliaries, and (b) the operation of the auxiliary equipment in the station by current from the main generators has been considered to introduce an element of uncertainty and unreliability into the service which it would be better to avoid.

To the first objection it can be stated that the thermal efficiency of the station can be shown to be higher when the

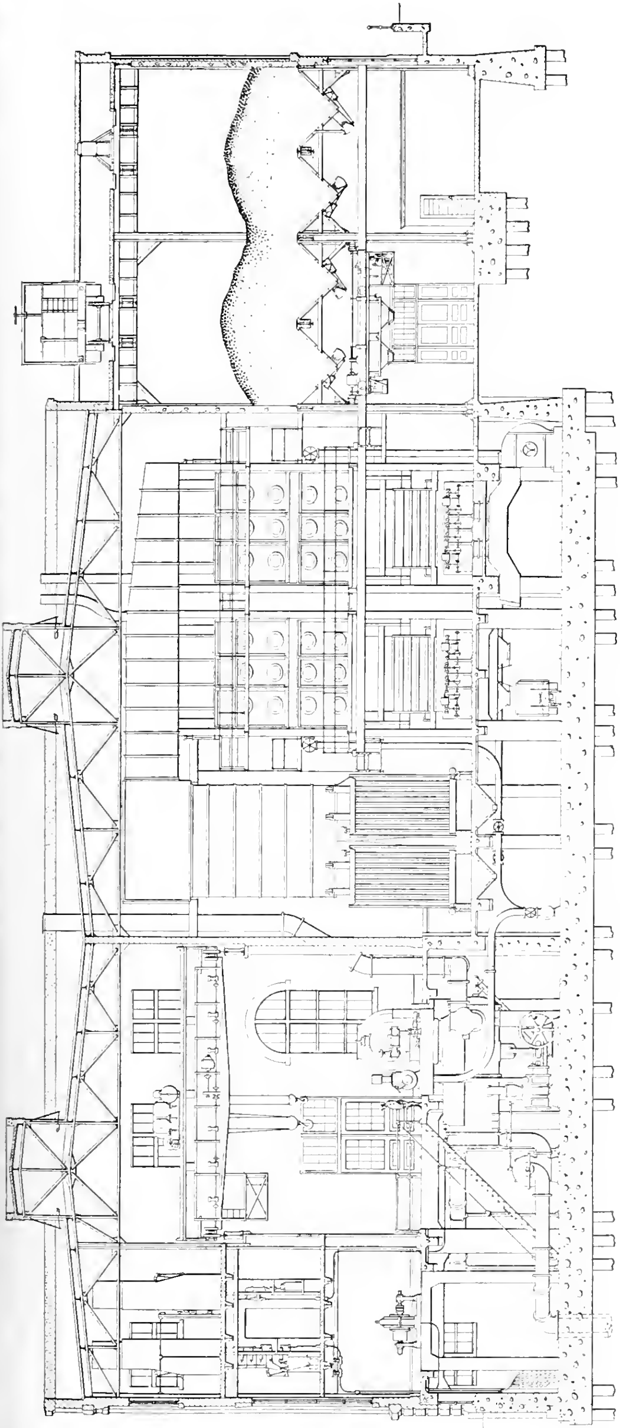

Fig. 1. Cross-Section of the Cleveland Municipal Lighting Plant

auxiliaries are motor driven and the heat for the boiler feed water is secured by the use of economizers from the flue gases. No arrangement of steam-driven auxiliaries would give just the proper amount of exhaust steam for heating the feed water properly at all loads on the station. There would always be periods when there would be either not enough or too much steam, and some would go to waste. There is also the complexity of steam piping necessary for supplying the auxiliary engines, with the incident losses from radiation and leakage. The second objection is answered by the installation of an auxiliary steam turbine. A 1000-kw. turbine with an overload capacity of 1500 kw. has been in operation in the Brooklyn Station for years and is now in good condition. This machine will be removed to the new station.

This machine will be operated in connection with a jet condenser, the cooling water for which will be drawn from a cistern which is used for the storage of the boiler feed water for the station. This cistern is divided into two compartments by a wall, the top of which is about two feet below the surface of the water. On one side of this wall will be the cold well and on the other side the hotwell. The condensate from the three main turbines will be discharged into the cold well and carried to a point near the bottom, where is located the suction end of a pipe carrying the circulating water to the jet condenser. The discharge from the jet condenser will be carried to the other side of the cistern, or the hotwell, and delivered at a point near the suction end of the pipe carrying feed water to the boilers. The makeup water for the system will be delivered into the cold well at the same point as the discharge of the condensate from the main turbines. The makeup water will be under control of a float valve designed to maintain the level of the water in the cistern at the required height.

It is not the intention that the quantity of water flowing through the feed piping system to the boilers shall determine the volume passing through the jet condenser as the volume of circulating water will be several times greater than the quantity of feed required by the boilers. The water in the cistern will, therefore, pass through the jet condenser several times before it goes as feed water to the boilers, and to prevent a uniform temperature throughout the cistern and a consequent lower vacuum in the jet condenser, the arrangement of hotwell and cold well was provided, and the piping was connected in such a manner as would supply the coldest water to the condenser and the hottest water to the boiler-feed system.

The auxiliary motors in the station will all be connected through a double bus system, so that each motor can be operated either by current from the auxiliary turbine or from the main generator. In this way the load on the auxiliary turbine can be adjusted so that the temperature of the feed water will be that best suited for delivery to the economizers. This temperature should be approximately 120 deg. F. If much less than this amount, the economizer tubes will scale with soot and cause trouble. If a greater temperature than that necessary to avoid this trouble is secured, there will be a sacrifice of economizer efficiency. Fig. 2 is a floor plan of the plant.

The use of large boiler units with high steam pressure was decided upon. The boilers ultimately installed were similar to those in the Delray Station in Detroit, and the dimensions are identical, except as to the length of the drums. These boilers (Fig. 3) each have 10,000 sq.ft. of heating surface and are designed to carry 275-lb. working pressure with a superheat ranging from 125 to 150 deg. F. They are equipped with underfeed stokers and are intended to be capable of operating up to 300 per cent. of rating.

The operation of the boilers at a high percentage of rating means a higher temperature of flue gases. This, with the low temperature of feed water, gives a temperature head between flue gases and feed water which will be practically double that ordinarily obtained in economizer practice. This alone would be sufficient to warrant a larger amount of economizer heating surface than would ordinarily be deemed advisable. However, there is another factor in the Cleveland situation which also warrants an increase in the economizer capacity. In economizer practice, the interest on the investment, generally figured at 6 per cent., is balanced against the saving which will be produced in the economizers, but in municipal engineering it is found that interest on the investment can be figured at 4½ per cent. instead of at 6 per cent. This fact alone would warrant an increased capacity in the economizer. Taking these factors into consideration, it was thought that a conservative estimate on economizer requirements would be 27,000 sq.ft. of heating surface. They are arranged in two parallel sections, independently, so that either section can be cut out by means of dampers for cleaning and repairing, leaving the other in operation.

The use of both forced and induced draft contributes to the flexibility of the installation and makes it possible to carry practically a balanced pressure in the combustion chamber, thus avoiding one of the greatest sources of loss in boiler practice, the leakage of air through the boiler settings. Two induced draft fans were put in, either of which has a capacity for taking care of the peak load requirements of the station. A separate forced-draft fan with an individual motor drive was placed in the boiler room basement for each furnace. The motors on the forced-draft fans are under automatic control, and their speed is governed by means of rheostats controlled by the boiler pressure. The motors for operating the stoker feed are also controlled by rheostats governed from the pressure in the air ducts underneath the boilers. The induced-draft fans are under manual control, and their speed is intended to be regulated by the man operating the boilers so as to give the proper draft for holding practically an atmospheric pressure in the furnaces.

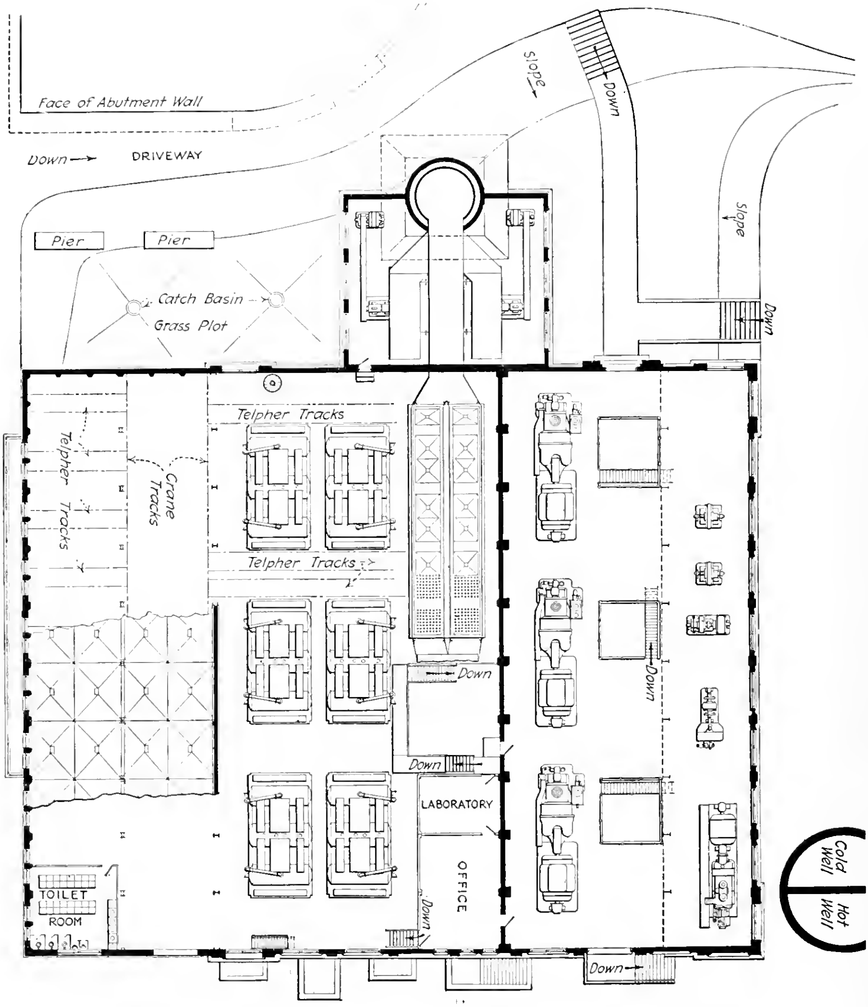

FIG. 2. FLOOR PLAN OF THE CLEVELAND MUNICIPAL LIGHTING PLANT

The steam piping is simple, because, outside of the auxiliary turbine and the emergency equipment consisting of a steam-turbine exciter and a turbine-driven feed pump, steam will be used only in the main generators. The plant is so arranged that each battery of two boilers is opposite one turbine generator, the steam lines from the boiler going to the header, from which a short branch is taken to the turbine. The header is capable of being cut into three sections by means of Hopkinson-Ferranti valves, with operative working parts of half the diameter of the steam main. The interior of these valves is shaped like a Venturi nozzle; they will pass an amount of steam equal to the full carrying capacity of the pipe with practically no reduction in pressure. The main steam header is located in the boiler-room basement near the floor, and the piping is arranged so as to drain to this header from all directions. This header is 135 ft. long and designed for the minimum of expansion which would effect a lateral movement in the branch pipes. It is divided in the middle by an expansion bend, which consists of two short headers carrying four small U-shaped pipes of only one-half the diameter of the main. Two halves of the main header are then anchored securely at their central points and carried on rollers from this point in both directions. This then divides the main header in such a way that at no place would the movement caused by expansion be more than that due to the expansion in one-fourth of its length. The main steam header is only 14 in. in diameter and is composed of ⅝-in. thick steel pipe with welded necks and flanges. The branch pipes contain no fittings except the valves, which are of heavy cast steel. All turns are of long bends and all sections have welded flanges.

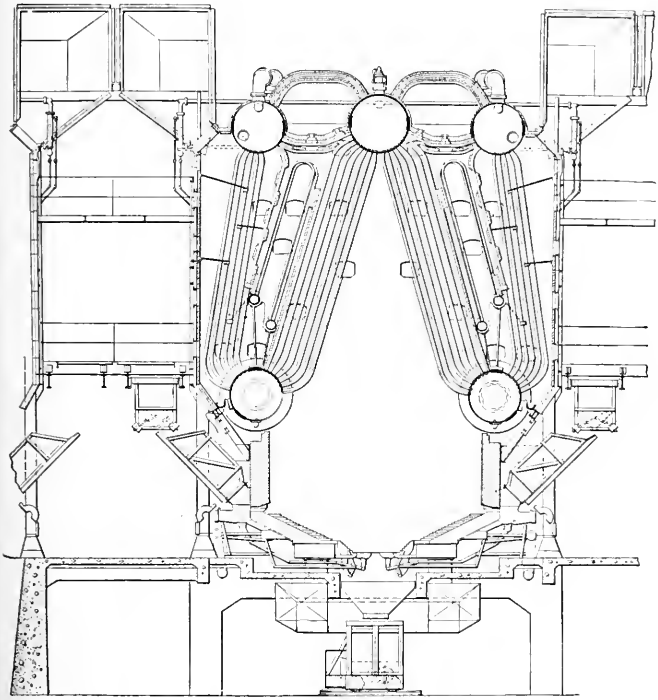

FIG. 3. SECTION THROUGH ONE OF THE BOILERS HAVING 10,000 SQ.FT. OF HEATING SURFACE

The feed-water pumps are all centrifugal. Two are constant speed and motor driven. One is steam-turbine driven and is designed for emergency purposes and for operation when no electric current is available. This pump is arranged with governor control for constant pressure and is therefore capable of being used in connection with either of the motor-driven pumps and to supply water to the boilers only when the demands are in excess of the capacity of the other pump.

In the chief engineer's office are located indicating and recording instruments for practically every operation in the station. There is a graphic recording totalizing watt-meter which gives a continuous record of the combined output of the station. The amount of feed water going to the boilers is shown by the indicating dial of a V-notch recorder, which also gives a continuous graphic record and the total quantity by means of integrating dials. The CO_2 in the flue gases is recorded, and recording thermometers keep record of the temperature of the feed water entering and leaving the economizer and the temperature of the flue gases in the boiler breechings as well as at the discharge end of the economizer. The steam pressure and the temperature of the steam in the main header are also recorded, thus giving a record of the superheat. This information, together with the record of the weight of coal going to each boiler, which is turned in to the chief engineer at the end of each 8-hr. shift, enables him to have a complete log of the performance of the station made up every day.

The use of 11,000 volts removes the necessity of having rotary converters, the absence of which is particularly notable when compared with the prevailing practice of supplying the congested districts of large cities from numerous substations in which there are placed rotary converters for changing alternating into direct current.

DISCUSSION FOLLOWING THE PRESENTATION OF MR. BALLARD'S PAPER

Robert L. Brunet, of Providence, R. I., in a written discussion, said that with low rates for energy the load factor of 40 per cent. would possibly be realized based on a peak of 18,000 kw., but when the peak of 18,000 kw. is reached the generating equipment will undoubtedly have to be increased to insure reliability and continuity of service. He has found that the income per $1 of investment varies from 20 per cent. to 25 per cent. in most private plants, while Mr. Ballard has estimated an income of 33 per cent. per $1 of the investment.

James R. Cravath, of Chicago, said that it would have to be demonstrated whether the estimated maximum load of 18,000 kw. could be brought to the Cleveland station with a distribution cost low enough to bring the total investment in power-plant and distribution systems to but $3,000,000. It is possible by cultivating the large motor-service business and ignoring the low-load-factor lighting business, such as residences and early-closing stores, that a 40 per cent. load factor might be maintained from the start. The natural tendency of rates as low as those given would be to load up the plant with low-load-factor business unless care was exercised to prevent it.

Alex Dow, president of the Detroit Edison Co., said that he had followed the construction and operation of the plant with interest; that the plant was a good one, a credit to Mr. Ballard, to the consulting engineer and to the city officers who let them go ahead and make a good plant. He said that what Mr. Ballard needed first was a distributing system, which he has not, and, second, a load, which he has not, and, third, the keeping of accounts in a manner acceptable to a public service commission. Mr. Dow was of the opinion that there was nothing radical in the station, inasmuch as it contained apparatus practically the same as that in the Delray Station.

Reginald Pelham Bolton, of New York, said that the rates are such as to offer little inducement to those consumers whose business is most desirable in producing a high load factor and that this rate does not include any service charge and is drawn merely on the relation of connected capacity and monthly consumption. He wanted to know if there were any data in the paper which justified the expectation that the small consumer can be served at the rate of 3c. per kw.-hr. without loss, which must be borne by other consumers or by a deficit in operation.

Mr. Ballard, in his response, said that he was delighted to learn that Mr. Dow did not consider that there was anything at all radical in the Cleveland station. He admitted it was true that everything in the station is the same as at the Delray plant, and inasmuch as this is so there was no reason why the Delray Station should not sell its current at the same price at which the Cleveland plant was selling it; and he hoped to see them do it. Regarding station rating, Mr. Ballard's understanding was that stations at the present time are generally rated at their maximum capacity for a 24-hr. service indefinitely. Tests show that the turbines in the Cleveland plant are capable of 7500-kw. continuous capacity, three giving 22,500 kw. and the 1500-kw. auxiliary machine bringing the total maximum capacity to 24,000 kw. Upon these figures his statements were based. In regard to capacity, in answer to Mr. Cravath's discussion of the 40 per cent. load factor, Mr. Ballard said: "I find it is not difficult for us to get a 40 per cent. load factor—to get it and to average it. We are running along every day between 60 and 80 per cent. load factor. As we build up the load on our stations we will probably secure a much lower power factor than that. We may go down to 40 per cent., but I hope we will not go below that."

Regarding the cost per kilowatt-hour being different for different customers, Mr. Ballard admitted that the plant was radical in that respect, saying: "Outside the question of competition, if there was only one station in the city and every customer had to take its terms or have none at all, you could not make one figure and a uniform load. You could not sell current to all your small resident customers at as low a rate as you would want to sell it to your power customers. On the other hand, you could not charge your power customers at a higher rate than your resident customers. If you did you could not get the business. That is not necessarily following out the plan of the National Electric Light Association of charging all that the service will bear. If you can sell current to large power companies at 1c. you are selling to the majority of them for less than one-half of what they can make it themselves."

Automatic Reclosing Circuit-Breaker*

BY E. C. RANEY

In the application of protective apparatus to the power circuits of industrial plants there are four conditions which should be fulfilled:

1. The current must be quickly interrupted in case of short-circuit or excessive overload.
2. The circuit should not be closed while the short-circuit still exists.
3. To avoid unnecessary delay the circuit should be closed instantly upon the removal of the short-circuit.
4. For the protection of motors on the circuit, power should not be restored until the controllers or starting-box levers have been moved to the "starting position."

The first of the above conditions may be met by placing either a fuse or a hand-operated circuit-breaker in the circuit to be protected. It will be readily seen, however, that the remaining conditions are difficult to meet by either the hand-operated breaker or the fuse, in cases where the line is of considerable length and the load is not in sight of the attendant.

These difficulties were forcibly brought to the writer's attention while in charge of power plants for mine work and while a motor inspector in steel mills. At that time there was no protective device on the market which met all four conditions, and it was the necessity for such a device which led the writer into the work of its development. The automatic reclosing circuit-breaker, here described, is the result of these efforts up to the present time.

THEORY

In order to make a circuit-breaker which will automatically reset after the overload condition has been removed, it is required that a shunt circuit with a resistance be provided around the main contacts, so that after the main contacts are open there may still be a small amount of current to act as an index to the condition of the line. The reclosing mechanism must be responsive to variation in this index current, which variation must be caused by the increase of resistance of the load or short-circuit. For example, take the case of the circuit-breaker on a 250-volt circuit, set at 500 amp. When the load resistance becomes such that more than 500 amp. will flow, this resistance will be

$$R = \frac{E}{I} = \frac{250}{500} = 0.5 \text{ ohm or less}$$

In case of a short-circuit the resistance of the load becomes practically zero and the breaker must be so constructed that it will not reclose while the load resistance is less than 0.5 ohm. Since in practical circuits it is always permissible to have lights or a constant load connected to circuit, the breaker should be capable of reclosing whenever the load resistance has reached a value slightly above that which caused the breaker to open. Assume that the constant load is 250 amp. and the motor load 250 amp. in the foregoing example. The load resistance will then never be greater than 1 ohm, which will require that the breaker shall not close on a load resistance of less than 0.5 ohm, but will reclose before the resistance has been increased to 1 ohm. In other words, the reclosing mechanism must be sensitive enough to respond to a change of resistance of less than 0.5 ohm in the load circuit.

The resistance of the shunt circuit around the breaker must be 125 ohms, if 2 amp. is allowed to flow at 250 volts on short-circuit as an index current. In commercial circuits the voltage variation is likely to be 10 per cent. or more, which means that the current variation through the 125-ohm shunt may be 10 per cent. of 2, or 0.2 amp. due to that cause alone. The variation of current in the shunt circuit resistance, caused by the load resistance being increased from 0 to 1 ohm, will be

$$2 - \frac{250}{126} = 0.096 \text{ amp.}$$

which is less than the variation due to permissible voltage variation.

It was this consideration which led to the adoption of the shunt circuit used in the present breaker, where two paths are provided for the current after passing through the load. In a branch circuit carrying a definite amount of current,

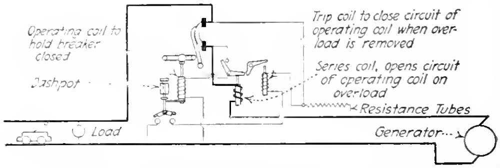

DIAGRAM ILLUSTRATING OPERATION OF CIRCUIT-BREAKER

the latter divides in the two branches inversely proportional to their respective resistances. When the load resistance is practically zero, on account of a short-circuit, nearly all the current flowing through the shunt resistance passes through the load circuit; but when the short-circuit is removed and the load resistance is increased to 1 ohm, if the load resistance coil has 1 ohm, then the current will be equally divided in the two branches and the current variation in the coil will be from 0 to 1 amp., which may be made enough to operate a relay setting the reclosing mechanism into operation.

OPERATION

Referring to the diagram, Fig. 1, it will be seen that the main contact brush is moved to the closed position and is held closed by the operating coil. The main load current passes through a series coil and main contacts. In case of an overload current in the series coil, its armature or core is raised and opens a contact which breaks the circuit of the operating magnet and allows the breaker to open.

The contact arm controlling the current in the operating coil is now held open by a latch until the trip coil operates to release the latch. After the opening of the main contact a small current is permitted to flow around the breaker through a high resistance. This current has two paths leading to the line of opposite polarity, one path around the breaker and through the load, and the other through the trip coil and the dashpot bridge. So long as there is a short-circuit or low resistance on the load circuit, this index current will be shunted past the trip coil, but whenever the short-circuit is removed or the load resistance is increased to a certain amount, enough current will be forced through the trip coil to operate the latch and allow the contact arm to again close the circuit of the operating coil. The breaker is then instantly closed by this action.

A dashpot is provided to prevent the breaker from closing instantly after being opened by a momentary overload. The object of this is to give sufficient time for motors to come to rest and for starting-box levers to be moved to starting position before the breaker recloses, regardless of the cause of the opening.

Briefly stated, the action is as follows: The breaker opens in case of either an overload or short-circuit, and remains

*From a paper read before the Ohio Society of Mechanical, Electrical and Steam Engineers.

open a few seconds in either case. At the expiration of this time limit, it closes, provided the overload condition has been removed; it remains open so long as a short-circuit exists and closes instantly upon its removal.

Recent Court Decisions

Digested by A. L. H. STREET

Electric Power as a "Municipal Purpose"—Provision in an electric power company's franchise granted by a city requiring the company to furnish power to the city for "municipal purposes," on certain terms, extends to the furnishing of current to operate an electric-light plant. (Colorado Supreme Court, City of Colorado Springs vs. Pike's Peak Hydro-Electric Co., 140 "Pacific Reporter," 921.)

Assumption of Risk by Engineer—An engineer in a stationary plant assumes the risk of falling into a pit after another employee has left the trapdoor covering it open, where he knows that it is apt to be open any time, according to the holding of the Massachusetts Supreme Judicial Court in the late case of Burnett vs. Worcester Brewing Corporation, 106 "Northeastern Reporter," 597.

Validity of Condemnation Statute—In a proceeding by an electric power company to condemn land for use of the company, under the laws of Tennessee, which restrict the right of condemnation to corporations, the landowner cannot question the validity of such laws on the ground that they constitute an unjust discrimination against individuals and partnerships who are not accorded the right of condemnation, since he is not injuriously affected by any such discrimination that may exist. (Tennessee Supreme Court, Noell vs. Tennessee Eastern Power Co., 169 "Southwestern Reporter," 1169.)

Right of Power Company to Condemn Land—In a decision announced by the Minnesota Supreme Court, the Minnesota Canal & Power Co. is denied the right to condemn land for one of its projects, on the ground that the enterprise could not be accomplished without impairing the navigability of the waters of the Birch Lake drainage basin. The court holds that a power company, or other public service corporation, cannot divert water from the navigable streams of one drainage basin into those of another basin, if the diversion impairs the navigability of the former; and that private property can be condemned only when the condemnation subserves some lawful public use.

Extent of "Water Power" Rights.—"Horsepower" Judicially Defined—When the right is granted to use the water of a canal or stream for the development of "water power," the grantee acquires no right to use the water for any purpose other than the propulsion of machinery; no water may be diverted or consumed for condensation purposes. This point was recently decided by the Pennsylvania Supreme Court in the case of the Eastern Pennsylvania Power Co. vs. Lehigh Coal & Navigation Co., 92 "Atlantic Reporter," 47. Referring to the term "horsepower," the court finds that it "has in popular acceptation a fixed, definite meaning. As originally employed it expressed the power of a steam engine. It has come to mean the unit in estimating the power required to drive machinery."

What Constitutes a "Stationary Steam Engine?"—Is a steam engine, which has been set upon a concrete foundation and so bolted and braced as to be free from vibration and which is used in quarrying rock and may be so used for two or three years, a stationary engine within the meaning of an ordinance prohibiting operation of stationary steam engines within certain limits in a city without first obtaining a license? This question, which was recently presented to the Massachusetts Supreme Judicial Court in the case of McDonough vs. Almy, 105 "Northeastern Reporter" 1012, was answered by that court in the affirmative. Justice Crosby said, in announcing the decision: "Whatever may have been the character of the engine when it was brought to the plaintiff's land, we have no doubt that when it was set upon the concrete foundation and permanently attached thereto for the purpose of being used two or three years, it became a 'stationary steam engine' within the meaning of the ordinance."

Remedy for Breach of Contract—According to the decision of the West Virginia Supreme Court of Appeals in the case of United Fuel Gas Co. vs. West Virginia Paving & Pressed Brick Co., 82 "Southeastern Reporter," 329, suit will not lie to enjoin a manufacturer from breaking a contract to buy fuel from plaintiff exclusively for a certain period. The court holds that the fuel company's only remedy is a suit to recover damages for breach of the contract. The defendant agreed to purchase from the plaintiff, for a period of three years, all the natural gas it should use in its manufacturing plant, and to pay for the same monthly at certain prices per thousand feet, graduated according to the quantity used. About the middle of the term the defendant purchased natural gas from another gas company and ceased using the plaintiff's product, whereupon the plaintiff applied for an injunction to restrain the defendant from purchasing gas from the other company during the term of the contract.

Effect of Power Rate Ordinance on Existing Contracts—When a consumer of electrical power makes a contract with a public service corporation for service, the parties are conclusively presumed to have contracted in contemplation of the power of the proper public authorities to fix rates, according to a decision handed down the other day by the Supreme Court of California in the case of Pinney & Boyle vs. Los Angeles Gas & Electric Corporation, 141 "Pacific Reporter," 620. The effect of this decision is to nullify the contract rate on a higher or lower rate being established by public authority. Plaintiff used electrical power to operate its machinery, and made a contract with defendant for future service. During the life of the contract, the city of Los Angeles adopted an ordinance fixing a schedule of rates which was higher for the service involved than that fixed by the contract, and the defendant declined to furnish service at the contract rate. The decision of the Supreme Court upholds the defendant's position and overrules the plaintiff's contention that the ordinance is invalid.

Power of Traction Engines—When a contract for the sale of a traction engine contains a warranty on the part of the seller that the engine will develop a certain horsepower, but does not specify whether the power is to be developed at the belt or at the drawbar, the transaction will be governed by a trade custom placing an interpretation on the point, according to a late decision of the Texas Court of Civil Appeals in the case of Southern Gas & Gasoline Engine Co. vs. Adams & Peters, 169 "Southwestern Reporter," 1143. Under the evidence in this case, such a contract is held to be properly interpreted under a trade custom requiring the rated horsepower to be developed at the drawbar. Referring to the rule of law that the provisions of a written contract cannot be varied by showing oral conversations or trade customs which are clearly inconsistent with such provisions, the court said:

> It is not varying the terms of a written instrument to explain what is meant by a term used therein, especially a scientific or trade term which is not generally understood. Here we have the written instrument merely stating that the engine is to develop 20 hp. It is nowhere stated that it is to develop that power at the belt or drawbar, and the only way a layman could understand the term would be by proof as to what is meant by such a term. If it had stated that the power should be tested at the drawbar or belt, there could be no question that oral evidence could not be introduced which would tend to vary the writing. But parol evidence is admissible to aid in the interpretation of a scientific or trade term.

Another Feeder Accident in Cleveland

The municipal lighting plant at Cleveland celebrated the end of the year by a short-circuit in an overhead feeder leading out of the West 41st St. substation, which is the distribution center for the part of the city bounded by Lake Erie, West 65th St., Brooklyn and west of the Cuyahoga River. The trouble started about 8 p.m. on Dec. 31, and service was not restored till after midnight. It is stated that the cause of the trouble was a short-circuit in changing over feeders to consumers who formerly were served from the South Brooklyn plant to the new plant on East 53d St. In the area within which service was cut off, several hospitals reverted to oil lamps or gas, street lights were out and a number of moving-picture shows had to suspend operations.

Long Southern Electric Transmission

The Tennessee Power Co.'s Sequatchie Valley transmission line was completed about the middle of last December. Electric current was then turned on from the $10,000,000 power plant at Hale's Bar (of which the Tennessee Power Co. is now the largest customer) to both of the three-phase conductor circuits.

Although the generators have been connected to the transmission line since last August, only one of the three-phase circuits had been in full working order until mid-December. The transmission line is one of the most permanently constructed in the South and the longest line of the kind, voltage capacity considered, in that part of the United States.

College, the village at which the Brady power plant is connected with the Ocoee-Nashville line, is about 36 miles from Hale's Bar on the Tennesseee River. The voltage capacity of the connecting line is 120,000, or nearly double that of the line from the two Ocoee plants to Chattanooga and Knoxville.

The two circuits, each three-phase, consist of six heavy aluminum cables. One circuit is of 250,000 and the other of 400,000 circ. mils area. At Hale's Bar the Tennessee River is spanned by a 2331-ft. stretch of steel-core aluminum cables of ⅞-in. diameter, suspended between four steel towers 60 ft. high. The towers are set on high elevations so that the cables are 115 ft. above the water. There are 435 galvanized steel towers supporting the double circuit between Hale's Bar and College, the towers being spaced at intervals averaging 453 ft. The tops of the towers are connected with a ⅜-in. ground wire.

The insulators of the high-powered cables are the suspension-type porcelain disks, eight units to each insulator, except at the river crossing, where specially constructed insulators are used to support the heavy span. They are made of treated wood strips inclosed in oil-filled porcelain shells, the largest of the kind ever made; no others like them are in use. The first and eighth disks are 6½ ft. apart, and the mechanism holds the cable 12 ft. from the steel tower's supporting arm.

OBITUARY

JOHN McDONALD

John McDonald, an engineer well known locally and in the N. A. S. E., died of heart failure at his home in Ludlow, Vt., Dec. 17, 1914. He was 63 years of age. The greater part of his life was spent in engineering work.

ENGINEERING AFFAIRS

Award of the John Scott Medal—The city of Philadelphia, acting on the recommendation of The Franklin Institute, has awarded the John Scott Legacy Medal and Premium to Arthur Atwater Kent, of Rosemont, Penn., for his "Unisparker," an essential element of the Atwater Kent ignition system for automobiles, consisting of a contact breaker, governor and distributor, in one structure, and to Elmer Ambrose Sperry, of New York, N. Y., for his gyro-compass.

On battleships under action, the shifting of large masses of magnetic material precludes the use of the magnetic compass, and even on ordinary iron vessels, the material of the ship and its disposition must be compensated for. The gyro-compass is entirely nonmagnetic and is unaffected by the proximity of iron.

The Engineering Foundation—A noteworthy incident in the history of the profession of engineering in the United States will be the inauguration of The Engineering Foundation on Jan. 27, 1915, in the auditorium of the United Engineering Society in New York. The Engineering Foundation is a fund to be administered for the advancement of the arts and sciences connected with engineering and the benefit of mankind, the basis of which is the initial gift of a considerable sum by a noted engineer for this purpose. The American Society of Civil Engineers, the American Institute of Mining Engineers, The American Society of Mechanical Engineers and the American Institute of Electrical Engineers are to be represented equally in the administrative Board of The Engineering Foundation by election by the Board of Trustees of the United Engineering Society, which had been made the custodian of the fund. All members and friends of the engineering profession are invited to these inaugural ceremonies.

TRADE CATALOGS

Massey Machine Co., Watertown, N. Y. Catalog No. 7. Governors, Class M. Illustrated, 16 pp., 6x9 in.

Watson-Stillman Co., Aldene, N. J. Booklet. Kromax leather packings. Illustrated, 16 pp., 3½x6 in.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Bulletin No. 34-S. Small power driven compressors. Illustrated, 16 pp., 6x9 in.

Neil & Smith Electric Tool Co., Cincinnati, O. Catalog No. 4. Portable electric drills, buffers, grinders, screwdrivers, etc. Illustrated, 56 pp., 6x9 in.

BUSINESS ITEMS

The Cling-Surface Co., of Buffalo, N. Y., has prepared a special calendar for members of the N. A. S. E., copies of which it will gladly mail free on request as long as the supply lasts.

The Lagonda Mfg. Co., Springfield, Ohio, has just published a new 32-page booklet on the Lagonda Boiler Tube Cleaners. It is called catalog L-8—contains many illustrations showing details of construction and also cleaners in actual use, and copies are mailed on request.

The New York office of the Kerr Turbine Co., Wellsville, N. Y., will hereafter be located in Room 801, Singer Bldg. Annex. Mr. Benjamin G. Fernald has been appointed district manager. Mr. Lawrence G. Hanmer will continue to be associated with the New York office and arrangements have been made for prompt and effective attention to all inquiries.

The Files Engineering Co., of Providence, steam specialists and engineers, have established a branch office at 120 Kossuth St., Bridgeport, Conn., where they will contract for power, heating, drying, evaporating and steam specialty work of every description. They request catalogs and other literature descriptive of apparatus and appliances relating to these lines sent to their Bridgeport office.

"Cochrane Multiport Vales," a booklet of 72 pages, just issued by the Harrison Safety Boiler Works, 17th and Clearfield St., Philadelphia, Penn., describes the multiport valves introduced by that concern for back-pressure, relief and vacuum service, flow service in connection with mixed flow turbines, and check-valve service with bleeder or extraction turbines. In addition to full descriptive and tabular matter, the book contains numerous diagrams and layouts, also data on the effects of air in condensers and upon turbine performance.

A booklet worth having is the new booklet issued by the United States Graphite Co., Saginaw, Mich., on the subject "U. S. G. Co.'s Mexican Graphite Paint—Its Uses and Users." It is an excellent booklet from the standpoint of printing as well as subject matter. Fine halftones are used throughout, illustrating many buildings, bridges, etc., where the paint was used. Complete details are given about graphite, the care used in making the paint, and the "reasons why" it should be used. And letters are used to show what success users have had with it. It's a 64-page booklet and is sent on request to anyone interested in graphite paint.

Among recent sales of Bruce-Macbeth gas engines, made by the Bruce-Macbeth Engine Co., Cleveland, Ohio, are the following: Magnolia Pipe Line Co., Fort Worth, Tex., two 150-hp. natural gas engines; Thompson Milling Co., Lockport, N. Y., one 350-hp. natural gas engine; Village of Wellington, Ohio, for municipal lighting plant, one 125-hp. natural gas engine; Kloss Ice Cream Co., Wheeling, W. Va., one 90-hp. natural gas engine; Broadway Market Co., Detroit, Mich., one 90-hp. artificial gas engine; one 70-hp. two-cylinder natural gas engine to J. K. Mosser Co., Parsons, W. Va.; one 150-hp. four-cylinder natural gas engine to Victor Auto Parts Co., Cincinnati, Ohio; one 70-hp. two-cylinder natural gas engine to the Willson Ave. Lumber Co., Cleveland; one 150-hp. four-cylinder natural gas engine to Chisholm Steel Shovel Works, Cleveland, Ohio.

The annual report of the Northern Equipment Co., Erie, Penn., manufacturer of the Copes boiler feed water regulator and the Cope pump goveraor, shows that 1914 was the greatest year in the history of its business. Its sales exceeded its next best year by 9½%. Larger quarters have again become necessary, and in order to provide this it has purchased the plant, equipment and business of the Erie Pump & Engine Works. The new plant is located in the heart of the city and affords excellent shipping facilities. Mr. J. H. Dougherty, formerly with the International Steam Pump Co., has been engaged to take charge of centrifugal pump design, and the well known line of Erie centrifugals is to be improved and extended. A consolidation of the two companies is being perfected and the new combination will be known as the Erie Pump & Equipment Co. The officers of the new company are: E. W. Nick, president and treasurer; D. H. DuMond, vice-president; V. V. Veenschoten, secretary. Mr. John G. Pfadt, former president of the Erie Pump & Engine Works, is not connected with the new company.

CONTRACTS TO BE LET

TREASURY DEPARTMENT, Supervising Architect's Office, Washington, D. C., January 5, 1915.—Plans and specifications are now approaching completion for a central heating, lighting and power plant, to be erected in this city under the direction of this office. These plans and specifications will be ready for delivery on or after January 15. Bids may be submitted for the entire work or for any one of the following sections: Power plant building complete, with steel stacks; boilers; generating apparatus; pumping equipment; condensers; coal and ash handling apparatus; steam and water piping; switching gear; tunnels; substation apparatus, etc. Prospective bidders should immediately submit to this office applications for plans and specifications, stating the portions of the work upon which they desire to bid. If it appears that the applicant is in a position to bid on all of the work in any one of the sections of the project, or upon the entire work, the plans and specifications will be forwarded. No plans or specifications will be furnished sub-bidders or others not in a position to submit a bid on all of the work comprised in at least one section. The Department will be able to allow only about 15 days for the preparation of estimates. At the time plans and specifications are forwarded to bidders the date for the opening of bids will be stated, and this date will not be extended. O. WENDEROTH, Supervising Architect.

POWER

Vol. 41 | NEW YORK, JANUARY 26, 1915 | No. 4

"GUESS I'LL STICK AROUND A WHILE."

Power Plant of the J. B. Stetson Company

By Warren O. Rogers

SYNOPSIS—A plant in which more capacity was required. The problem was solved by putting in a mixed-pressure turbine, utilizing the exhaust steam from the engines and numerous pumps. The condensing water goes to a cooling tower which, owing to the restricted ground area, is supported on concrete posts in the yard.

When an engineer puts on his "Stetson," he gives but little thought to the power plant which made the manufacture of this hat possible or to the immense factory in which it was made. While the power plant of the J. B. Stetson Co., Philadelphia, Penn., is not new, it has interesting features, and illustrates how more power and greater economy may be obtained in a plant where the engine room cannot well accommodate additional units.

Fig. 1 is a general view of the engine room, which houses three 24x48-in. and two 30x48-in. horizontal engines, one $8\frac{1}{2}$x8-in. single-acting, vertical reciprocating engine, and a Rateau-Smoot mixed-pressure steam turbine which uses the exhaust steam from such engines as are run. Before the turbine was put in, both of the large units and two of the small ones were used, leaving one 250-kw. unit as a reserve. On the average these engines consumed $24\frac{1}{2}$ lb. of steam per horsepower-hour. With the turbine, but one 500-kw. unit and one 250-kw. set are operated, with a large and two small units held as reserve. This means cutting out a 375-hp. and a 750-hp. unit, which at $24\frac{1}{2}$ lb. of steam per hour represents a saving of 27,562 lb. of live steam per hour. Crediting the boilers with evaporating 9 lb. of water per pound of coal fired, a saving of 3062 lb. of coal would be had. This makes $1\frac{1}{2}$ tons per hour, or 15 tons per day of 10 hours, and is a saving of $48.75 per day if the coal cost is $3.25 per ton.

As there are 14 boilers in the three boiler rooms, all connected to the same steam main, and as the turbine is a recent addition to the plant equipment, figures regarding the actual saving in fuel are not available. The foregoing, however, gives a fairly good idea of what the turbine is doing in the way of economy.

Exhaust-Steam Lines

The exhaust line from the two 30x48- and the two 24x48-in. engines begins with a 12-in. pipe and increases to 14-, 16-, 18- and 20-in., as indicated by Fig. 2. The other 30x48-in. engine exhausts into a 16-in. line, which also receives the exhaust from the steam pumps, and a 16x42-in. Corliss engine used to belt-drive a lineshaft in the pump room. This pipe line loops one end of the engine-room basement and joins the 20-in. main exhaust header. Exhaust steam is not only utilized by the turbine, but some is also used in the two 3000-hp. vertical heaters, which are piped as shown. Both are connected to a 30-in. atmospheric exhaust. The exhaust and the main steam lines in the basement (Fig. 3) are supported by brick

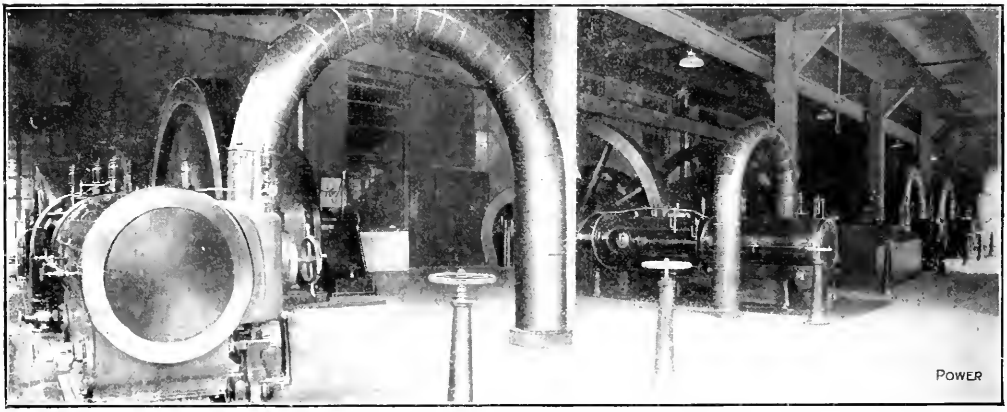

Fig. 1. General View of the Engine Room

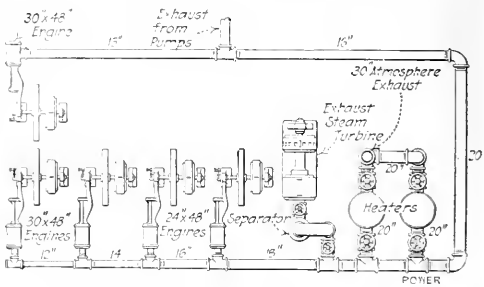

Fig. 2. Diagram of Exhaust-Steam Piping

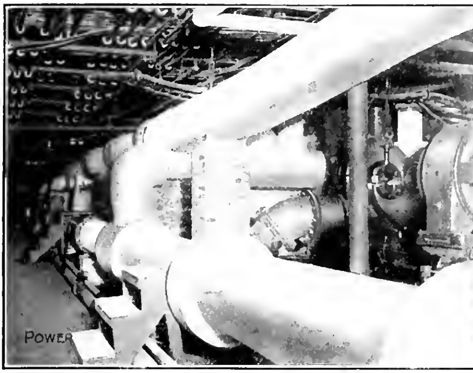

FIG. 3. LIVE- AND EXHAUST-STEAM MAINS

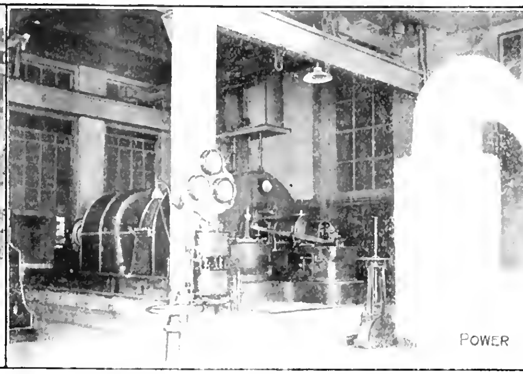

FIG. 4. LOW-PRESSURE STEAM TURBINE

piers; the lower pipe is the exhaust line. The motor-driven circulating pump supplies the surface condenser, which is further to the right, but not shown.

TURBINE AND CONDENSING APPARATUS

The low-pressure turbine (Fig. 4) is of 750-kw. capacity, generating 230-volt direct current at 1500 r.p.m. It is at the end of the engine room and rests on a con-

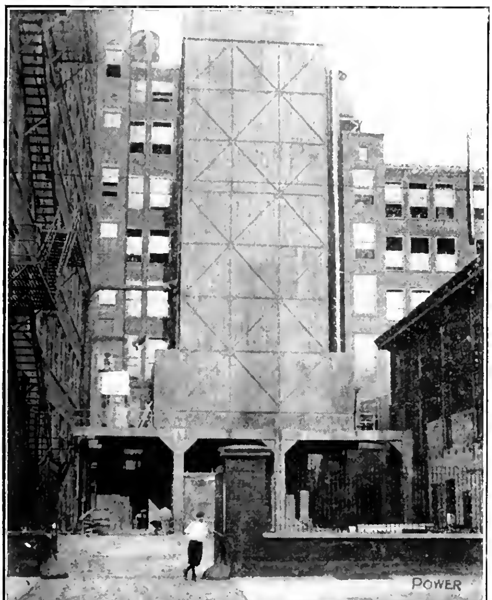

FIG. 5. COMBINED NATURAL- AND FORCED-DRAFT COOLING TOWER

crete foundation. In the basement below the turbine is the condensing apparatus. The surface condenser has 4200 sq.ft. of cooling surface made up of 1-in. outside diameter No. 18-gage tubes. Condensing water is supplied by a 12-in. centrifugal pump, having a capacity of 3000 gal. per min., and being driven by a 70-hp., 220-volt, direct-current motor at 950 r.p.m. The "rotrex" air pump is driven by a 14-hp., 220-volt, direct-current motor.

Owing to a restricted ground area, the cooling tower is in the yard and rests on a concrete base supported by concrete posts (Fig. 5). The tower is 27x27 ft. and is 75 ft. high. The condensing water is cooled by a combination of forced and natural draft, the forced draft being supplied by four 8-ft. fans driven by direct-connected motors. The hot water from the condenser is used in the factory for manufacturing purposes, thus utilizing the heat imparted to it in condensing the steam, the temperature of the water being 90 deg. The water from the cooling tower goes to the condenser at 89 deg. during the ordinary summer temperatures.

There are more than 500 motors throughout the factory

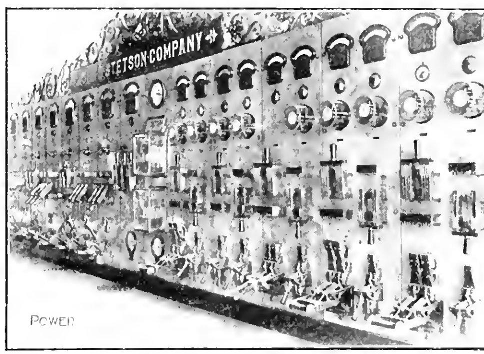

FIG. 6. DIRECT-CURRENT SWITCHBOARD

which range from 1/6 to 70 hp. in capacity. The load on the turbine is from 270 to 3000 amp., and that on the engines is from 3000 to 3500 amp. There is an average load of 6000 amp., or about 1500 kw.

The motor and lighting circuits are controlled from a 14-panel marble switchboard (Fig. 6), the generator panels showing in the foreground. The turbine generator is controlled from a bench switchboard (Fig. 4), between the second and third engines.

BOILERS AND PUMPS

Steam is supplied for the engines and for manufacturing purposes by fourteen water-tube boilers in three rooms. Fig. 7 shows the five large boilers.

Coal is delivered by wagons from the street into two

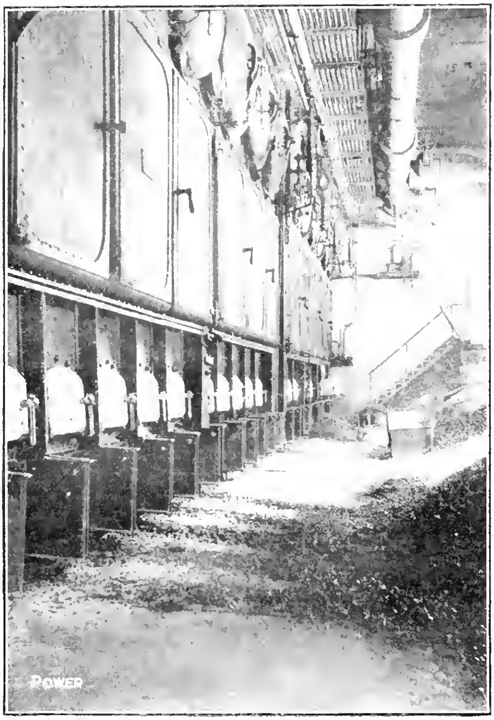

Fig. 7. One of the Boiler Rooms, Containing Five of the 14 Boilers

of the boiler rooms, which are below the street level, but in the third room it is elevated by a bucket conveyor to a storage bin. Ashes are wheeled to an ash conveyor and elevated to a bin on the outside of the boiler house, from which they are loaded into wagons on the street level and carted away.

The pump room (Fig. 8) is a fair-sized steam plant in itself. The largest unit is the 16x12-in. engine, already mentioned. From the lineshaft which this engine drives there are belted a 5½x8- and an 8x10-in. triple-plunger house pump for supplying fresh water to the factory, washrooms, etc. Both are equipped with regulators which maintain a pressure of 90 lb. on the pipe system.

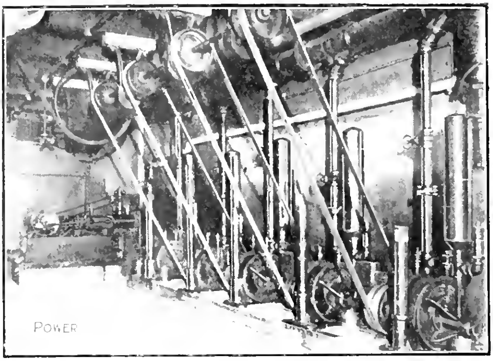

Fig. 9. Belt-Driven High-Pressure Blowers

Air for the factory is supplied by two compressors, one belt-driven from the lineshaft, the other being a compound steam-driven unit. Both supply air at 90 lb. pressure.

The factory has a system of vacuum cleaning. Vacuum is produced by two vacuum pumps, driven by a noiseless chain drive; each has a 24x18-in. cylinder and rated at 60 hp.

The refrigerating system not only keeps a proper temperature in the storage room for hat bodies, but it cools the drinking water for the factory. Since the introduction of this system of cooling the drinking water the rate of sickness among the workmen has greatly decreased. The system for cooling the brine supply consists of one 45-ton, 14x32-in. ammonia compressor, two 5x4-in. brine pumps, and the necessary apparatus. The drinking water is pumped to the factory by two 10x6x10-in. duplex steam pumps.

Boiler-feed water is supplied by a 14 & 20x40x18-in. and a 12x8½x12-in. duplex pump, working against 120 lb. pressure. Among the other apparatus is a 12x7x10-in. cold-water house pump, two vacuum pumps for the factory heating system, and a hydraulic pump for producing water pressures up to 300 lb. per sq.in. for the factory on various presses used in the process of manufacture.

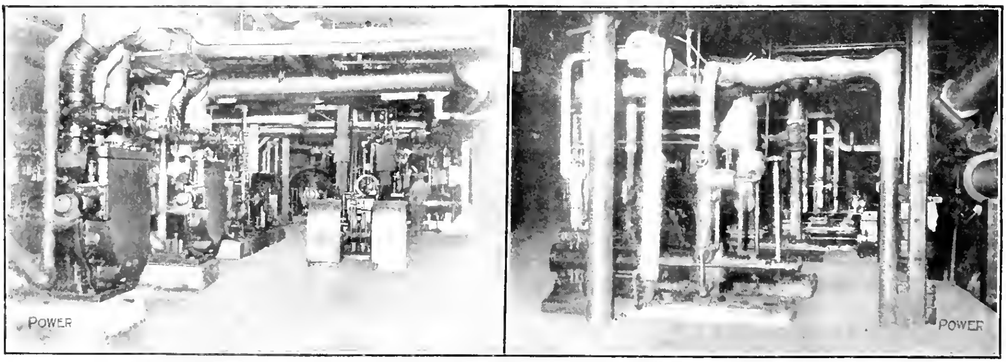

Fig. 8. Two Views of the Pump Room, Which Is a Fair-Sized Power Plant in Itself

At one end of the pump room is a set of five belt-driven, high-pressure blowers (Fig. 9) for the gas-heated irons in the factory. Each is fitted with a tight and loose pulley and is driven from an overhead shaft.

Miscellaneous

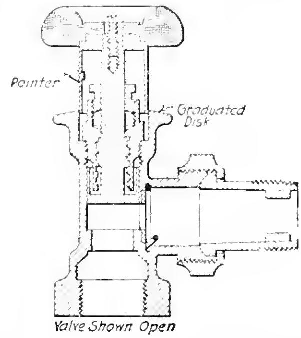
For the convenience of the employees a garage has been built, having steam heat, electric light, hot and cold water, compressed air, water for washing cars, asbestos and iron lockers, and a small machine shop for light repair work; also a charging station for electric automobiles. Out in the yard there is a rack for the accommodation of bicycles; they are stacked on end to occupy a minimum of room. A hospital is also maintained by the company and a large auditorium is available for entertainments.

The factory is wired with six trunk telephone lines, serving over 200 instruments, placed at convenient points. The 22 elevators are equipped with telephones, making it an easy matter for heads of departments to be reached when away from their desks.

A system of call bells has also been put in, so that no matter where the head of any department may be, the ringing of his signal denotes that his presence is required at his office.

amount of steam condensed per square foot of radiation under average demand conditions.

When used in connection with the atmospheric system



Section through Atmospheric Radiator Valve

of steam heating, it affords control of individual radiators, and just the amount of steam needed is used in each radiator to maintain the desired temperature.

PRINCIPAL EQUIPMENT OF THE JOHN B. STETSON CO. POWER PLANT

No. Equipment	Kind	Size	Use	Operating Conditions	Maker
3 Engines	Reciprocating	24x48-in.	Main units	90 r.p.m. saturated steam	Brown Engine Co.
2 Engines	Reciprocating	30x48-in.	Main units	90 r.p.m. saturated steam	Brown Engine Co.
1 Engine	Reciprocating	8x8½-in	Used after work hours	Saturated steam	Westinghouse Machine Co.
1 Turbine	Rateau-Smoot	750 kw	Main unit	1500 r.p.m. exhaust steam	Ridgeway Dynamo & Engine Co.
3 Generators	Direct current	250 kw	Main generators	90 r.p.m., 230 volts, 800 amp.	Crocker-Wheeler Co.
2 Generators	Direct current	500 kw	Main generators	90 r.p.m., 230 volts, 2000 amp.	Crocker-Wheeler Co.
1 Generator	Direct current		Used after hours	250 volts	Westinghouse Elec. & Mfg. Co.
1 Generator	Direct current	750 kw.	Main generator	1500 r.p.m., 230 volts, 3000 amp.	Ridgway Dynamo & Engine Co.
1 Engine	Corliss	16x42-in.	Driving lineshaft, pump room	101 r.p.m.	Allis-Chalmers Co.
1 Condenser	Surface	4200 sq.ft. cooling surface	With turbine	27½-in. vacuum	C. H. Wheeler Mfg. Co.
1 Motor	Direct current	70 hp.	Driving circulating pump	950 r.p.m., 220 volts	General Electric Co.
1 Pump	Centrifugal	12-in.	With condenser	950 r.p.m.	C. H. Wheeler Mfg. Co.
1 Pump	Air Rotrex	18x36-in.	With condenser	225 r.p.m.	C. H. Wheeler Mfg. Co.
1 Motor	Direct current	14 hp.	Driving air pump	225 r.p.m., 220 volts	Sprague Electric Works
2 Heaters	Berryman	3000 hp.	Feed water	Exhaust steam	Benj. F. Kelley & Sons
6 Boilers	Parker down draft	500 hp.	Steam generation	Hand fired	Parker Boiler Co.

Adsco Graduated Radiator Valve

The improved Adsco radiator valve, illustrated herewith, is calibrated to supply a definite amount of radiation, and is designed to supply steam to standard sizes of radiators of the hot-water type.

The various capacities of valves are arranged in multiples of five square feet of direct radiation. These capacities have been established as the result of tests to determine the ratio of the amount of steam under a given pressure passing through the radiator valve, to the

The valve body is fitted with a graduated disk at the outlet. The valve travels from a closed to a full open position with a three-quarter turn. A pointer on the valve stem indicates on the graduated disk any fractional position between the two extremes. The claims for this valve, manufactured by the American District Steam Co., North Tonawanda, N. Y., are economy, freedom from clogging and that it will not stick after remaining idle.

A Common Error when trouble appears in the form of scored cylinders and valves is to hold the oil responsible for the damage. After the necessary repairs are made and possibly the mechanical cause of the trouble removed, another oil is substituted with very satisfactory results. Both oils may have come from the same field, had the same composition and physical properties, in fact, be the same oil, but from barrels with different trade names, so that the admiration for the second, together with the condemnation of the first, would be unjustified.

Lauson Heavy-Duty Kerosene Engine

Recently the John Lauson Manufacturing Co., New Holstein, Wis., placed on the market a four-cylinder, vertical, heavy-duty oil engine, of 80 and 100 hp., with cylinders $10\frac{1}{4}$x12 in. and 11x12 in., respectively. Primarily, the engine is intended for small lighting-plant work, the regulation being close enough to permit operating alternating-current generators in parallel.

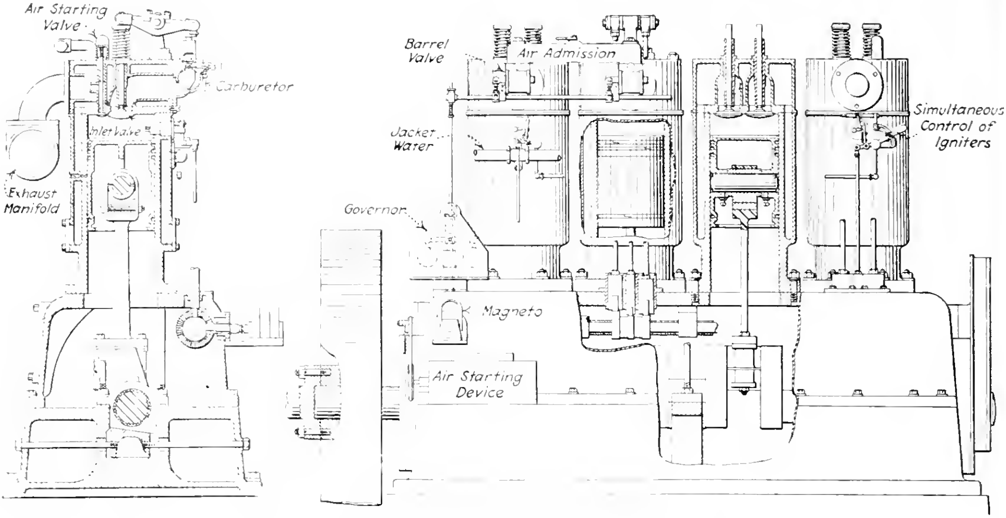

FIG. 1. TRANSVERSE SECTION AND LONGITUDINAL VIEW OF LAUSON ENGINE

The general construction is shown in Fig. 1. The crank case is of the two-piece type split horizontally at the center of the shaft. The valves are mechanically operated and located in the head. Make-and-break ignition is employed and cooling water for the cylinder jackets is supplied by a pump driven through a chain and sprocket by the main shaft.

The feature of the engine is the special carburetor or "Venturia" mixing nozzle, of which there is one for each cylinder. The principle of this device is to maintain a high velocity of air through a venturi tube having radial holes in its restricted portion through which the fuel is drawn by the suction of the air. The amount of air passing through the nozzle is controlled by the governor. The carburetor consists of a cast-iron body containing a cylindrical throttling chamber within which is fitted the barrel valve shown at *F*, Fig. 2. This valve is controlled by the governor through a bell crank and a horizontal shaft running the length of the four cylinders.

Fuel is admitted through the nozzle *D*, which has two sets of holes. The upper set is for the admission of gasoline for starting and kerosene for running, and the lower set for the admission of water to prevent premature ignition at full load. Three needle valves, one for each liquid, control the supply to the nozzle. On each side of the nozzle *D* is a port *I*, and when the engine is at rest these ports are wide open. Below the nozzle the governing port *P* will also be open. Thus, a certain proportion of the air passes through ports *I* and the balance through the nozzle *D*. As soon as the engine picks up in speed, valve *F* is rotated by the governor, gradually closing the ports *P* and *I*, so that a greater proportion of the air is deflected through the nozzle, thus maintaining a practically uniform velocity at this point. The high velocity of the air and the feeding of the fuel through a number of small holes insure atomization and a proper mixture before the fuel passes to the cylinder. A butterfly valve controlled by the handle *E* is provided to facilitate starting and for additional air adjustment at full load.

The igniters are of standard make-and-break design and operated from the camshaft. Two timing adjustments are provided, one individual and one simultaneous, the latter being used to shift all igniters at times of starting by a single lever. The mechanism is shown in Fig. 1. An insulated brass bar charged by a gear-driven alternating-current magneto is placed above the igniter plug. A spring coming in contact with the bar puts the igniter in the circuit and eliminates the need for wiring.

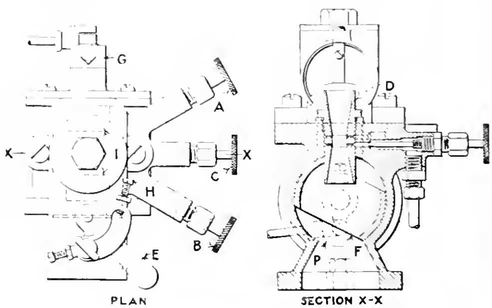

FIG. 2. THROTTLING CHAMBER

For starting, a special device furnishes the air in turn to each cylinder. The device consists of a main body having four radial air ports connected by piping to the different cylinders. These ports are covered and uncovered by a rotary disk valve having one port. The valve is held to its seat by the pressure of the air and is free to revolve when the air is shut off. Rotation is effected by means of a flexible coupling between the device and the camshaft. Compressed air, provided in the usual way, is admitted to the cylinder through a small valve in the head, which is shown at the left in the sectional view of the engine. As soon as the engine fires, this valve is held to its seat by the pressure within the cylinder. The engine is run for about ten minutes on gasoline and the fuel is then changed to kerosene.

The fuel reservoir has three compartments: one for gasoline, one for kerosene and one for water. The gasoline and kerosene compartments are kept full by means of pumps, and the water is controlled by a float inside the chamber.

The governor is of the vertical flyball type driven from a bevel gear on the camshaft. It is inclosed, as indicated in Fig. 1, and the speed may be adjusted by shortening or lengthening the rod from the governor to the regulating valve under its control. Lubrication of the five main bearings and the cylinders is effected by a force-feed pump. The connecting-rods depend on splash lubrication.

Quarter-Turn Rod Coupling

To obviate the noise and wear of a bevel gear between a jackshaft belt driven by a motor set on the engine-room floor and a centrifugal pump some distance below, C. P. Hall, chief engineer of the Rookery Building, Chicago,

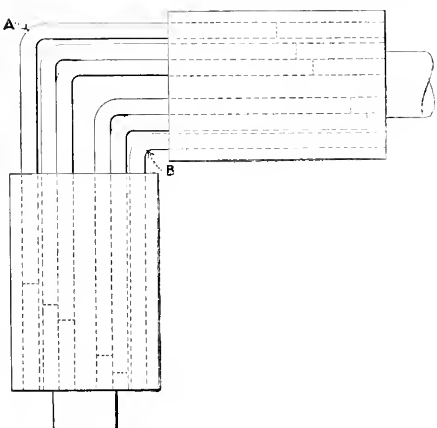

Fig. 1. Diagram of Coupling

invented an ingenious quarter-turn coupling consisting of two heads, bored to receive six rods of equal length. The jackshaft is horizontal and the pump shaft vertical, as indicated in Fig. 2. The coupling heads are merely solid pieces, bored for and keyed to their respective shafts. Within one-half inch of the circumference and spaced evenly around it, six holes are drilled to comfortably receive the rods. These rods are twice the length of a head plus the shortest exposed length shown in Fig. 1. They are free to turn in their sockets and slide lengthwise as the relative movements of the heads demand. When in the extreme position *A*, the ends of a rod are midway in the heads and in position *B* the ends are flush with the outer faces.

At first glance it would look as though the rods would twist together in a single turn of the heads. That this is not the case has been successfully demonstrated by Mr. Hall. Several couplings of the same kind as illustrated are in use in his plant. Fig. 2 shows a coupling connecting a jackshaft, driven by a 3-hp. motor, to a 3-in. centrifugal pump. The speed is 500 r.p.m., and at a distance of only a foot it was impossible to detect any noise from the coupling. The rods are well greased and as a precautionary measure a hood is placed over the coupling. The largest coupling is for a 10-hp. motor, but there is no reason why higher powers could not be transmitted; it is merely a question of size. To be safe the combined area of three rods should be equal to the area of the shaft.

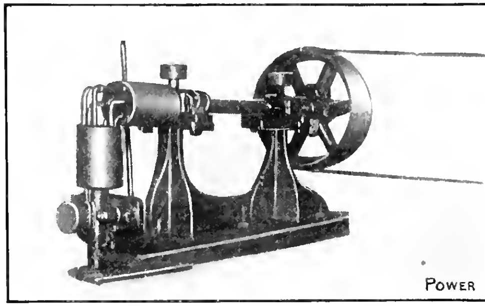

Fig. 2. Jackshaft and Coupling with Hood Removed

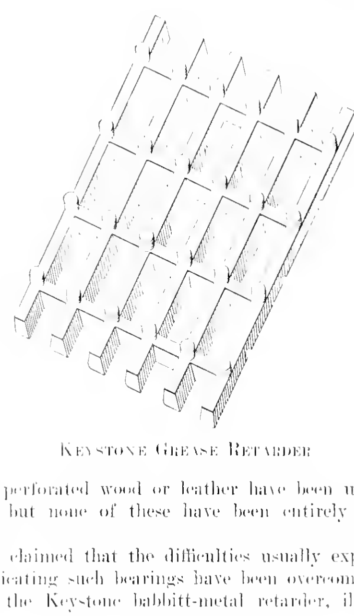
Keystone Grease Retarder

On large bearings where grease is used for lubrication, if the grooves are not cut in line with the center of the bearing, part of the journal is without lubrication. Retarders made from copper-wire gauze, perforated copper



Keystone Grease Retarder

plates, perforated wood or leather have been used with grease, but none of these have been entirely satisfactory.

It is claimed that the difficulties usually experienced in lubricating such bearings have been overcome by the use of the Keystone babbitt-metal retarder, illustrated herewith. This retarder is bent to conform to the curve of the journal and is made slightly narrower and shorter than the grease well; the grease is placed on top of the retarder in the usual manner.

The under side of the retarder is grooved, and one edge of each bar is rounded, so that the grease is wedged between the retarder and the journal instead of being scraped off. The grease is spread over the bearing surface and fed into the groove in the bearing cap, providing efficient and economical lubrication.

This device was designed by Thomas O. Organ, consulting engineer of the Keystone Lubricating Co.

Two New Nordberg Engines

SYNOPSIS—Cylinder a plain casting. Balanced poppet valves contained in heads. Valves positively operated by eccentric on lay-shaft and cam. Relief valves avoid over-compression.

Two new types of engine being built by the Nordberg Manufacturing Co., of Milwaukee, Wis., are shown in the shop photographs, Figs. 1 and 2. The former is an 18x32-in. poppet uniflow engine for the city of Bartow, Fla. It will drive directly a 150-kw. alternator at 164 r.p.m. Fig. 2 shows an 18x24-in. poppet valve "counterflow" engine which will be directly connected to a 175-kw. alternator and run at a speed of 164 r.p.m. Waupun, Wis., is to have this unit. All but the lower half of the flywheel on each engine is assembled. The simplicity of design will be apparent, especially that of the uniflow engine.

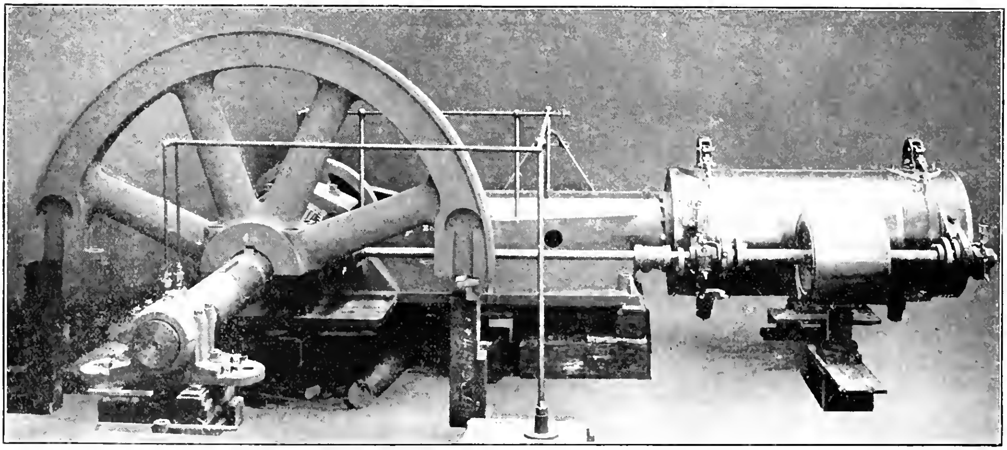


FIG. 1. NORDBERG POPPET-VALVE UNIFLOW ENGINE, 18X32-IN. CYLINDER

The word "counterflow" is used to make clearer the distinction between the uniflow type and an engine into which the steam flows in the ordinary way. So many new engines have been perfected within recent years that there is some confusion as to what the different names mean. The word "uniflow" has been coined to designate an engine in which the steam flow within the cylinder is only in one direction—unidirectional flow. In the usual engine there is a reversal of steam flow; on the out-stroke the flow is toward the advancing piston, and on the return stroke the same steam flows toward the cylinder head. In the uniflow engine the steam is admitted at the ends, as in the ordinary engine, but is exhausted through ports at the center of the cylinder, the piston acting as its own exhaust valve, as shown in Fig. 3.

The uniflow principle has to do with only the cylinder and exhaust-valve design, so that an engine of this type may be fitted with any style of valves and valve-gear for controlling the steam inlet. Corliss valves may be

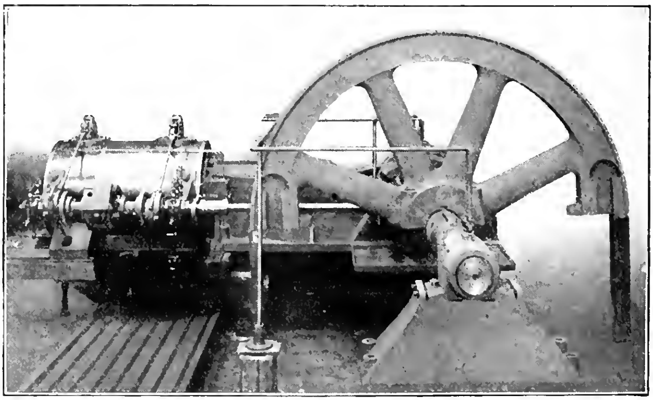

FIG. 2. POPPET-VALVE COUNTERFLOW ENGINE, 18X24-IN. CYLINDER

used, and a number of Nordberg uniflow engines have been so equipped. A description of this engine appeared in the June 11, 1912, issue of POWER. For high pressures and superheats, however, poppet valves are to be preferred.

Line drawings of both of the new engines are shown in Figs. 4 and 5. The frame is the standard Nordberg

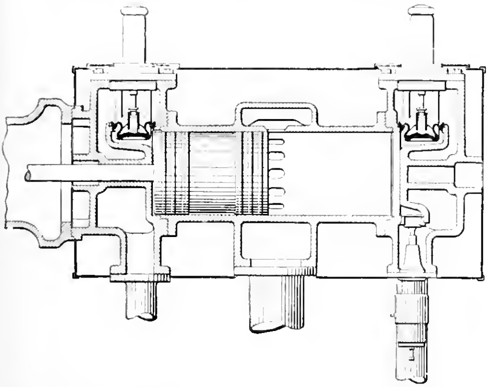

FIG. 3. SECTIONAL VIEW OF UNIFLOW CYLINDER

heavy-duty design with an oil pan cast integral under the crank and rod. The bearing, rods, guides and crosshead are also standard. The cylinders of these engines are of plain cylindrical form without steam chests—this to avoid distortion under high superheat. The steam removed by backing off on the rack. The cylinder may then be removed from the crank-end head. The valves are of the double-beat balanced poppet design, shown together with the operating cam and follower in Fig. 7. The valves seat on removable cages, which are steam tight in the cylinder-head casting. This construction was adopted to obviate the distortion common to seats cast integral with the cylinder casting. These cages can be renewed or removed for regrinding. No stuffing-boxes or metallic packing are used on the valve stems. These are ground to a close fit and then made tight by grooves which prevent leakage, on the principle of the labyrinth used in centrifugal pumps, compressors, etc.

The stubby, compact appearance of the valve bonnets is due to the absence of springs for closing the valves. In this construction the valve is opened and closed positively by one cam oscillated by an eccentric on the lay shaft, the throw of which is varied by an inertia and centrifugal governor located between the eccentrics. The design of cam, eccentric and governor is shown by the illustrations.

In the counterflow type of engine there are four cams—two at each end—one for the steam inlet, the other for the steam exhaust valve. In the poppet uniflow engine there are only two cams—one for each steam-inlet valve—the exhaust, as already explained, being controlled by the piston itself.

The uniflow engine is primarily a condensing engine. Expansion may be carried from high boiler pressure to 26 in. of vacuum within one cylinder at as good economy as ordinarily obtained with a compound condensing engine, owing to the reduction in cylinder condensation

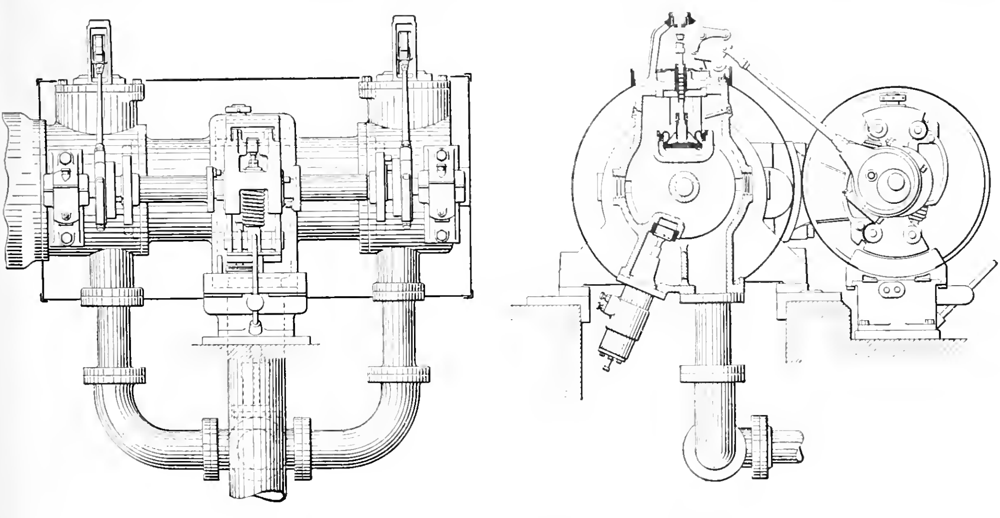

FIG. 4. LONGITUDINAL VIEW AND TRANSVERSE SECTION OF UNIFLOW CYLINDER

is led to each valve separately from the throttle valve placed under the floor. The cylinder heads are cast separately and contain the valves, and, as shown in Fig. 3, the design is such that the entering steam jackets the ends of the cylinder.

The arrangement of the cylinder and heads is shown in Fig. 6. To dismantle, the head with the valves is

effected by the uniflow construction. This type of engine has the further advantage of large overload capacity and a flat steam curve. It is claimed that it will carry 100 per cent. overload with a 10 per cent. increase in steam per horsepower-hour over the full load rate. At half load the steam rate is about 5 per cent. in excess of normal.

An objectionable feature of the uniflow engine is the high compression obtained when the vacuum is lost on when the engine is run noncondensing. In the present design this difficulty has been met by placing an automatic relief valve at each end of the cylinder. One of these valves is shown in Fig. 4. It opens from the clearance

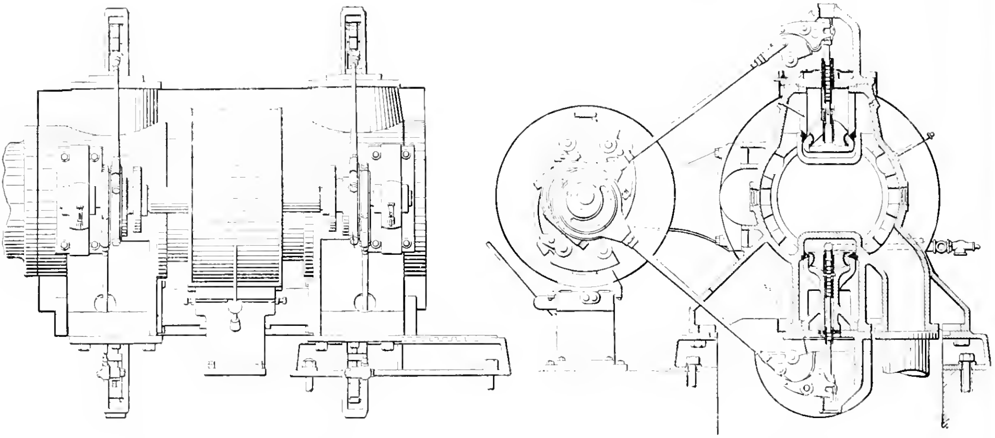

Fig. 5. The Poppet-Valve Cylinder with Positive High-Speed Valve-Gear

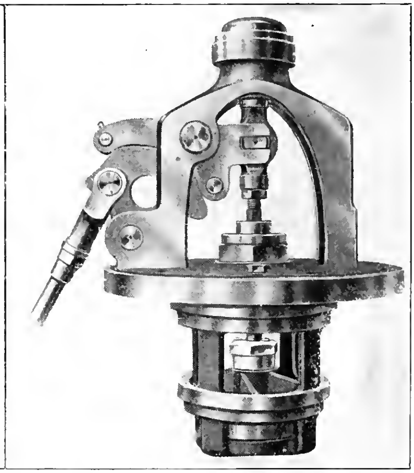

Fig. 7. Balanced Poppet Valve with Operating Cam and Follower

space and discharges the steam in its superheated state at the end of compression back to the steam piping; overcompression is thus avoided.

Pumping Water with Compressed Air—A 12x14¼x14-in. compressor furnished air for a mine pump 14x8x3 in. No other uses were made of the air and the air line was tight. Indicator cards were taken from both the air and steam cylinders of the compressor. The valve adjustments were good and the pistons tight. The total pumping head of the pump, including suction and pipe friction, was 103.1 ft. The water pumped was measured by a 4-in. orifice in a tank at the surface. The over-all efficiency from steam indicated horsepower to useful work done on the water was only 6.81%.

Crankpin Troubles

By C. W. Haynes

One of the common troubles encountered in the engine room is the undue heating of crankpins. Not properly relieving the brasses at the parting is one cause, and another is in not allowing sufficient clearance at the fillets.

A brass with no clearance may run for some time with little or no trouble, but after heating has taken place, it will be found upon taking it down that it has developed a decided tendency to grip the pin. To avoid this the clearance should be ample to reduce the bearing on the brass to the crown of the pin.

In roundhouse work, in a locality where the road was hilly, it was the common practice to reduce the area to nearly one-half of the arc of the brass without bad results. It would seem that this excessive clearance would result in heating, but it did not, even when the engines were pulling hard and running at high speed, or going down hill with the steam shut off, at which times the thrashing of the rods tries the pins severely. This shows that seemingly excessive clearance will not cause heating.

The locomotive engineer has troubles that the stationary engineer does not experience. In dry times the wind blows the dust, and in wet weather the mud between the ties is thrown up into the bearings; then when the oil is used up, out goes the babbitt. If the babbitt is all thrown out, there can be but little injury, but if the engine is stopped and the partly melted babbitt is allowed to freeze on the pin, cutting is liable to occur.

It is essential that the brasses be properly fitted and no high spots left to cause severe local heating. All of the flaky substance which covers a brass after heating should be filed or scraped away. It is not necessary, however, to scrape away all the file marks, which, being crosswise, afford lodgment for oil and are beneficial in newly fitted bearings.

A soft babbitt gives satisfaction when used in the inserts, but it should be peened in or it will get loose. Good results have been secured by fitting the brasses first and babbitting afterward. In doing so it is easy to leave the babbitt a little higher than the crown of the brass, insuring the benefit of the good qualities of the babbitt.

The following experience illustrates the benefits of babbitt inserts in bronze bearings. Certain gasoline engines using phosphor bronze on the crankpins gave trouble frequently until we put two rows of button inserts across each brass. Later, the use of phosphor bronze was discontinued in favor of a high-grade antifriction metal.

Not all the trouble with crankpins, however, is due to mechanical faults. The quality of the oil is responsible in many cases of heating. The superintendent one day wanted to know the cause of the poor condition of the crankpin bearings of a two-cylinder engine. He said the engine must have run dry earlier in the day. It was contended, however, that if the engine had run dry, the metal would have melted, but with a poor grade of oil the bearing had heated gradually, softening the metal and allowing it to crush out at the sides. That same grade of oil did give much trouble later.

When a newly fitted brass is put in hard service, a little tallow in the clearances helps to prevent heating. Fast-running engines must be kept snugly keyed up or the brasses and straps will chafe. When straps are off it is advisable to look them over for cracks, especially in the corners, where they are often easy to see. It is, however, good practice to wipe them carefully and paint with a thin coat of white-lead paint, then strike the strap or rod end with a soft hammer and if there are any cracks the oil in them will discolor the paint, thus indicating the extent of the fracture.

Brasses running loose at high speed will pound themselves hot and may fracture the running parts.

Forced-Draft Cooling Towers

By E. Raymond Goodrich

SYNOPSIS—Analyses and test data of forced-draft cooling towers, with heat-temperature curves for moist air, and examples illustrating their use.

In a rapidly increasing number of condenser installations, some sort of water-cooling medium becomes a necessity, and, on account of its small space requirements, the forced-draft cooling tower is generally the most feasible. Since apparently little is known of the theory involved and also the practical limitations of the problem, it is the writer's intention to lay down certain principles, substantiated by accurate experimental data, which will enable one to choose intelligently between different designs and estimate the quantities involved.

The physics of water cooling is comparatively simple, and for present purposes is best illustrated by reference to Fig. 1, which represents a typical vertical section of an inclosed tower. Briefly, the operation is as follows:

Hot water enters the tank *a*, is broken up into streams as it leaves the distributing troughs at *b*, and trickles down through the filling *c* where it is still further broken up and comes into contact with the up-going air which enters at *d*. The cooled water is withdrawn from the reservoir *e*.

Inclosed towers are divided into two classes, forced and natural draft, according as the air is forced in at *d* by fans or flows in naturally due to the upward chimney effect when a tall stack is used. The types of towers on the market are identical with the section given in Fig. 1, the distinguishing feature of different manufacturers being merely the arrangement of the distributing system and the kind of filling used. The following analysis holds good for all types.

Water passing through a cooling tower gives up its heat in three ways: First, by radiation through the walls of the tower; second, by direct contact with the up-going air; and third, by evaporation of a part of the water to be cooled. The first item is so small as to be well within the errors of any test and consequently may be regarded as negligible. The amount of cooling due to contact with the out-going air will now be considered. Call this h_1, in B.t.u. per minute. Then

$$h_1 = WS\ (t_2 - t_1);$$

where

W = Pounds of air passing through per minute;
S = Specific heat of air at constant pressure (0.2375);
t_2 = Temperature of the outgoing air;
t_1 = Temperature of the incoming air;

or, as it will be more convenient to express the air in thousands of cubic feet per minute,

$$h_1 = QK\ (t_2 - t_1) \qquad (1)$$

Where Q is the quantity of air in thousands of cubic feet per minute, and the factor K represents the amount of heat required to raise the temperature of 1000 cu.ft. of air through 1 deg. F., taking into account that as the temperature rises, a pound of air increases correspondingly in volume. This value is given by the curve marked K, Fig. 2, and should be taken at the temperature of the outgoing air.

The heat loss represented by h_1 is between 15 and 20 per cent. of the total cooling, depending on atmospheric conditions.

Next consider the third item, the amount of heat abstracted by evaporation of part of the entering water, which represents by far the greater part of the cooling. Obviously, since all the heat lost by the water must be carried away by the air, the amount of this evaporation and consequent cooling will be limited only by the moisture-carrying capacity of the air. A cubic foot of air can contain only a certain amount of moisture, depending on its temperature, and when this maximum condition obtains, the air is said to be saturated at that temperature. When the air actually contains a smaller amount than this, then the ratio of this amount to the maximum possible amount is called the relative humidity, expressed in per cent. When air contains its maximum moisture at any temperature—that is, the humidity is 100 per cent.—if the temperature is decreased moisture will be precipitated; on the other hand, if the temperature is raised, the air will no longer be saturated but will be capable of absorbing a certain additional quantity of water vapor. It is this increasing moisture capacity with increasing temperature that has made the inclosed cooling tower the most efficient means of water cooling; in it the air is heated to the highest possible temperature, approaching that of the inlet water, and consequently evaporates the maximum quantity of moisture. The curve marked *P*, Fig. 2, gives the vapor-carrying capacity of air in pounds per thousand cubic feet at 100 per cent. humidity for different temperatures, the moisture content at any other degree of humidity being obtained by taking the corresponding percentage of these values.

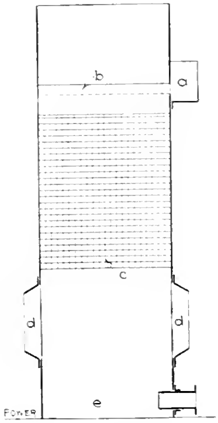

FIG. 1. DIAGRAM OF TYPICAL COOLING TOWER

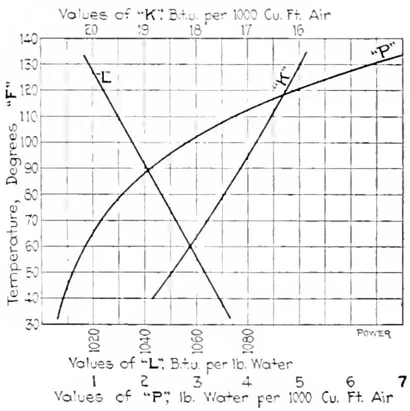

FIG. 2. VALUES OF K, L AND P WITH VARYING TEMPERATURES

Atmospheric air entering a cooling tower is rarely saturated, its degree of humidity being readily obtainable by taking simultaneous readings with the "wet-and-dry-bulb" thermometer and referring to tables in any engineering handbook; but as all cooling-tower estimates are made with direct reference to the humidity and proposals and guarantees are based on this factor, we will not extend our calculations further than this as a starting point. Calling the heat lost by evaporation h_2 and remembering that all the heat lost by the water is gained by the air, the general equation of heat transfer in a cooling tower becomes

$$H = h_1 + h_2 \qquad (2)$$

where,

$$H \text{ (heat lost by the water)} = 8.3\,G\,(T_2 - T_1) \qquad (3)$$

G being the gallons per minute passing through the tower, and T_2 and T_1 the respective temperatures of the incoming and outgoing water.

In order to best illustrate this, the analysis will be applied to test No. 1 in the table of "Tests on a Forced-draft Cooling Tower." The quantities are: $G = 651$; $T_2 = 105$ deg.; $T_1 = 84.7$ deg.; $t_2 = 90$ deg.; $t_1 = 71$ deg.; humidity in = 40 per cent.; humidity out = 100 per cent.

Therefore,

$$H = 8.3\,(651 \times 20.3) = 110{,}000 \textit{ B.t.u. per min.}$$

The B.t.u. by direct heating will be

$$h_1 = QK\,(90 - 71)$$

where Q is the quantity of air in thousands of cubic feet per minute, and K is taken at 90 deg., equal to 17.15 (see Fig. 2). Therefore,

$$h_1 = 17.15 \times 19 \times Q = 326\,Q \qquad (4)$$

The term h_2 is obtained as follows: The moisture content at 71 deg. and 40 per cent. humidity will be $1.16 \times 0.40 = 0.464$ lb., which is the amount of moisture entering the tower with every thousand cubic feet of air. On leaving the tower, the entering air will have increased in volume due to the rise in temperature, so that the quantity of air leaving per minute will be

$$Q\left(\frac{550}{531}\right) = 1.034\,Q$$

where 550 and 531 are the absolute temperatures of the outgoing and incoming air. The moisture content of 1000 cu.ft. at 90 deg. and 100 per cent. humidity is 2.13 lb., the humidity of the outgoing air always being approximately 100 per cent. in a properly designed tower. As there is $1.034\,Q$ thousands of cubic feet leaving the tower, the moisture carried away by the original air that entered the tower will be $2.13 \times 1.034\,Q = 2.205\,Q$. Subtracting from this the moisture held by the air as it entered, gives

$$M = 2.025\,Q - 0.464\,Q = 1.561\,Q \qquad (5)$$

which is the amount of moisture actually evaporated from the water going through the tower, and represents the quantity of makeup water to be supplied per minute.

In order that water may evaporate, it must absorb a certain amount of heat per pound evaporated, called the latent heat of evaporation, the value of which depends upon the temperature at which evaporation takes place; this is given by curve *L*, Fig. 2. As all the moisture is finally heated up to the temperature of the outgoing air, it is correct to use the value of *L* at this temperature. Therefore, the heat absorbed due to evaporation by the air leaving the tower will be $h_2 = 1.561\ Q \times 1041 = 1628\ Q$.

Now by equation (2),

$$H = h_1 + h_2$$

Substituting:

$$110{,}000 = 326\ Q + 1628\ Q$$

and,

$$Q = \frac{110{,}000}{1954} \times 1000 = 56{,}294\ \textit{cu.ft. per min.}$$

By referring to the test, it will be seen that 53,900 cu.ft. of air was actually measured by the anemometer, which is

RESULTS OF TESTS ON A FORCED-DRAFT COOLING TOWER, AVERAGES OF THREE-HOUR READINGS

*Natural draft, fan not running.

NOTE—These tests were conducted with utmost regard as to the accuracy of measurements. The quantities of air per minute were obtained by anemometers being moved back and forth across the top of the tower at regular intervals, and the results were corrected so as to give the actual amount entering the tower. The water was measured both by a venturi meter and a calibrated pitot tube.

or about 10.5 gal. per min. of makeup water must be supplied to compensate for the loss by evaporation.

In order to greatly lessen the foregoing calculations, the "heat-temperature curves for moist air" (Fig. 3) have been compiled with special reference to cooling-tower work. A few remarks on these are necessary. The ordinates represent Fahrenheit temperatures and the abscissas total heat content in B.t.u. per thousand cubic feet of air. This heat content by no means represents an exact "heat potential" at any temperature, and it is only the difference of any two values which has a physical meaning. Neither are the quantities absolutely correct from a theoretical standpoint, as certain factors have been omitted to make the calculation possible; but they will give results which are correct to within 4 or 5 per cent., which is close enough for this class of work. To illustrate the use of the chart, again assume the conditions of test No. 1 in the table. As before, the heat H lost by the water equals 110,000 B.t.u. per min. From the curves the heat content per thousand cubic feet at 90 deg. and 100 per cent. humidity is 3350 B.t.u. The heat content at 71 deg. and 40 per cent. humidity is 1240 B.t.u. Therefore, 3340 — 1250 = 2090 B.t.u. is absorbed per thousand cubic feet passing through the tower, and

$$Q = \frac{110{,}000}{2090} \times 1000 = 52{,}631\ \textit{cu.ft. of air per min.}$$

By simply reversing the process, the terminal temperature may be found if the quantity of air is known. The column marked "Quantity Calculated" in the table was figured

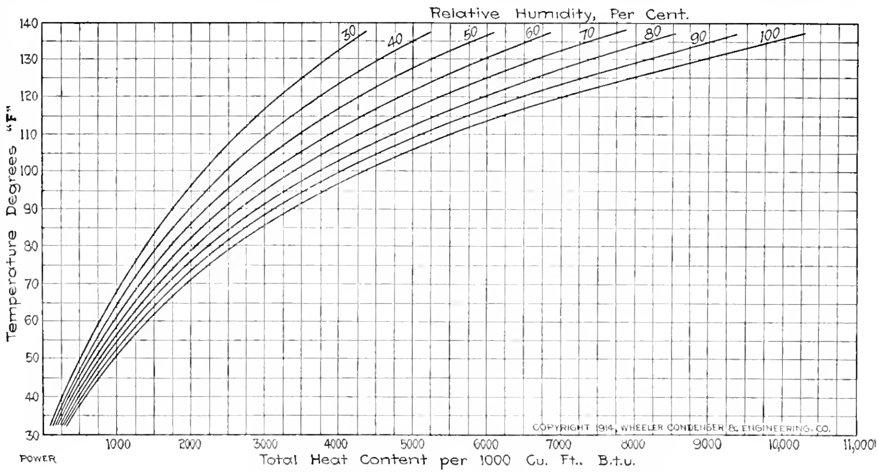

Fig. 3. Heat-Temperature Curves for Moist Air

a variation of only 4 per cent., or as close as might be expected, considering the difficulties involved in this kind of measurement.

By substitution of Q in (4) and (5), we have

$$h_1 = 326 \left(\frac{56{,}200}{1000}\right) = 18{,}321\ \textit{B.t.u. per min.}$$

This is 16.7 per cent. of the total 110,000 B.t.u. given up by the water; that is, approximately 83.3 per cent. of the cooling is due to the evaporation effect alone. Also,

$$M = 1.561 \left(\frac{56{,}200}{1000}\right) = 87.5\ \textit{lb.}$$

from these curves and shows how closely they check with actual results under a wide variety of conditions.

The maximum temperature of the outgoing air is limited by the temperature of the incoming water, and from an examination of curve P, Fig. 2, it is seen that as air increases in temperature, its water-carrying capacity, which represents about 85 per cent. of the total cooling, increases very rapidly. Due to this enormous increase in water absorption at the upper part of the temperature scale, it is evident that the air should leave the tower as near as possible to the temperature of the inlet water, and that an exact knowledge of this terminal difference is essential in figuring the amount of air required for a given duty. In fact, with other conditions remaining the same, the ratio of the temperature of the outgoing air to that of the incoming water represents the real efficiency of any cooling tower. A short calculation will bear this out. Suppose that the air in test No. 1 left at 5 deg. below the incoming water temperature—that is, at 100 deg.: then,

heat content at 100 *deg. and* 100 *per cent. humidity* = 4350 *B.t.u.*

heat content at 71 *deg. and* 40 *per cent. humidity* = 1240 *B.t.u.*

The difference is 3110 B.t.u. Therefore, the air required will be

$$\frac{110{,}000}{3110}(1000) = 35{,}369 \textit{ cu.ft. per min.}$$

as against 52,631 cu.ft. with 15 deg. difference. This means a saving of 34 per cent. in fan power as well as a much lower air velocity, lessening the tendency to cause spray, which is sometimes very objectionable, as well as wasteful. The terminal difference of 15 deg. obtained in the test is by no means average practice, and the results are given merely to show the close agreement of theory and practice in calculating air quantities. In later experiments, made with a view to increasing the efficiency, the quantity of air was not measured. Just how successful these experiments have been is demonstrated by the report of a test recently made on a large installation in the Middle West, consisting of a special Wheeler-Balcke forced-draft tower. The results were as follows, the readings given being the average of a five-hour test:

WATER

Gal. per min.	3200
Temp. in	109 deg.
Temp. out	97 deg.

AIR

Temp. in	91 deg., 59 per cent. humidity.
Temp. out	106 deg., 100 per cent. humidity.

The noticeable feature of these readings is the small difference of 3 deg. between the temperatures of the water in and the air out, giving a terminal efficiency of $\frac{106}{109} = 97$ per cent., which is remarkably high for forced-draft work.

Concerning natural-draft towers, but few remarks are necessary. In general, these will require from four to five times the ground area taken up by a forced-draft tower for the same duty, but where space is available they often find favor on account of requiring no power for operation and needing minimum attention. There are two classes of these towers, the open and the inclosed types. The open type is of cheaper construction, without sides, and admits air throughout its entire height. In the inclosed tower the air is admitted around the base only, and in its upward passage it is entirely protected from the cooling effects of the outside atmosphere. Moreover, due to its low velocity, the air leaves the tower at the same temperature as the inlet water; in fact, repeated tests have shown that the terminal efficiency is practically 100 per cent. In addition to this, the sides give a positive chimney effect, which insures a maximum draft and consequently minimum space requirements for this type of apparatus. In the open tower the quantity of air entering at the bottom is necessarily small, due to the absence of draft effect, and its temperature is prevented from approaching very close to that of the inlet water by a continual inflow of outside air along its entire height. As these towers or racks, as they are sometimes called, lack the positive draft created in an inclosed tower, they are necessarily dependent upon prevailing winds, so that, even in the most advantageous spots, their operation is not reliable nor uniform.

As to guarantees, these usually specify the cooling of a certain amount of water through a fixed temperature range under one definite atmospheric condition (usually 75 deg. and 70 per cent. humidity). Prospective buyers often wish a detailed guarantee for some thirty or forty different conditions of temperature and humidity. This the manufacturer is unwilling to make, as it means waiting for payment until all these different weather conditions happen to prevail. In this connection, the curves of Fig. 3 become useful, especially in a natural-draft system, where the amount of air is not given. To illustrate, suppose a tower is guaranteed to cool 1000 gal. of water per minute from 105 to 85 deg., with the usually assumed air conditions of 75 deg. and 70 per cent. humidity, and that it is required to find the cooling under atmospheric conditions of 70 deg. and 50 per cent. humidity. In a natural-draft tower of the inclosed type, with the conditions of test No. 1, the air would leave at 105 deg. and 100 per cent. humidity. By equation (3)

$$H = 8.3\ (1000)\ (105 - 85) = 166{,}000 \textit{ B.t.u.}$$

By the curves

heat content at 105 *deg. and* 100 *per cent. humidity* = 4850 *B.t.u.*

heat content at 75 *deg. and* 70 *per cent. humidity* = 1800 *B.t.u.*

Heat taken up within the tower = 4850 — 1800 = 3050 B.t.u. Therefore,

$$Q = \frac{166{,}000}{3050}(1000) = 54{,}426 \textit{ cu.ft. per min.}$$

With a given load on the condenser, the heat interchange, the gallons per minute and the cubic feet of air will remain the same; namely, 166,000 B.t.u., 1000 gal. per min. and 54,500 cu.ft. per min. The heat content at 70 deg. and 50 per cent. humidity is 1320 B.t.u. Let X be the heat content of the outgoing air, then:

$$\frac{166{,}000}{X - 1320}(1000) = 54{,}426$$

Therefore,

$$X = 4370 \textit{ B.t.u.}$$

Locating the point 4370 on the 100 per cent. humidity curve, it will be found to correspond to an air temperature of 100 deg. This is also the temperature of the inlet water under the terminal conditions for this type of tower. By equation (3)

$$166{,}000 = 8.3\ (1000)\ (100 - T);$$

whence, T_1 = 80 deg. (outlet-water temperature), representing a total cooling of 20 deg., the same as in the first case. This is obvious when it is considered that both the heat interchange and the gallons per minute remain the same.

By assuming a terminal difference of from 5 to 10 deg., the same method may be applied to a forced-draft system.

For Power Plants at Mines when located near the mine itself an easy and economical method of disposing of the ash is to arrange a tunnel under the fireboxes, with a slope of not less than ⅜ in. to the foot. Connect this with a borehole and wash the ashes down the latter with mine water, where they may be used for flushing abandoned workings if desired.—"Coal Age."

Speed Characteristics of Direct-Current Motors

By Alan M. Bennett

SYNOPSIS—The factors affecting the speed of shunt, series and compound motors under different conditions of load and temperature.

Direct-current motors are classified as shunt, series and compound, depending on the method of field winding employed. While this classification is generally well understood, the speed characteristics of these types under various conditions of load, and while attaining their working temperatures, are not so well known. As these characteristics vary greatly in these types, the behavior of the motor under the above conditions becomes an important factor in determining its fitness for certain classes of work.

All motors are supposed to develop their rated speed at full load after having run a sufficient time to reach maximum temperature; and when the speed of a motor is referred to, it is understood to mean that which obtains under these conditions. Variations from the rated speed occur at two periods in the operation, namely, at the time when the motor is started cold and at no load but after the motor has reached its working temperature. The amount by which the speed under the first condition differs from the rated speed is known as the speed variation of the motor; it is sometimes spoken of as the variation from cold to hot. The change from rated speed under the second condition is known as the regulation of the motor. In each case the departure from rated speed is expressed as a percentage of this speed. Both the speed variation and the regulation may differ in motors of the same class and rating, these characteristics depending on design.

In order to determine the changes in speed under the conditions named it will be necessary to note the changes which take place in the factors that influence the speed. It is a characteristic of the electric motor that, under any condition of load and speed, it takes only the amount of current necessary to develop the torque required to do its work at that speed. This it does automatically in the following manner:

Any motor when running, by reason of its conductors cutting flux, must generate a voltage in opposition to that impressed on the motor terminals, and this will tend to limit the current which would otherwise pass through the armature due to its resistance alone. This voltage is termed the counter electromotive force of the motor, and, like that generated in any dynamo-electric machine, is directly proportional to the speed and the flux. For greater convenience in use, the relation shown by these factors may be written

$$e \propto r.p.m. \times \phi \qquad (1)$$

where

e = Counter electromotive force;

ϕ = Flux.

The above expression may be read: Counter electromotive force varies as the speed and the flux. The value of e is always such that the voltage drop in the motor plus e equals the impressed voltage, or letting I represent the armature current, R the resistance of the motor windings and brush contact, and E the impressed voltage: then

$$e + IR = E, \text{ or } e = E - IR$$

Substituting this value of e in equation (1),

$$(E - IR) \propto r.p.m. \times \phi$$

which by transposition gives,

$$r.p.m. \propto \frac{E - IR}{\phi} \qquad (2)$$

This expression, termed the speed equation of the motor, furnishes a basis for determining changes in the motor speed under any condition. It will be seen that the speed varies directly as the impressed voltage minus the IR drop, and inversely as the flux. Therefore, any condition in the motor operation tending to increase either the IR drop or the flux lowers its speed. Likewise, a decrease in either of these factors raises the speed.

Take the case of a shunt motor starting cold and consider the effect of heating on its speed. The voltage on the field of the motor will be the same as that impressed on its terminals, and whether the motor is loaded or not, the field will receive an amount of current depending on its resistance. This establishes the flux of the motor and fixes its speed. As the field rises in temperature its resistance increases and the field current becomes less. The flux passing through the armature is thus lessened, and from equation (2) it will be seen that the effect must be an increase of speed. This condition continues until the field reaches its final temperature. In commercial motors the speed increase from this source will vary from 4 to 8 per cent., depending on the amount of temperature increase and the degree of saturation of the magnetic circuit. The higher the saturation is carried, the less will be the variation in speed.

Temperature increase of the armature affects the speed slightly by reason of increased IR drop. With the motor starting under load there is a certain amount of drop, determined by the motor current and the resistance of the armature. As the armature heats, this resistance increases and with it the drop. From the speed equation it will be seen that an increase in IR drop means a decrease in speed. The amount of variation from this source is always small, however, averaging approximately 0.7 per cent. While for practical purposes it may be neglected, its effect will be seen to be opposite to that caused by field heating; that is, it tends to lessen the motor speed, whereas field heating increases it.

The regulation of the shunt motor, or its change in speed from full load to no load, while not entirely independent of field action, is caused chiefly by IR drop. This drop increases with the load, being the product of the current taken by the motor and the resistance of the armature and brush contact. Equation (2) shows that the effect of increasing the IR drop is to lower the speed of the motor. Therefore, over the range from no load to full load the motor will drop in speed. Regulation, as stated previously, is measured in percentage of full load speed, and in commercial motors will vary from 4 to 6 per cent.

The effect of the field on regulation is caused by armature reaction. By giving a slight backward shift to the brushes a certain portion of the armature ampere-turns are opposed to the field, which is thus weakened, with the result that the speed is raised. The effect increases with the load and compensates to a certain extent for the decrease in speed caused by the IR drop. This shifting, however, can be done only within limits determined by the sparking of the motor.

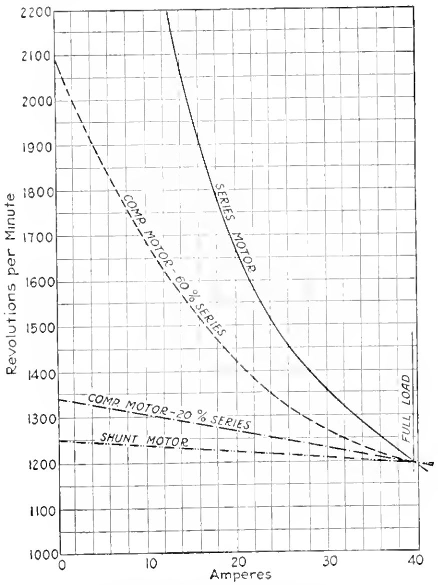

FIG. 1. SPEED CURVES FOR 10-HP. SHUNT, SERIES AND COMPOUND MOTORS

The regulation of motors is most conveniently represented by curves, as in Fig. 1. That for a 10-hp. shunt motor with a 5 per cent. drop in armature winding and brushes shows a decrease in speed from no load to full load of approximately 4.5 per cent.

In the case of the series motor, heating does not play so important a part in its effect on the speed. What variation there is from this source is caused by the IR drop only. As the motor heats, the resistance of the armature and series windings increases, and at constant load the drop increases, with the result that the speed is lowered. This effect is opposite to that in the shunt motor, where the speed increases with increase of temperature. The amount of this variation in the ordinary series motor will approximate 2 per cent., which is small compared to the change in speed caused by a change in load. In the series motor a change in load affects the speed both through the flux and the IR drop. The field current is dependent on the load, being the same as the armature current at all times. The flux passing through the armature being subject to the same variation, the effect on the speed can be seen. Theoretically, the latter would increase from its rated value at full load to infinity at no load. For this reason it is not practical to run series motors without some load in order that they may at all times have a field on them to prevent excessive speed. This is sometimes provided for by winding on a few shunt turns.

The effect of the IR drop due to change of load, while greater in the series than in the shunt motor—because there is a drop in the series winding as well as in the armature and brush contact—will still be small compared to the change caused by flux variation. For this reason the speed of the series motor, particularly below the saturation point of the field, will vary almost in exact inverse ratio with the change in flux and, for all practical purposes, the IR drop need not be taken into account. The speed curve for a series motor is shown in Fig. 1. For the sake of comparison it is made on the basis of the same armature and strength of field as that of the shunt motor whose curve is shown in the same figure. The rapid increase in speed as the load decreases will be noted.

The compound motor, having a field composed of shunt and series windings, partakes somewhat of the characteristics of both the shunt and the series motors. The speed will increase with the heating of the shunt field, as in the case of the shunt-wound machine. Heating of the armature and series field will cause an increased drop in those parts, with a consequent lowering of the speed. However, this drop and the resulting change in speed will be greater than in the shunt motor on account of the added resistance of the series field, the amount depending on the percentage of series windings carried by the motor.

Regulation will depend both on the IR drop and the change in flux due to the action of the series field. Of these two factors, the latter will have the greater effect. In fact, in those cases where the series field strength is in excess of 20 per cent. of the total, the change in flux will practically determine the regulation. As the percentage is increased, the change in speed with the change of load becomes more pronounced and approaches more

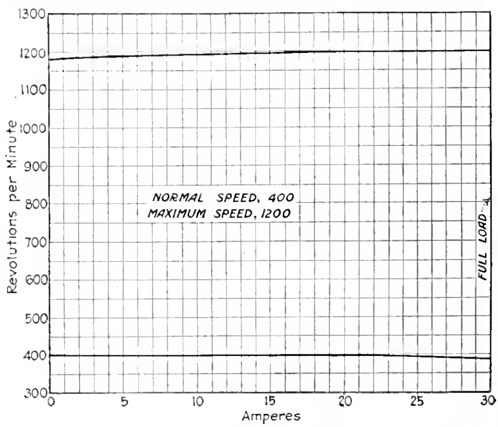

FIG. 2. SPEED CURVES FOR 7½-HP. INTERPOLE SHUNT MOTOR

nearly that of the all-series motor. There is the difference, however, that, due to the shunt field, the compound motor is not deprived of all its flux at no load, and there is not the danger of excessive speed, as in the case of the series motor. In Fig. 1 are shown two speed curves of compound motors, one having 20 per cent. series field, and the other 60 per cent. In the former the regulation is as close as 12 per cent., while in the latter it approaches very nearly that of the series motor. Both of these curves are on the same basis as regards armature and total field strength, as the curve for the shunt motor.

The compound motor, as generally known, has its series field so connected as to strengthen the effect of the shunt field as the load increases, and thus to gain some of the benefits obtained with the series motor, namely, a powerful starting torque and rapid acceleration. By connecting the series winding so that it opposes the shunt field, there is had what is known as the differential motor. This is done to compensate for *IR* drop from no load to full load and render the motor constant in speed over that range. As the load increases, the flux established by the shunt field is lessened by the action of the series, with the result that the speed, instead of falling off due to the *IR* drop, is maintained constant. The differential motor is not widely used, however, on account of other features which are a disadvantage, among these being low starting torque and lack of ability to stand overloads.

In the three regular types of motors described, it has been seen that the *IR* drop causes a falling off in speed from no load to full load, this being the least in the case of the shunt motor. Also, up to certain limits this can be compensated for by shifting the brushes and getting the effect of armature reaction on the field. In a motor fitted with interpoles this same compensation will be noted, only in a more pronounced degree. The action of the interpoles has a weakening effect on the main field similar to that produced by the armature. The result is an increase in speed as the load comes on. This action may even be so exaggerated as to cause a higher speed at full load than at no load, particularly with adjustable-speed motors at their weak field points. There is the difference, however, in the case of the interpole motor that the brushes must be kept at the neutral point on the commutator and brush shifting cannot be taken advantage of.

Fig. 2 shows speed curves for a 7½-hp. interpole shunt motor having a normal speed of 400 r.p.m., and a maximum of 1200 r.p.m. by means of field control. At the low speed it will be noted that the regulation is within 1½ per cent., the speed being practically constant, while with a weak field there is an actual increase of speed from no load to full load.

Powell Automatic and Double-Automatic Stop Valves

The Powell double-automatic stop valve prevents steam from entering a boiler not under pressure from a header, even should a handwheel be operated for this purpose, as the valve cannot be opened by hand until pressure is again raised in the boiler, but it can be closed and screwed down tight by hand. It also prevents steam from leaving the boiler in case of an accident to the pipe line.

The valve disk is of one piece, top and bottom guided at *A* and *B*, Fig. 1, and has a seat on both sides at *C* and *D*. The disk seats at *C* should anything happen on the boiler end and on *D* if there is any trouble on the main steam line.

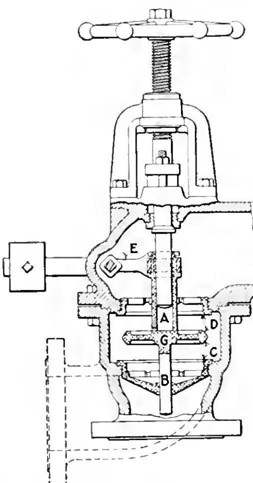

Fig. 1. Side View of Double Stop Valve

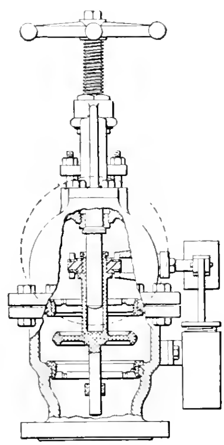

Fig. 2. End View of Double Stop Valve

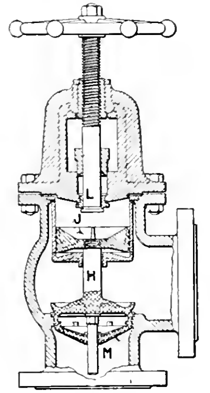

Fig. 3. Section through Single Disk Valve

The upper and lower valve seats are of special nickel composition to resist the corrosive action of the steam. The fork *E* is fastened to the balancing lever stem and holds the valve disk *G* in position, the weight balancing the valve disk. The oil dashpot, Fig. 2, the chamber of which is filled with oil, is to prevent the valve from chattering.

The valve also acts as an automatic equalizing valve between a battery of boilers and can be used as an ordinary stop valve by screwing down the stem onto the disk.

In the automatic stop valve, Fig. 3, the valve disk *H* is attached to the plunger *J*. The disk and plunger are made with but one screw part and are permanently fastened with two sets of screws, making practically one solid piece, guided at both the upper and the lower end. The dashpot fits snugly in the valve body. The rim of the upper part of the disk plunger *J* is grooved to work with a minimum of friction and respond readily to any variation in the pressure. The dashpot has two vent holes at the top and two at the bottom, to allow draining any condensed water that may collect therein. As the lift of the disk is equal to the depth of the dashpot, a full opening of the valve is insured. The height of lift is regulated as desired by raising or lowering the screw stem L.

The seat ring M is made with a guide for the lower part of the valve disk. When necessary, the seat can be readily renewed by inserting a flat tool between the lugs projecting from the circle and unscrewing. This valve will automatically shut off the flow of steam from the header to the boiler in case a tube should burst. It can only be opened by the pressure in the boiler, thus acting as an automatic equalizing valve between the battery of boilers, and also making it impossible to accidentally turn steam into a boiler when it is being cleaned.

These valves are manufactured by the William Powell Co., Cincinnati, Ohio.

Condensation in Hot-Blast Heaters

By James D. White

In the design of a hot-blast heating system it is necessary to know the number of pounds of steam required per minute to heat the specified volume of air through the desired range in temperature. Multiplying the cubic feet of air per minute by the weight of one cubic foot by the specific heat of air and by the temperature rise gives the number of British thermal units required. Dividing this product by the latent heat of steam at the average pressure in the heating coils gives the number of pounds of steam required per minute. Expressing this as a formula:

$$C = \frac{C.F.M. \times W \times S \times T}{L}$$

In which

C = Condensation in pounds of steam per minute;

$C.F.M.$ = Cubic feet of air per minute passing through the heater;

W = Weight of one cubic foot of air in pounds;

S = Specific heat of air;

T = Rise in temperature through the heater;

L = Latent heat of steam.

If steam is purchased from an outside source the formula may be used to determine the service to be provided. If steam is generated in the building it will determine the boiler-horsepower required, or the pounds of exhaust steam from the engines or turbines.

The main supply pipe to hot-blast heaters is often made too small, due to the fact that the actual requirements are not carefully considered. A rule of thumb common among steam fitters is to make the supply pipe equal in size to that required for direct radiation of five times the surface contained in the hot-blast heater. Cast-iron direct radiation for low-pressure steam will transmit about 250 B.t.u. per sq.ft. per hr. On the rule of thumb basis this would mean a transmission of 1250 B.t.u. per sq.ft. per hr. for the hot-blast heater. This transmission rate is correct for deep heaters with low velocities over the surface. For shallow heaters or high velocities this rate may run as high as 2500 B.t.u. per sq.ft. per hr., showing the error that may be made by the use of the above rule.

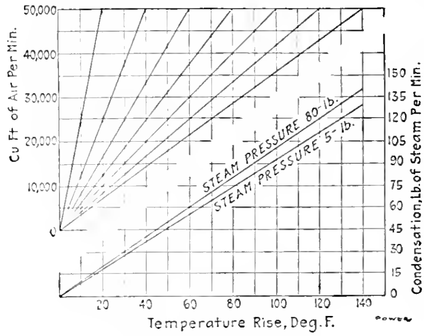
The following values are taken from published data regarding a well known type of hot-blast heater:

Number of Sections	Temperature Rise
1	32
2	59
3	82
4	100
5	116
6	129

From an inspection of the above values it will be noted that nearly one-fourth of the total heat rise is obtained in the first section of the heater. Since condensation is directly proportional to heat rise it follows that nearly one-fourth of the total steam required by a heater will be condensed in the first section.

It is customary to tap all sections of a hot-blast heater for the same size of pipe, this size being ample for the first section of the heater. There appear to be no good reason for this since a substantial saving could be made by tapping the sections in proportion to their steam requirements. The amount of condensation as calculated above is also useful in determining the size of steam trap or pump for returning the water of condensation back to the boiler.

The standard curves of hot-blast heater manufacturers are usually based on the heat rise with velocities of air



Condensation Curves

measured at a standard temperature of 70 deg. This temperature of air has been assumed for the volumes of air as given in the condensation curves presented herewith.

As an example, assume that it is desired to know the pounds of steam required to heat 40,000 cu.ft. of air per minute from zero to 100 deg. with steam at 5 lb. pressure. Starting at the line in the upper left-hand corner of the diagram corresponding to 40,000, draw a horizontal line until it intersects the 100-deg. line. Drop a vertical line intersecting the steam-pressure curve; then draw a horizontal to the right and find that the condensation is $74\frac{1}{4}$ lb. of steam per minute.

Safety Suggestions—If any employee shows signs of carelessness, tell him about it. If he persists, report him. Otherwise you may be the one to receive an injury through his negligence. Careless men are a menace to all around the power station.

Don't forget the other fellow. Careful men are hurt and killed every hour through the negligence of others. Better be safe than sorry.

Don't fail to look up occasionally; there is danger from above as well as below.

Don't fail to have any defective tools or equipment repaired at once.

Always treat conductors and switches as though they were alive.—"Aera."

Editorials

Obstructive Legislation

Large power interests, hiding behind the plea of states' rights, are attempting to defeat the Ferris water-power bill by creating a situation that will prevent the measure coming to a vote in the Senate before March 4, and there is growing apprehension that the same interests which have prevented conservation legislation for the last ten years will still be able this year to keep the natural resources in the public domain out of use and development.

It is a big game for big stakes that large financial and political interests are playing. Hydro-electric power is still in its infancy. Its possibilities are hardly to be conjectured. Even under present conditions of development, there is enough potential water power in the United States to take the place of the total coal consumption. In some parts of the country and under some conditions of construction, production of power from coal entails a lower installation cost than hydro-electric production, even where water power is available. Constantly improving methods of hydro-electric development and improving methods of power transmission, however, make it impossible for anyone to say what this water power will be worth or what its development will cost in the next decade or two. When the diminishing supply and increasing price of coal are considered, water power assumes an importance that can hardly be over-estimated.

So far-reaching were the plans and so rapid has been the progress of the hydro-electric monopoly that in 1913 twenty companies or groups of financial interests, all more or less closely interrelated, had acquired control of 2,710,866 of the 7,000,000 horsepower developed in the United States, and these same combinations also controlled 3,556,500 undeveloped horsepower. In California one corporation owns 27 per cent. of the total developed horsepower in the state, and two groups own 57 per cent. of the total development; in Oregon 90 per cent. of the developed horsepower is controlled by these allied groups.

With a few exceptions, the power sites not remaining in the ownership of the Federal Government have passed into private ownership in perpetuity. State governments generally have been notoriously profligate in giving away public property and franchises for small return or for no return, and until recent years, generally with no provision for regulation. In many sections state governments, to induce development and industries, have made it a rule not only to give away such valuable public assets, without price or restriction, but also to exempt such grants or gifts from taxation for a longer or shorter time.

Conservative estimates place the total available water power in the United States at 25,000,000 horsepower, of which 7,000,000 horsepower has been developed. Of the undeveloped water powers, about three-quarters are owned by "Uncle Sam," the power sites being located on public lands. Control and monopoly of this undeveloped power are the stake for which the big interests are playing.

To prevent more of the remaining water powers being grabbed by private monopoly through fraud or misrepresentation, the Government several years ago located all the valuable power sites in the public domain, and the President withdrew them from entry. Most of them are still withdrawn. Special interests protested, but the prevailing public sentiment was in favor of conservation, and then the interests changed their tune. Now they are all for states' rights. They are for conservation, and they are for regulation, but they want the Government to give the lands to the states and let the states do the regulating. The reason is that they can do business more profitably with state governments, governors, legislatures and utility commissioners than they can with the President, Cabinet officers, Congress and the Interstate Commerce Commission.

Secretary Lane, who is a Western man and who wants to see the resources of the West developed, has been backing legislation to encourage the use of water power and the mining of coal, oil, phosphates and potash under a leasing system. President Wilson supports this policy. The House of Representatives has passed the Adamson and the Ferris water-power bills, drawn along these lines. The Ferris bill provides that power sites may be leased for a term of not more than fifty years, with a twenty-year renewal of the lease at the end of the fifty-year period, on terms to be fixed by the Secretary of the Interior. At any time after the end of fifty years, the Government would have the right to take over the power plants by paying their fair value to the owners, and thereafter to either operate the plants as government institutions, or to sell or lease them to municipalities, states or individuals.

In support of this legislation, the President, Secretary Lane, such conservationists as Gifford Pinchot, and others have urged that a fifty-year permit would enable power companies to enlist capital and finance their operations profitably, giving the communities the advantage of early development and insuring against monopoly and extortion, with a reversion of these valuable rights to the public at the end of the franchise term.

Some of the big power interests have agreed to this program; others are opposing it, some of them openly, but more of them under cover. Senators who for years have been notoriously representative of big interests and special privileges are opposing the bill. The opposition, however, is subtle. It is not openly in opposition to limited franchises or regulation. To defeat the legislation, the old Civil War issue of states' rights has been dug up. Corporation lawyers, bankers, politicians and lobbyists are busy telling the Senate that the public lands, including the mineral resources and water powers, should be given to the states in which they are located.

The corporations and the politicians know what the states have done in the past with their resources and what they may reasonably be expected to do in the future. State utility commissions generally have few powers, and do not exercise them. Some of the Western states have no utility commissions and have never made any pretense of regulating anything. Mineral lands, water powers and similar natural resources belonging to these states have often been considered fair loot for anybody who could get them.

There are votes enough in the Senate to pass the bill if it can be got to a vote, but the opponents are prepared to play all the legislative tricks they know to prevent this. If they can stave off a vote until after March 4, the bill will then be dead, and a new bill will have to be passed by the House, which means more years of delay and disuse for the water power.

Purchasing Coal

The question of the ultimate advantage of purchasing coal on the B.t.u. basis is raised by Mr. Brownell on page 131 of this issue.

It is true that all of the coal mined must, or should, be used as fuel, and if the dealer cannot market inferior stuff in one place he will send it to some other place. This is, of course, an unavoidable condition of affairs to the dealer, and may be entirely satisfactory to the user so long as he is equipped to handle such fuel economically; but the purchaser or user should know what he is paying for or trying to make steam with. The crux of the whole matter is as the pure-food advocate, Dr. Wiley, has often said—he has no desire to dictate to or to prevent any individual from using adulterated foodstuff, but he does want him to have every opportunity of knowing what he is using and what the probable effect will be. Likewise in the use of coal, the consumer should know as much as possible of the characteristics of the available fuel supply in order to modify his furnace and equipment to suit the conditions. The total cost in fuel, labor and upkeep of evaporating water is the basis of comparison and the final test of the value of fuels. If the consumer has no alternative he must take what he can get and make the best of it.

13.8 Kw. per Boiler Horsepower

At a recent lecture by W. A. Blonck, of Chicago, before the New York Electrical Society, the interesting information was given out by Mr. Pigott, of the Interborough Rapid Transit Co., that eight boilers of 520 horsepower each are to serve 30,000-kilowatt turbo-generator capacity. This gives 7.21 kilowatts per boiler horsepower, which is considerably higher than that heretofore practiced. The Connors Creek station of the Detroit Edison Co. was designed so that in emergencies 5.65 kilowatts per boiler horsepower might be attained. This was the highest ratio heretofore.

The statement that so and so many kilowatts of output is obtained from a boiler horsepower does not tell much about the rating at which the boiler must be run unless the water rate of the prime mover is given, because the ratio is dependent both upon boiler rating or capacity and the steam consumption of the unit or units served by the boilers. The ratio is, however, an indication of the advance in boiler practice and turbine economy.

In this respect the Interborough's Seventy-fourth Street plant is interesting. The steam consumption of the 30,000-kilowatt turbine, served by eight 520-horsepower boilers, is 11.25 pounds at normal load. This gives 3.06 kilowatts per boiler horsepower at the normal rating of the boilers. So at a little over 200 per cent. of rating these eight boilers carry the load of 30,000 kilowatts, giving 7.21 kilowatts per boiler horsepower. A statement to us by Mr. Stott, superintendent of motive power for the Interborough Rapid Transit Co., that there might be times when it would be necessary to operate the boilers at 450 per cent. of rating for short periods, as in emergencies, is of much interest here. A boiler rating of 450 per cent. is possible, for with a clean and well designed boiler and furnace, the only limit to capacity is the amount of fuel that can be burned on the grate. As 3.06 kilowatts per boiler horsepower is obtained at 200 per cent. of rating, at 450 per cent. 13.8 kilowatts could be had per boiler horsepower.

James Watt must turn over in his grave at this.

Summary of Boiler Accidents

The list of boiler explosions which occurred during the first half of the year 1914 contains 320 as the total number. Of the number mentioned in our Jan. 5 issue, 20 are not included, because of denials on further inquiry that explosions had occurred. It frequently happens that in reply to our inquiry to the parties concerned a complete denial is received, but later information verifies the original report. This, in some cases, may have been due to an interpretation of the term "explosion" as a violent disruption of the body of the vessel used to generate steam. In general, for the purpose of tabulation the word is taken to apply to any failure which even temporarily puts the boiler out of use, including tube, header and blowoff-pipe failures. The nature of the failure is stated in every case in which the facts are obtainable. These statements are not always as full and satisfactory as might be desired.

The greatest number of accidents from any one cause was due to tube failures, but cast-iron header failures show an alarmingly increased percentage. When it is considered that from four to ten or more tubes are connected to a pair of headers and that a number of types of water-tube boilers in use are not so constructed, the total header failures compared with tubes is enormous.

Next in number comes the blowoff pipe. Considering the severe service and exposure of these pipes it is not surprising that they should deteriorate rapidly. This being generally recognized, it is evident that this part of the boiler should receive more careful and frequent scrutiny and should be replaced on the first appearance of weakness or danger. Cast-iron heating or domestic boilers are shown to be frequently neglected and mismanaged. In view of the damage done (in some cases well up in the thousands) when one of these boilers explodes, it cannot be said that they are receiving the inspection and supervision they should have. Even kitchen ranges and boilers have contributed a considerable amount to the total wreckage. A comparison of the totals for the first half of 1913 with those for the same period in 1914 follows:

Total number of accidents, 264 (1913), against 320 (1914), with a loss of life of 53 against 120, and injured, 192 against 240. The monetary loss was $193,000 (1913) and $246,000 (1914), respectively, with an average for those for which estimates were obtainable of approximately $1330 against $3000. Tube failures appear to have been more numerous during the year 1913, as 70 are shown, while a year later only 60 are reported. Header failures were only an incident, however, in 1913, while 30 occurred in 1914. Blowoff accidents stand 13 to 17, and cast-iron heating boilers 33 to 70 for the two periods, respectively.

Correspondence

Purchasing Coal

The writer recently had occasion to condemn a car of No. 1 buckwheat coal on account of excessive slate and screenings. A representative of the coal company arrived a few days later, and upon screening a 50-lb. sample from the car he found 12 per cent. rice or barley coal. A 10-lb. sample showed 14 per cent. slate.

The inspector passed the car, as he said the percentage was well within the allowance. Upon being pressed for some definite understanding as to what we were forced to accept, he made the statement that the coal company allowed itself 15 per cent. screenings and 15 per cent. slate. He was then asked if his company sold anthracite on a heat-unit basis. He replied that it would not sell coal on such a contract. Consequently, if the slate test is the only one which is acceptable, it becomes the test we are forced to use.

The large consumer situated on a navigable stream or where he can be served by more than one railroad can buy his coal on the heat basis, and he has this advantage over the smaller consumer who can obtain coal from only one railroad.

After all, does it pay? Is it to the consumer's advantage? Buying coal on a B.t.u. basis resolves itself into a matter of service. The consumer pays for that service whether he, the coal company or some disinterested party analyzes the coal, and when the cost of this service is put over against the gain, will not the apparent saving effected be wiped out?

R. A. Brownell.

Middletown, N. Y

Concrete for Furnace Lining

A concrete that could be used successfully as a boiler-furnace lining would do much to reduce the maintenance cost of the furnace. The largest item in furnace maintenance is labor, and when the labor is inexperienced, as when a bricklayer who never laid firebrick is engaged for the job and insists on laying the brick with a $\frac{3}{16}$-in. joint, the cost of upkeep is indeed high.

A concrete containing limestone would be unfit for the purpose because limestone calcines at a comparatively low temperature. The writer's experience with concrete furnace lining is limited to a test in which two patches 18 in. square were made, one on each side of the furnace, one patch being of slag concrete and the other of cinders. Neither proved satisfactory, probably because the concrete was not given sufficient time to set, the boilers being put back in service within 36 hours.

A concrete that may fulfill the requirements could be made of portland-cement clinker, graded from fine to coarse so as to make unnecessary the addition of sand. This concrete should be made with a minimum of water. Such material is sometimes used as a lining for cement kilns. Engineers in cement plants may be able to give some information on the use of clinker concrete in boiler furnaces.

Could boiler settings be made of concrete a great convenience would be effected; the two-inch air space is no longer fashionable, and the form work being simplified thereby, all the work could be done by the boiler-room force, thus eliminating the bricklayer.

C. O. Sandstrom.

Kansas City, Mo.

I have tried several different mixtures of cement and sand with hard-coal ash, soft-coal ash, flue cinder and salt for furnace lining, bridge-wall and fire-door arches. A mixture of one part cement, three parts hard-coal ash, one part fireclay, one-half as much sand as cement and about one per cent. salt made a bridge-wall that outlasted firebrick. For lining, I have been able to get a cement mixture that would outlast a good firebrick lining when properly laid, if there is time to let the wall harden thoroughly before it is necessary to start the fire.

The mixture described in Power, Dec. 15, p. 840—i.e., one of cement to five of hard-coal ash and one-half of sand—ought to be good, but I would add about one per cent. of salt to the mixture. When the wall gets hot the salt and sand will tend to melt and will fill up the pores and cracks showing in the cement.

For fire-door arches about the same conditions prevail. One part of cement, one of sand and five of hard-coal ash or broken soft-coal cinders or clinkers holds up better than firebrick set with fireclay. It is necessary, however, to let the arch have at least four weeks to set before putting the furnace into operation, and in many cases this is not possible.

A. A. Blanchard.

Oxford, N. J.

Graphite in Boilers

Much has been said in Power relative to the use of graphite in boilers. I first used graphite in a plant having four 300-hp. water-tube boilers. No compounds had been used in this plant and the tubes were in fair condition. It required, however, from twelve to fifteen minutes to get through a tube with a turbine cleaner, maintaining 180 lb. water pressure at the turbine, and occasionally we encountered tubes which required twenty to thirty minutes, but fifteen was a fair average. Before using graphite we turbined the boilers every ninety days, and this practice was followed for about nine months after it had been in use.

Notwithstanding that the output of the plant was increased more than 30 per cent. during the first nine months' use of graphite, we were enabled to increase the continuous runs of the boilers. Records show that two boilers were operated for 139 and 143 days, respectively, without turbining any of the tubes. Then they were opened and turbined throughout without difficulty. Furthermore, we were able to get through most of the tubes in less than eight minutes for each. Graphite did not show favorable signs until it had been in use more than five months and did not get in any good work until we had used it for about seven months; at this time one and one-half barrels had been used.

At the end of seven months we began loosening large pieces of scale in the steam drums. The writer put two good men in the drums for over two days, who succeeded in getting off large quantities of scale which ranged from 1/8 to 5/16 in. thick.

In my next plant I found dirty boilers and lost no time in ordering a turbine cleaner and a barrel of graphite. It required more than five months to get the cleaner, and this gave the graphite a chance to act before its arrival. I find that graphite will soften incrustation and loosen the heavy scale in the drums or on the sheets; it is, however, essential that mechanical methods be employed to remove the scale.

If maximum results are to be realized from the use of graphite, the boilers must be cooled down thoroughly before they are opened, and the drums must be washed immediately with a large hose and high water pressure. The scale will be soft mud when wet, but it will get hard when it dries.

It is much easier to wash the surfaces and then scrape them than to allow the accumulation to solidify and then pound it loose with the peen of a hammer. Do not take the tube caps or the man-heads off and allow a boiler to stand over night before washing and turbining. Take the tube caps off and put the turbine through the tubes as fast as possible. Then if any scale of consequence still remains, replace the cutters on the turbine cleaner with new ones and go through the tubes carefully the next day.

WALDO WEAVER.

Underfeed Stokers

In Osborn Monnett's article, "Underfeed Stokers," in the Dec. 15 issue of POWER, there is illustrated a "typical setting of American Stoker" under a return-tubular boiler. The stoker shown is not the American Stoker, but is the Type "D" of the Combustion Engineering Corporation. This stoker was formerly made by the American Stoker Co., and the drawing from which the illustration was made is of an installation made by that company. Mr. Monnett's assumption was natural, but it is regretted that he did not have the data on the Type "E" stoker for his article.

The Type "D" stoker is designed primarily for internally fired boilers with cylindrical or corrugated furnaces, but it may be applied to other boilers of 100- and 150-hp. capacity.

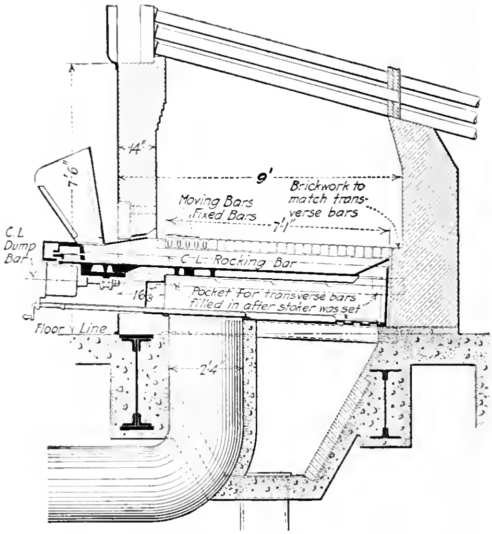
For boilers of 200 hp. and upward, the Type "E" stoker of the Combustion Engineering Corporation will effectually prevent smoke at ratings of 150 and 200 per cent. But one retort is installed in furnaces up to 12½ ft. wide.

The illustration shows a typical setting under a horizontal water-tube boiler. For vertically baffled boilers the minimum height of setting is 7 ft. 6 in. from the floor line to the header, and on Eastern coal of 16 to 26 per cent. volatile matter, 50 lb. per sq.ft. of furnace area may be burned without smoke. This is equivalent to 175 to 225 per cent. of the boiler rating. For Western coals of 30 to 40 per cent. volatile matter the height of the setting should be 8 ft. or more for similar results. There will, of course, be proportionately larger grate surface for Western coal if high ratings are required.

Operating

When starting fires with a Type "E" stoker, fill the retort and over-grates with coal about two inches deep, throw several shovelfuls of live coal along the retort and on the grates and start the blower slowly, increasing the speed as the coal becomes ignited. As soon as the coal is well ignited, start the stoker, increasing the coal feed and the air supply as required.

The fires should not be carried at over 8 to 12 in. in thickness with coking coal, or 4 to 8 in. with free-burning coal. The distribution of coal is uniform, making it unnecessary to poke, slice or rake the fires. The auto-



TYPE "E" STOKER UNDER A WATER-TUBE BOILER

matic regulation will take care of any variations in load between 100 and 200 per cent. of rating.

When ashes have accumulated on the dump trays to such a depth that the trays will not hold more, they should be dumped. Slow down the stoker slightly and burn out all coke on the trays, using forced draft if necessary. Drop the dump trays and if any clinker has adhered to the side walls or overhangs the ends of the fire bars it can easily be removed with a slice bar. Then restore the trays to the running position and operate the stoker a little faster than normal for a few moments; then throw in the automatic. Ashes should be dumped every two to four hours under ordinary conditions. The ash on the fire bars should not be disturbed.

When banking fires, shut off the air and feed in enough coal to make the required bank, then close the fire-doors and damper. If necessary the bank may be replenished by feeding in more coal.

To start from a banked fire, dump the ash, open the air gate a very little for a minute, break any large lumps of coke and then start the stoker, increasing the coal feed and air pressure as required. To kill the fire in case of accident, shut off the air, drop the dumps and feed coal to maximum capacity. Turn a hose into the ashpit to quench the live coal dumped.

JOHN VAN BRUNT,
Combustion Engineering Corporation.
New York City.

Centrifugal Pumps for Boiler-Feed Service

We have read with interest the extract from a paper by E. S. Adams, in the Dec. 29 issue, p. 934. From our experience we are inclined to disagree with this statement which appears on page 935:

> While this is especially true with motor-driven pumps, it also applies to turbine-driven pumps, as a serious overload (due to the enormously increased capacities which are obtained on some designs of pumps when the pressure is dropped) sometimes destroys the turbine.

The condition mentioned by Mr. Adams is impossible, as an overload beyond the designed capacity of the turbine would only cause it to slow down. We would be interested to learn of any turbine-driven installations where the action referred to has apparently taken place.

RAINES KESSLER,
Terry Steam Turbine Co.
Hartford, Conn.

Thick Boiler Plates

The article by S. F. Jeter in the issue of Dec. 22, p. 884, recalls to the writer a battery of horizontal tubular boilers in which the plates are $\frac{23}{32}$ in. thick (just $\frac{1}{32}$ under $\frac{3}{4}$ in.). At the girth seams the plates are reduced to $\frac{7}{16}$ in. in a way similar to that shown in Fig. 2 in Mr. Jeter's article, except that in this case, and in fact in all cases of heavy fire sheets that have come to my notice, both the inside and the outside plates have been reduced in the manner shown in Fig. 1 herewith. These boilers have been in service day and night for 12 years. Stokers are used and a steam pressure of 145 lb. is carried. The

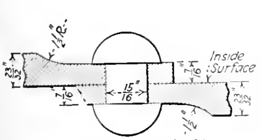


FIG. 1. GIRTH SEAM BELOW FIRE-LINE

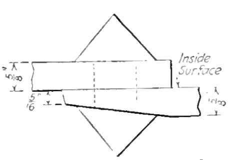

FIG. 2. INDICATING POINT OF OVERHEATING BY SCARFING OUTER SHEET ONLY

ONE FORM FOUND SATISFACTORY: THE OTHER QUESTIONED

service required of the boilers is much more severe than in the average plant, yet there has never been a leak or a fire crack at the girth seams.

Plates $\frac{23}{32}$ in. thick are the heaviest I have known in an externally fired boiler, and I have seen them with $\frac{9}{16}$-in. plates with the thickness of each plate reduced at the girth seams to about half the original thickness and none of them ever developed defects at this seam.

As Mr. Jeter points out in his Fig. 4, there is a tendency to crystallize at the calking edge when exposed to high temperatures. Crystallization of the plate at the point indicated might result in a fire crack extending from the edge of the outside sheet to the rivet hole, not a very serious defect and one easily repaired. In his Fig. 5 he suggests a method which would no doubt overcome the tendency to overheat at the edge of the plate, but which would transfer the crystallization to a point farther back, or about as shown in Fig. 2 herewith. A fire crack developing at this point would open into the solid plate.

Experiment or practice has not yet determined the heaviest plate practicable in an externally fired boiler. We do not know, however, that fire sheets $\frac{1}{2}$ in. thick stand up well under heavy firing with two full thicknesses of plate at the girth seam and that plates $\frac{5}{8}$ in. thick will fire-crack with a double thickness of plate under comparatively easy conditions. The limit of thickness at the girth seam may or may not lie within this range, but we do know that the girth seam shown in Fig. 1 has stood up well under severe conditions for a number of years, and the thickness of the joint is less than that made by two $\frac{1}{2}$-in. plates, and that the tendency to crystallize at the calked edge due to high temperatures is less than it would be in a girth seam with a total thickness of 1 in. through the joint.

THOMAS GRIMES.
Houghs Neck, Mass.

Cost of Steam

The cost of steam regardless of its use is an important matter to every live engineer. The information on this subject which occasionally appears is interesting and valuable, as it shows us what the other fellow is doing with his equipment, fuel, etc., and enables us to compare notes. I think we can stand a generous amount of steam cost data, but to be of maximum value the reports should be fully and accurately comparable. Most of them simply show that A has a small plant and pays $4 a ton for coal, and give a figure on the cost of steam per thousand pounds, based on the cost of labor and coal only.

B has a different plant, equipped with all of the latest devices for producing steam cheaply, and is able to buy and use a low-grade coal which gives an equivalent heat value. He therefore produces steam for much less money than A, which makes A feel like thirty cents when he sees it. Of course, we care nothing about A's feelings. Besides, it may wake him up and do him good. There is doubt, however, whether B has a right to feel so chesty. We have but part of the actual cost to A and perhaps less information from B, therefore, a fair comparison is out of the question.

It may be satisfactory enough to charge only coal and labor as the cost of steam as a means of comparing different coals, or for other comparisons within that plant, but when an attempt is made to get at the actual cost of steam or compare one plant's results with those of another, the need of reducing the results to a common basis is evident. This means a full description of the equipment, repairs, interest on the investment, insurance, taxes and depreciation. The cost of operating draft machinery, stokers, etc., should be included with the cost of labor and fuel. Until this is done no one can discuss relative steam costs intelligently. Any useful information is acceptable, but full and exact information is needed.

Yarmouthville, Maine.

Shaft Coupling Made into a Belt Pulley

While employed at Fort Yuma Indian School, I needed a six-inch belt pulley for a wood saw. As some readers may know, getting such supplies on an Indian reservation is a long and trying ordeal. Therefore, I used a flange coupling keyed to the saw mandrel, with thick planks bolted between and sawed to the same circle as the flanges. This served the purpose while we sawed 100 cords of wood for our winter's supply.

J. E. STROTHER.

Rock Island, Ill.

Calculating How to Cut a Manhole Gasket

The following questions were asked me recently in a steam-engineer's license examination. I also give my answers:

Could you cut a manhole gasket if the manhole head was not convenient to be used and do it correctly?

Yes, if I knew the distance between the two foci of the ellipse.

Given the long and the short diameters, how would you find the distance between the two foci?

Square half the long diameter, from it subtract the square of half the short diameter; the square root of the remainder is half the distance between the two foci.

I spent three days hunting for the answer to the last question, and I found another item that helps to show why the above answer is true.

To locate the two foci of an ellipse graphically, take one end of the short diameter as a center and half the long diameter as a radius and describe arcs intersecting the long diameter each side of the short diameter. These points of intersection are the two foci.

F. C. WIRES.

Seattle, Wash.

New vs. Second-Hand Machinery

M. E. Griffin's experience (POWER, Dec. 22, p. 889) with the man who wanted an exceptionally economical engine and finally purchased an old second-hand one reminds me of some of my own experiences with would-be cheap-power-plant owners.

A man in southern Florida hired me to install a three-ton ice machine and set up a new (?) sawmill. When I arrived I found an old belted compressor rated at three tons, but which its former owners had never been able to drive past one ton of ice in 24 hours, with a one-ton capacity brine tank and a cold-storage room taking approximately one ton of refrigeration for 24 hours, an old internally fired boiler all pitted and having several soft patches on it, also an old locomotive-type boiler with an engine mounted on it.

I set up the outfit, but refused to run it, and the last I heard it was still idle because it is cheaper to buy ice and pay freight on it than to make it with the outfit. The sawmill part of the equipment was a little better, and after getting a new boiler the owner finally did get a man to run it.

I was engaged another time as a millwright and master mechanic for a lumber company, the president and superintendent of which were experienced millwrights. The boiler and engine were too small, so they made up their minds to install larger ones. I advised them to get a new boiler and engine and get them from a reliable manufacturer, but they decided this was too expensive and finally bought a second-hand Scotch boiler that had been run about six months and then replaced by a return-tubular boiler of the same rated capacity, because the Scotch boiler would not do the work required.

I begged both the president and the superintendent not to take the boiler, as it was entirely unsuited to their work and to the fuel that they must use, and pointed out other defects, but they got it and the results turned out as I said; the furnace was too small to burn the fuel, and after trying several kinds of grates they finally inclosed the boiler in a brick setting, making virtually a double furnace. The outfit cost $250 more when finished than a new return-tubular boiler with a full brick setting would have cost.

The engine they bought was an old sawmill engine which had been over twenty years in service and through two fires. They paid $150 for it and $300 to have it repaired. A better engine could have been purchased new for less than $500, and would have been an engine, not a junk heap.

Why men will pay good money for worthless piles of scrap iron in the shape of second-hand engines and boilers I could never understand, for new outfits are always cheaper in the end.

A. A. BLANCHARD.

Oxford, N. J.

Testing Out Automatic Safety Devices

The editorial on "Testing Out Automatic Safety Devices," in the Dec. 1 issue, reminded me of a plant in which I was oiler. The engines were cross-compound Corliss, with the governor on the low-pressure side and a safety stop valve in the high-pressure steam pipe, operated by fly balls on the high-pressure side. These fly balls were called the high-pressure governor by the engineers.

I wanted to know if, in case of overspeed, the engineer or oiler could operate the valve. I was told yes, and that the automatic stop could be used instead of the throttle at shutting-down time.

I suggested that we try it at the first chance, and we did. Did the automatic safety-device work? Sure it worked, but not until we had spent several days scraping off burned oil and repacking.

G. D. Crain says in the same issue that "owners of larger plants have their boilers insured, which results in high-grade inspection." I beg to differ. I know of boilers that were insured and regularly inspected and, just as regularly reported in good condition; I also know that many of the tubes were packed solid with scale.

The editorial already mentioned says, "He is a wise engineer who will use those safety devices which lend themselves to hand as well as automatic control in handling the machinery which they should safeguard."

He also is a wise engineer who will inspect his own boilers, no matter how many inspectors may do it besides.

Chicago, Ill. W. H. MACKING.

Inquiries of General Interest

Grate Area with Mechanical Stokers—For a given boiler capacity, why is less grate area required for mechanical stokers than for hand-fired grates?

H. C.

The motion of the mechanical stoker maintains a cleaner fire by continuously disturbing the film of ash which is formed on the burning coal, so that the rate of combustion is greater per square foot of grate.

Causes of Pump Running Lame—What causes a duplex pump to run lame—i.e., the strokes on one side are shorter in length of time than those of the other?

B. L.

The slower-running side may have a leaky steam piston or the resistances of the water cylinders may be different, as from a worn pump valve, a leaky water piston or leaky valves on the quicker-running side or tighter water piston or stuffing-boxes on the slower-running side. When such faults have been corrected the lost motion of the steam valves should be adjusted to obtain the desired equality of strokes.

Using Soda Ash for Removal of Scale—Will a boiler be injured by using soda ash in the following manner? Before washing the boiler put in about 40 lb. of the soda ash, again close the boiler, and with the water a little above working level, boil slowly for a few hours, and after allowing the boiler to stand for three or four days, wash thoroughly.

R. G. T.

There should be no injurious results if care is taken to thoroughly wash out all traces of sludge from the try-cock and water-column connection and the soda solution is not permitted to enter the safety valve, for upon drying it would be likely to cement the valve to its seat.

Pipe Sizes for Hot-Water Heating—What is the rule for determining the sizes of supply and return pipes for a gravity hot-water heating apparatus with direct radiation?

J. M.

As there is no sensible change in bulk between the supply and the return water, the supply and return pipes should be of the same diameter. With ordinary conditions, and where the supply or return pipe is less than 200 ft. in length, it is a good practical rule to allow one pipe size greater than the square root of the number of square feet of radiating surface, divided by 9 for the first story, by 10 for the second story, and by 11 for the third story of a building.

Relative Volumes of Water and Steam—What are the relative volumes of a pound of water at 212 deg. F. and a pound of steam at atmospheric pressure?

W. R.

A cubic foot of water at 212 deg. F. weighs 59.833 lb., and one pound occupies a space of

$$\frac{1}{59.833} = 0.0167 \text{ cu.ft.}$$

while one pound of dry saturated steam at atmospheric pressure (14.7 lb. per sq.in.) occupies a space of 26.79 cu.ft., which is

$$\frac{26.79}{0.0167} = 1604.19 \text{ times the space occupied by the water.}$$

Indicated, Brake and Friction Horsepower—What is meant by indicated, brake and friction horsepower of a reciprocating engine?

S. C. M.

Indicated horsepower (abbreviated i.hp.) is the power delivered to the piston by the steam or other working fluid which is employed for moving the piston, and is so called because the effective pressure is usually determined by use of a steam-engine indicator. Brake horsepower (abbreviated b.hp.) is the power delivered by the engine exclusive of the power wasted in overcoming the friction of its moving parts. The brake horsepower is therefore always less than the indicated horsepower, the difference being the power required to overcome the friction of the engine. This difference is sometimes called the friction horsepower.

Capacity of Triplex Plunger Pump—What is the capacity in gallons pumped per minute of a single-acting triplex plunger pump having plungers 5½ in. diameter by 8 in. stroke and making 28 r.p.m.?

M. M. G.

The cross-sectional area of each plunger would be 5½ × 5½ × 0.7854 = 23.758 sq.in., and having three plungers, each with 8-in stroke, the total displacement would be:

$$23.758 \times 8 \times 3 = 570.192 \text{ cu.in. or}$$
$$570.192 \div 231 = 2.468 \text{ gal. per rev. or}$$
$$2.468 \times 28 = 69.1 \text{ gal. per min.}$$

The actual amount of water pumped would be less according to the "slippage," which would depend on the temperature of the water, height of suction lift, size, design and arrangement of suction and discharge valves and piping, and adjustment of the plunger packing. Under ordinary conditions the slippage would amount to about 5 per cent. and the net pumpage would be 95 per cent. of 69.1 or about 65½ gal. per min.

Racing of Electric Elevator—What would cause an electric elevator to race occasionally on its upward trip?

J. B.

If the electrical connections are not making good contact and the shunt field circuit is open, the motor will race, if compound-wound, or if shunt-wound the fuse will blow. A ground in the field coils, combined with a ground on some other part of the system, will also cause high speed. If the car is over counterweighted it may race on the up travel if the series field winding is not cut out of circuit. This is accomplished when the starting resistance is cut out, consequently it may be that the rheostat arm has stuck. Again, the operating mechanism may have drifted back to where it cut off the current from the motor, but not far enough to apply the brake. This would cause the car to race on the up travel without load if the counterweights are heavier than the car. Also, if the controller has been recently overhauled, some of the connections may have been misplaced.

Copper-Ball Pyrometer—How is the temperature of gases escaping from a boiler determined by means of a copper-ball pyrometer?

R. G.

A copper ball of known weight is suspended in the uptake at a point where the temperature is to be taken and after the ball has attained the same temperature as the surrounding gases it is quickly dropped into a vessel containing a known weight and temperature of water. The water is rapidly stirred and its maximum temperature is taken, i.e., when the ball and water have attained the same temperature. The temperature of the copper ball before being cooled would then be given by the formula:

$$x = \frac{W\,(T - t)}{w\,S} + T$$

in which

x = Temperature sought;
W = Weight of the water, in pounds;
w = Weight of the copper ball, in pounds;
t = Initial temperature of the water;
T = Maximum temperature of the water and final temperature of the copper;
S = Specific heat of copper, which may be taken as 0.095.

For example, if the weight of water is 20 lb., the weight of copper ball 12 lb., the initial temperature of the water 52 deg. F. and the maximum temperature of the water and final temperature of the copper is 85 deg. F., then the temperature of the copper ball before being cooled would be

$$\frac{20 \times (85 - 52)}{12 \times 0.095} + 85 = 663.9 \text{ deg. F.}$$

The actual temperature of the waste gases will be somewhat more than the result obtained by use of the formula, on account of corrections for variations in the specific heat of the water and metal for different temperatures, losses of heat by radiation of the metal during transfer from the uptake to the water, and heat lost during the heating of the water and absorbed by the vessel containing it.

Engineers' Study Course

The Efficiency of Heat Engines

A heat engine is an apparatus for converting heat energy into mechanical work. In engines of the internal-combustion class this whole process is carried out within the self-contained machine to which the name "engine" is commonly given. In a steam plant functioning begins at the heating surface of the boiler (where heat is received) and extends to the condenser (where heat is given up), so that here the term "heat engine" covers a good deal more than the steam engine or turbine alone.

The efficiency of any energy converter is the ratio of useful output to total input. There is a class of transformations—typically, those of the electric generator and motor and of machinery transmitting power—in which output is, or may be, nearly equal to input. The difference (decrease) is due to secondary losses, which may be controlled and diminished, but never wholly eliminated. However, it is easy to imagine a perfect electro-dynamo, or a frictionless machine, which shall have no losses and, therefore, unit efficiency. This ideal action, with the apparatus delivering in useful form all the energy that it receives, stands as a limit of performance to which the actual machine approaches more or less closely.

But the heat engine does not tend to approach unit efficiency or complete conversion of heat as its action is improved. Instead, there is a limiting efficiency of lower value, which depends upon the general conditions of operation and is expressed by a fraction ranging in various cases from 0.15 to perhaps 0.65. The typical range for good steam plants, running condensing, is 0.30 to 0.35—this being in terms of heat received by the steam from the fire and, therefore, not including boiler efficiency. In other words, an ideally perfect steam-engine plant, with losses by reason of radiation, cylinder-wall action, or resistance to flow of steam, could convert into work 30 to 35 per cent. of the heat received, and would unavoidably reject in its exhaust the remaining 70 to 65 per cent. The actual plant will do about two-thirds as well as the ideal, converting 20 to 24 per cent.

Having given nothing more than the general law or principle that energy is convertible from one kind to another, one might think that the conversion, for instance, of heat into work could be effected in a number of ways, of which the best or most convenient would be chosen for practical application. Really, however, no such freedom of choice exists with this particular conversion; rather, there is but one general method available, that which depends upon the use of an expansive medium, a vapor or gas. Of course, attempts have been made to find or invent some other way, but these have been altogether fruitless, and the heat engine of common type is the only known device for getting work from heat.

The question now to be considered is, "How is it that the heat engine, even under ideal conditions, cannot have unit efficiency?" The word "how" is used instead of "why," of intention. The latter might imply that the question was one to be solved by some train of abstract reasoning based upon an initial concept of the general nature of energy. On the contrary, there must be study and analysis of the physical processes involved, bringing them to expression in simplest terms and leading to a simple final statement of physical impossibility.

In the manner just indicated let us now consider two typical heat engines, taking the steam plant with piston engine and the gas engine with explosive or Otto cycle as representative examples. Their cycles of operation, briefly described in parallel schedules, are as follows:

1. Taking the charge and bringing it to the state where it begins to receive heat.

Steam plant: For each working cycle of the engine, a certain amount of water under atmospheric pressure and at a temperature not higher than the atmospheric boiling point is put into the boiler by the feed pump, which performs the work necessary to that end.

Gas engine: A cylinderful of mixed air and gas is drawn in and then compressed. In the ideal case the charge would neither receive nor yield up any heat during this operation, so that the compression would begin at atmospheric temperature and would be truly adiabatic.*

2. Imparting heat to the charge.

Steam plant: The water is first raised to the temperature of steam formation and then vaporized, the latter effect requiring by far the larger part of the heat supplied. Room for the very great increase of volume from liquid to vapor is made by the advance of the engine piston, out to cutoff. The work of this expansion is, of course, performed usefully upon the piston.

Gas engine: The charge is ignited and its heat of combustion causes a great rise of temperature and pressure, the volume remaining nearly constant while the piston is moving slowly near dead-center.

3. Expansion without heat supply.

Steam plant: After cutoff, the steam expands behind the advancing piston.

Gas engine: This expansion constitutes the whole of the working stroke.

In both cases the ideal condition for best effect would be to have this expansion take place in a cylinder that was thermally neutral, or that would neither conduct, absorb, nor give up heat. The unavoidable departure from adiabatic action, with real metal cylinders, is one of the chief causes of the gap between ideal and actual performance.

4. Exhaust and removal of unused heat.

Steam plant: Except for a small amount of radiation, the heat not converted goes out in the exhaust steam. Whether taken into the atmosphere directly or into a current of condensing water, it ultimately settles down to the general level of outside temperature.

Gas engine: Heat is taken from the cylinder continually by the jacket water, and the rest of the unconverted heat goes out into the atmosphere in the exhaust gases.

The purpose of the preceding brief review of well

*Adiabatic is a short equivalent for the phrase, "without giving or receiving heat."

known facts is to furnish a reason for, and a practical illustration of, the following general statements:

To get work from heat it must be available at some high temperature, well above that prevailing in the atmosphere and other surrounding bodies.

This heat is applied to some liquid or gaseous medium, causing it to expand and do work.

When at the end of expansion, which is limited by its falling to a pressure below which no useful effect can be got, the medium still contains a large part—commonly much the larger part—of the heat which it has received. Nothing can be done with this heat but to reject it to the atmosphere or surrounding bodies.

All of the work done by the steam or gas in its expansion is not useful output, because the piston must give back some work in expelling the exhaust or compressing the new charge.

These statements are more nearly related to the actual practical engine than to the abstract and, in several respects, imaginary apparatus which is assumed in thermodynamic discussions. They leave some loose ends, but cover the ground well enough. To sum up, the reason why the heat engine cannot attain unit efficiency is that at the end of expansion, when the working medium has performed all the work of which it is capable, it still contains a large portion of the original supply of heat, which has been reduced in temperature and can only be given up or thrown away at this low temperature.

In connection with the performance of any heat engine there are three efficiencies to be considered, which can most clearly be defined in relation to an example. The best test of the Brown-Boveri-Parsons turbine at Newcastle-on-Tyne, which was reported in POWER for Apr. 18, 1911, gave the following data and results:

Load, 6257 kw., on a rating of 6000 kw.; steam pressure, 204 lb. abs.; steam temperature, 560 deg. F., or 176 deg. of superheat; exhaust (condenser) pressure, 0.44 lb. abs., corresponding with a steam temperature of 76 deg.; steam consumption, 11.95 lb. per kw.-hr.

Since one kilowatt-hour is equivalent to 3412 B.t.u., the heat energy converted and delivered at the busbars for each pound of steam is

$$3412 \div 11.95 = 286 \textit{ B.t.u.}$$

The heat of formation of one pound of steam, assuming feed water at the temperature of the exhaust steam, is

$$1299 - 44 = 1255 \textit{ B.t.u.}$$

With ideal Rankine-cycle performance, the output per pound of steam would be 416 B.t.u. converted into work. Then the ideal efficiency is

$$\frac{\textit{Ideal output}}{\textit{Heat input}} = \frac{416}{1255} = 0.332$$

The actual, absolute efficiency is

$$\frac{\textit{Actual output}}{\textit{Heat input}} = \frac{286}{1255} = 0.228$$

And the relative efficiency, the ratio of actual to ideal performance, is either

$$\frac{\textit{Actual efficiency}}{\textit{Ideal efficiency}} = \frac{0.228}{0.332} = 0.687, \text{ or}$$

$$\frac{\textit{Actual output}}{\textit{Ideal output}} = \frac{286}{416} = 0.687$$

This ratio is the real criterion of effectiveness, since it shows how well those losses which are more or less subject to control are kept down. Of course, the 0.228 and 0.687 include the combined mechanical and electrical efficiency of the turbo-generator, which is probably about 0.96. Therefore, the efficiencies in terms of power developed by the steam on the turbine rotor are probably about 0.24 and 0.72.

As Dangerous as Dynamite

A steam boiler with an inoperative safety valve is about as dangerous as a supply of dynamite. Wagons loaded with high explosives may be seen any day passing through the streets of crowded New York. Attention, however, is drawn to the danger by means of large red letters and and a red flag hung conspicuously from the rear of the vehicle. But boilers carrying high steam pressure and having plugged safety valves exist under the sidewalks of this great city without any warning visible to the unsuspecting pedestrian.

This statement may seem sensational, but it is based upon fact.

Just recently an insurance company was asked to insure a boiler carrying a pressure of 30 lb. After examining the boiler the inspector ordered the pressure reduced to 15 lb., but the owner wanted to carry 30 lb., and upon his earnest request the insurance company consented to make a re-examination. When the inspector arrived he found the safety valve blocked, a stick of wood having been wedged between the top of the valve lever and the bottom of the ceiling joist in the building. Needless to say, the insurance was immediately suspended. Insurance on this boiler would not now be accepted even after the pressure had been reduced and the safety valve unlocked.

Fortunately, it is a rare occurrence to find a safety valve that has been purposely blocked to permit the carrying of higher steam pressure. In fact, the writer knows of but one other case, and that was done by a negro fireman who stated that he had to do it to prevent the safety valve from discharging steam.

Safety valves, however, are often blocked unintentionally or by accident. Not long ago a boiler located under a Broadway sidewalk at Forty-first St., after undergoing repairs, was tested by hydrostatic pressure. To apply this pressure it was necessary to block the safety valve. The boiler attendant, unaware that the boiler tester had not removed the block, raised steam on the boiler. The boiler exploded, badly damaged the surrounding property and fatally injured the son of the owner.

In another case the corrugated ceiling over two boilers sagged to such an extent as to come into direct contact with the top of the safety valves. The boilers were located under the sidewalk of a crowded thoroughfare. Fortunately, the danger was discovered by an inspector before explosion occurred.

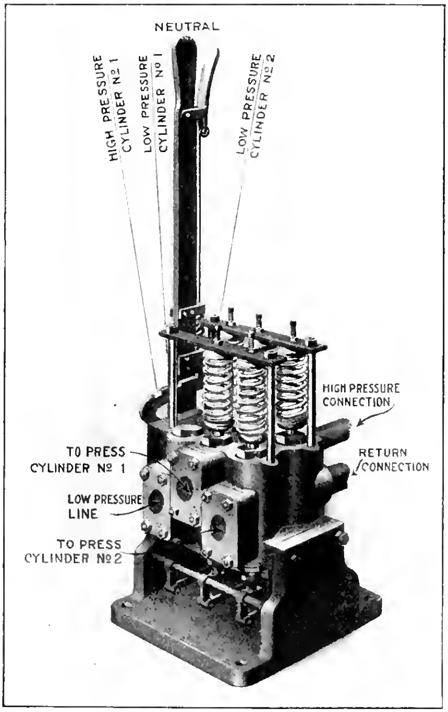
All but one of the instances here cited occurred in New York City within the last two or three months. Considering the vast number of boilers throughout the United States, it is reasonable to suppose that a very considerable number are operated under dangerous conditions.

It is obvious, therefore, that frequent inspections by trained experts are absolutely necessary. There is reason for the movement recently inaugurated in so many states for the adoption of a uniform compulsory boiler-inspection law—a law which will provide for regular inspections, either by state inspectors or by the inspectors of boiler-insuring companies duly authorized to insure boilers in the given state.—*Monthly Bulletin of the Fidelity and Casualty Co., Jan., 1915.*

New Hydraulic Valve

Operators of hydraulic equipment of the double-acting character have experienced difficulty in obtaining proper pressure control with their valve equipment when the ram is forced in both directions by hydraulic pressure.

To meet this demand the Hydraulic Press Manufacturing Co., Mount Gilead, Ohio, has designed the five-way high- and low-pressure double-acting balanced poppet operating valve illustrated herewith.



Five-Way High- and Low-Pressure Double-Acting Balanced Poppet Operating Valve

The low pressure is admitted to the first cylinder, leaving the second cylinder open to the return line. When the low pressure has done its work in the first cylinder, the high pressure is turned on. A check prevents the liquid from the high-pressure line from flowing into the low-pressure line. The valve can then be shifted to the position which applies low pressure to cylinder No. 2 and releases cylinder No. 1. A similar valve is made with another position, which applies high pressure to cylinder No. 2 with No. 1 still open. In most cases the latter position is not necessary, as the work of cylinder No. 2 is done at low pressure only, as in the case of auxiliary return cylinders. On account of the length of the operating lever it is necessary for the operator to stand above the level upon which the valve rests.

The valve has five stems and checks and is suitable for use with pressures up to 5000 lb.

Appearance as an Element in Power-Plant Value

By Edwin D. Dreyfus

Doubtless the mentioning of the fact that the appearance of and the general care accorded a power plant or other operating system possess concrete value will at first seem commonplace. Everyone will contend that he realizes the importance of good order in any working institution. But do the majority of us take sufficiently seriously the slogan of "watchful care and attention" and make the necessary effort to keep our house in the very best order both from an interior and an exterior standpoint? We may neglect the equipment entrusted to our care so long as no accounting is required, but let the occasion arise and we will quickly find means to do vastly more than we had previously attempted. As it is inherent in us to accomplish greater things, why do we not assume the initiative rather than have the doing of these things urged upon us?

A new era has dawned wherein we find ourselves in a condition of strict regulation, either by keen competition or else through municipal, state or federal supervision. The "survival of the fittest" is going to be more pronouncedly the byword in the future, and it is with this in view that the writer attempts to point to instances wherein the orderliness of the plant may represent an indirect monetary value of material consequence.

Regulation is the order of the day—mainly that of public-service corporations, but to an increasing extent of industrial companies doing an interstate business as well—and though there may be other angles by which this is approached, price or rate control is the one of immediate interest. To determine the proper prices for the output of any plant, we must fix upon a reasonable return upon the investment in or the value of the plant. We need not concern ourselves in this article with what this should be as it is governed by the financial risk. However, the fair value is another matter, and should not be a variable quantity, as it is dependent upon the legitimate investment. The book records of the operating company should show this, but it is only recently that records have been kept that exhibit the construction cost separate from other charges.

Consequently, to derive the value as of a certain date, an appraisal must be made in the majority of cases. Herein lies the tangible value of the general appearance of the plant, because some courts and commissions hold that the present value shall be determined by the "reproduction cost new less depreciation" method. Evidently, if the plant gives an impression of neglect, the deterioration and consequent depreciation may appear more exaggerated than they actually are. Whatever diminution in value may result from the inspection (presuming the regulatory body to be guided strictly by the investigator's report) will in all probability represent a permanent loss unless an appeal is made by the company affected.

It is hardly to be disputed that the company's and the employees' interests are interwoven. If the company possesses an efficient management the welfare of the employee is enhanced, and if the employees are individually efficient the company is insured of greater prosperity.

Let us attempt to illustrate the relationship numerically, taking the power plant as an example. Suppose it is to be appraised for price or rate regulation. Assume that the normal rated capacity is 1000 kw. and the cost to install was $100 per kilowatt, or a total of $100,000. Say where the plant was well maintained the condition was found to be 85 per cent. and where indifferent attention obtained the property was considered to be worth 75 per cent. of its original value of $100,000. Accordingly, the less industrious engineer would have lost his employer 10 per cent., or $10,000. Now if the company had been allowed to earn 8 per cent. upon the present value of its property devoted to public interest and to set aside 5 per cent. to cover necessary renewals and replacements, together with 1 per cent. for insurance and taxes, it should receive 14 per cent. after operating expenses have been met. Through the writing down of the 10 per cent. greater depreciation in one case than in the other the company's earnings may have been reduced 14 per cent. of $10,000, or $1400 per year. And this in a larger degree represents the value of the ambitious engineer-in-charge over the one less energetic.

Volumes have been written upon the different methods of arriving theoretically at depreciation. During the early stages of regulation the "life" method principally was in vogue. Now the theoretical method has substantially given way to determining the amount by actual inspection. Upon this development rests the fact that the plant appearance, irrespective of the running condition, becomes of intrinsic value.

By the life, or theoretical, method the depreciation was arrived at by taking the average length of service obtained from machinery and property as was shown by a wide range of experience. Such results had to be predicated upon the performance of equipment both carefully and carelessly maintained, and consequently this method worked an injustice in some cases and disproportionately favored others. Hence, we have come to employ the actual inspection by a competent person in virtually all recent work.

Inspection to determine the reduction in value, like a great many other things in our daily life, is not an exact science, and in this field particularly the psychological influence and mental impression produced may play a considerable part in the results.

To a great many this discussion may seem mere platitude, but the writer has been in many plants where there was apparently no appreciation of the value of appearances. It is not uncommon to find engineers studying indicator cards, analyzing flue gases and carefully observing the general load and operating conditions, but otherwise unmindful of orderliness. The man who not only secures the last fraction of economy and high efficiency but maintains orderly arrangement is going to be the most highly valued. I have known of two engines which were both running satisfactorily, but the older one was the more carefully groomed and was accordingly marked down for far less depreciation.

In enumerating what could be done in a power plant to maintain a good appearance it might be mentioned that in boiler settings all cracks should be calked and the brickwork pointed up; in rotating machinery all side play and any wabbling due to sprung shafts should be eliminated, although having no bad effect upon the operation of the machinery; pumps in the boiler room subject to accumulation of ash and coal dust caked with grease should be kept rubbed down; boiler fronts kept in brightened condition; water- and steam-pipe leaks stopped even where they are of trifling consequence from an economical standpoint; and the tools and all material and supplies arranged in order.

The old adage that "Cleanliness is next to godliness" is thereby a virtue growing in significance. It is of course understood that "surface" conditions alone will not be sufficient, but the internal state of repairs is sometimes more important. However, it is quite clear that outside appearances virtually have a tangible value.

Dead-Man Broke

On Monday, Jan. 4, at about 3 p.m., a peculiar accident occurred at No. 2 pumping plant of the Jamaica Water Supply Co., Jamaica, Long Island, N. Y. The erection of two new smoke-stacks had just been completed, and the riggers were preparing to leave the premises when the guy stub, or dead-man, broke off near the ground, allowing the stacks to fall over. The dead-man was a short length of railroad rail, probably steel, set into the ground. At the point of failure it showed no bend whatever, but simply a short break.

By prompt and wise action on the part of the chief engineer and the riggers, the service was not interrupted and the output was but slightly reduced for a short time only. The rivets were cut at a joint five or six courses from the bottom, and these short stacks set up in their original places, as shown in the illustration. By this means the boilers were operated by forced-draft blowers while the other sections of the stacks were repaired and made ready to replace.

Although there were several men near-by, no one was hurt.

Condition of Stacks Which Fell When Guy Stub or Dead-Man Broke

Boiler Explosions During First Half of 1914

Date	Place	Plant	Time of Day	Kind of Boiler	Pressure Carried, Lb	Size	Killed	Injured	Property Loss	Probable Cause
Jan. 1	St. Louis, Mo	Martin-Haloran-Klaus Laundry Co	12 M	Water-tube	125	75 hp.	1	2	$100	Tube ruptured

Water-Power Legislation

In the deadlock between the President and the Senate over patronage, waterpower legislation at this session of Congress seems likely to be lost in the shuffle. States-right senators, like Smoot of Utah, Borah of Idaho and Clarke of Wyoming, backed by big water-power interests, are understood to be preparing to talk to death the Ferris bill, which has passed the House, providing for the leasing of power sites in the public domain, while the conservationists have declared war on the Shields bill, reported to the Senate as a substitute for the Adamson general dam bill which passed the House last year. The Shields bill is denounced by Gifford Pinchot, president of the National Conservation Association, as "the bill of the water-power monopolists."

The Adamson bill, which had the indorsement of President Wilson, provided for the granting of permits for dams and power plants on navigable streams for periods of not more than fifty years, with reversion of the property to the Government at the end of that period. The Shields bill, while it purports to do this same thing, leaves the way open to endless litigation for determining the fair value of the property at the end of the franchise term, so that it is declared by conservationists that it would be practically impossible for the Government to ever take over the property. Although the only grant to be made by the Government is for the right to build a dam and works adjacent to a navigable stream, the language of the Shields bill would require the United States to take over the entire lighting plant of a city, if it were operated in connection with such power plant, in order to recapture the water power in the stream. The Shields bill also gives to the water-power interests the right to condemn land, either public or private, for their own uses, and would require the Government, on taking over the plant, to pay the increased value of land so taken.

These features of the bill, which are not the only ones to which the conservationists object, are in direct opposition to the policies declared for by Secretary Lane, of the Interior Department, and at odds with the principles set forth in the Ferris bill for the granting of franchises for power sites on public lands.

Of the Shields bill, Mr. Pinchot says in his statement:

There has been no clearer attempt to defeat the conservation policy since water power first became a great National problem. It is a direct reversal of the wise and fair provisions contained in the Adamson bill as it passed the House. President Roosevelt vetoed the James River bill in 1909, President Taft vetoed the Coosa River Dam bill in 1911, because they did not provide for proper payment to the public for value received from the power companies. The House of Representatives by an overwhelming vote adopted the Sherley amendment providing for such payment. The Shields bill proposes to give these rights away. It is a surrender to the special interests, and its passage would be a public calamity.

Recent Court Decisions

Digested by A. L. H. STREET

Remedy for Breach of Power Contract—According to a decision lately handed down by the Georgia Supreme Court, an electric-power company which has an unexpired exclusive contract to furnish a consumer with all electricity used by him for power purposes cannot maintain a suit to enjoin breach of the contract through the consumer's refusal to receive further service, where it appears that the company has an adequate remedy by suing for damages for such breach. (Macon Ry. & Light Co. vs. Palace Amusement Co., 83 "Southeastern Reporter," 105.)

Power as Basis of Mechanic's Lien—The Minnesota Supreme Court has just been called upon to determine the interesting question whether one who furnishes fuel and lubricating oils for the production of power in operating excavating machinery in constructing a building foundation is entitled to a lien against the real estate to secure payment for the fuel and oils on the theory of having contributed toward the improvement of the land. (Johnson vs. Starret, 149 "Northwestern Reporter," 6.) In answering this question in the affirmative, the court said: "Had the excavation and removal of the earth been done by manual labor, the right to a lien therefor would be undoubted, and we cannot differentiate such a case from one where the same result is reached by other and modern methods. The value of the defendant's property was thereby enhanced, and it can make no difference that this was accomplished by the use of power obtained from materials furnished by the lien claimants instead of by common labor."

Thermodynamics of the Marine Oil Engine*

By John F. Wentworth

SYNOPSIS—This paper is intended to present certain experimental data obtained by the writer as well as to reintroduce certain old and well established facts in a new garb, in order that the oil engine may be looked at from a new viewpoint.

The marine plant must be capable of running at full load with maximum power or of running at partial load with maximum efficiency, and most essential at times is the ability to run at extremely slow speeds. Moreover, to meet all conditions and take its place as a perfect prime mover at sea the marine oil engine must be capable of being built in large single units, which means that extreme pressures must be avoided. Therefore, an attempt will be made to show:

First, that if possible the extreme high pressure of compression must be reduced.

Second, that to give the greatest possible efficiency under all conditions the proportions of air to fuel must be kept constant regardless of load.

Third, that to get extreme or emergency slow speed the injection of the fuel and the ratio of air to fuel should be varied contrary to the condition for maximum efficiency.

Fourth, that the percentage of the stroke during which the fuel valve is held open should be under the control of the operator in order that injection air losses may be reduced.

Fifth, that by reducing the compression and at the same time hastening the fuel injection the advantage of the high compression is not materially impaired.

Sixth, that by reducing the compression it is possible to obtain substantially the same power with the same theoretical efficiency, but with an increased mechanical efficiency.

Seventh, that by increasing the temperature of the injection air a saving of practically 10 per cent. of the fuel now used may be effected without danger to the plant.

To understand best the effect of the high-pressure of compression and its relation to the cycle, temperature-volume diagrams of the oil engine and of other types will be considered. Fig. 1 shows two typical Diesel diagrams copied from catalogs of 1898 and 1913. The end of the expansion stroke corresponds with 100 per cent. volume and the beginning with the clearance of the engine, making it possible to read pressures and also percentage volume. Assuming that the compression is begun with air at 14.7 lb. and 60 deg. F., the specific volume will be 13.09, and the specific volume at any other point will be 13.09 times the percentage volume. Thus, from the formula $PV = RT$, the temperature of the charge can be figured with a fair degree of accuracy. The constant R for air is 53.22 in English units. By plotting the two indicator diagrams and figuring a certain number of points the temperature-volume diagrams were drawn in. It will be noted first that the temperature rises almost vertically during injection. This shows, comparing the 1898 and the 1913 diagrams, that the trend of Diesel engine practice approaches the conditions of the gas engine.

If the Diesel engine can start with a compression of 500 lb., the charge igniting at a temperature around 920 deg. F., then after it has been running awhile the temperature at the end of compression must be around 1450 deg. F. If this be so, the charge will ignite at any time after the pressure has exceeded 120 lb., provided the engine has run long enough to become normally warm.

This is demonstrated by the diagrams shown in Fig. 2, which were taken from the writer's experimental engine, although it was not possible to vary the amount of air compressed per stroke as much as desired. Also, the timing of the fuel valve caused slight trouble. Hence, the fuel valve was arranged so that the timing of the injection could be changed, and these diagrams are the result. So far as the writer knows, this is the first instance in which a timing arrangement has been used on the fuel valve. The ignition of the fuel was obtained under conditions which were possible only in an engine which had been run long enough to get warmed up, and it seems a fair assumption that, if the fuel ignited as shown, it would have ignited if the clearance had been so increased that these low pressures were obtained at the end of compression. The fuel is shown igniting at from 70 lb. up to full compression pressure. Diagram No. 6, where the ignition was at 130 lb., makes it apparent that much energy is lost by radiation during the time of high pressure and high temperature. This loss at the end of compression should be somewhat reduced in the low-pressure type, for although the cylinder volume at the end of compression might be doubled, the radiating surface would be only slightly increased.

Next consider the proposition that the ratio of air to fuel be kept constant. This has been done on the best gas engines as a means of governing, but it has not been done on the Diesel, because apparently the full amount of air must be compressed per stroke in order that the ignition temperature may be obtained. In the Mar. 11, 1913, issue of "Power" the writer brought this out, proposing that if only two-thirds of the fuel were used, only two-thirds of the regular amount of air should be compressed. Moreover, if the friction loss is a function of the unit pressure on the piston, then the friction of the Diesel at two-thirds load would be 50 per cent. greater than in the proposed form of governing. This can be stated in another way; namely, the friction is not a percentage of the net load, but is a percentage of the work done in the cylinder, regardless of whether the effect is plus or minus on the brake.

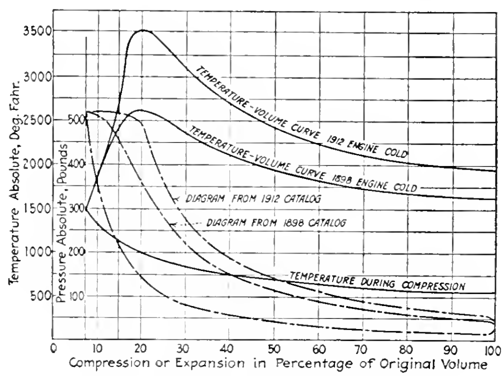

Fig. 1. Temperature-Volume Curves

Fig. 3 is a set of curves constructed from tests made by Professor Denton in 1898 on a small Diesel engine. Improvements have been made in the engine, but the cycle is unchanged, so that results obtained in these early tests are at least indicative of what goes on in the present engines. This diagram shows that the friction is practically constant at all loads and would seem to bear out the contention that the friction is toll taken out of both the compression and the working strokes. With the compression pressure constant the sum of the compression work and expansion work would vary but little for a wide variation in the net work done in the cylinder. However, the sum of the compression and the expansion strokes would vary greatly if the compression pressure was decreased.

Air is compressed and then expanded. The air in itself does nothing. All the work put into compression will be given up in expansion except the losses. If the quantity used per stroke is reduced, the losses per stroke will be diminished by this same amount. Unnecessary compression of air is an extravagance, therefore, for it is needless to compress more than is required for the proper combustion of the fuel.

Next, consider the problem of extremely slow speed. In order to reduce to a very slow speed care must be taken to obtain a maximum temperature at the end of the compression stroke. Diagram No. 6, Fig. 2, shows the effect of cooling

*Excerpts from a paper read at the recent meeting of the Society of Naval Architects and Marine Engineers, at New York.

at the end of compression. For moderate speeds with a falling horsepower the amount of air compressed per stroke can be varied. Under present conditions there is a limit to the speed of the oil engine, at which limit the ignition will be uncertain. To go beyond this in the present engines the air should be heated before it enters the cylinder and the temperature of the jacket water should be raised. It might even be wise in an emergency to cut out the circulating water entirely.

Need for this slow speed was painfully evident when the Diesel-engined ship "Christian X" fell in with a disabled ship in midocean. It was stated at the time that tow lines were repeatedly passed to the disabled ship only to part. Presumably the best that could be done would have been to keep starting and stopping the engines in the hope of gradually accelerating the tow to the point where the line would stand the lowest possible speed of the engine.

A steam vessel under the same conditions would have run her engine very slowly, just enough to give steerage way, until she had taken up the slack of the tow line, and then would have increased the revolutions gradually until the desired speed was obtained. This is manifestly impossible in the present oil engine. In the plant proposed at the end of this paper the motive power would be steam and the engine would start at a few turns per minute with steam from the economizer boilers.

At this point it may not be out of place to call attention to the fact that the cylinders of a Diesel engine should be kept as hot as possible, up to the point of encountering lubricating troubles. This is true whether extremely slow speed or maximum efficiency is required.

Passing to a discussion of the advantages of fuel valve control as to timing, etc., in the present oil engine the duration of the fuel injection does not take into account the amount of fuel to be fed nor the speed. If an engine be slowed down to half speed, considerably less fuel will be used than when running at full speed. Notwithstanding this, the fuel valve is open for the same length of time. This results in a waste of injection air, the thermodynamics of which will be taken up later. If the fuel be injected early in the stroke, a rise in pressure can be obtained which will increase the efficiency. If the fuel be fed into the cylinder a considerable time after the end of the compression stroke, it is possible to produce the same result that is obtained in the explosion engine by retarding the spark. Thus, it seems to be highly desirable to be able to control at will both the timing of the injection and the duration of the fuel feed.

The method of compensating the theoretical loss encountered in reducing the compression pressure next calls for consideration.

If the compression pressure is reduced, the fuel injection can be hastened and combustion completed earlier in the stroke. If high compression is used, then the fuel must be slowly injected, as is now done in the Diesel engine in order that extreme pressure may be avoided. If the fuel be injected rapidly and timed for the end of high compression, results are to be expected similar to those shown in diagram No. 8, Fig. 2.

High compression means small clearance and a relatively large number of expansions, which is desirable, but the full effect is lost through the slow fuel injection. Why this is so is shown in Fig. 4. Assume the indicator diagram to be divided into four similar ones by means of the adiabatic lines shown. Each may be considered separately. In the case of D the average clearance is 16.1 per cent. of the whole cylinder contents, hence it has only 6.2 expansions. Diagram A, on the other hand, has 11.34 expansions. If the fuel be injected rapidly into a cylinder whose clearance gives a compression pressure of 275 lb., then the number of expansions will be 8, or the same as the average of this Diesel diagram.

Attention will now be directed to some of the benefits to be derived from reduced compression. In the engineering press the idea of reducing the compression pressure and at the same time making up for this lower compression temperature by means of a higher temperature of the incoming air has been opposed, the objection being that the volumetric efficiency would be decreased; in other words, the power of the cylinder would be reduced, making the engine more bulky. The original idea was to save fuel by a process similar to compounding; that is, when only a partial load was called for, a partial cylinderful of air would be compressed. If this were done by closing the admission valve at the middle of the suction stroke, a vacuum would be formed in the cylinder during the rest of the stroke which would be maintained during the first half of the compression stroke. In this case volumetric efficiency will not suffer, whereas in the present method of governing the engine at partial loads the efficiency is handicapped by the presence of an unnecessary excess of air.

The economy possible in the injection air is the last point for discussion pertaining to the present type of engine.

From the best information available the injection air compressor must develop about 10 per cent. of the brake horsepower of the main engine. Of this 10 per cent., what care has been used to maintain an economical cycle? The air is compressed in two or more stages to 1000 lb., and then cooled to the original temperature or lower. The total energy in the air after it has been compressed to 1000 lb. and cooled to its original temperature is exactly what it was in the beginning. All that the work of compression has done is to make a part of this original energy available. Our natural conception of the energy of compressed air would lead to the consideration that the energy depended upon the pressure of the air; as a matter of fact, the determining factor is not pressure, but temperature. There are several simple proofs for this statement. One is: "Isoenergic lines are lines representing changes during which the intrinsic energy remains constant. It will be seen later that the isoenergic and isothermal lines for a gas are the same" (Peabody). When the air

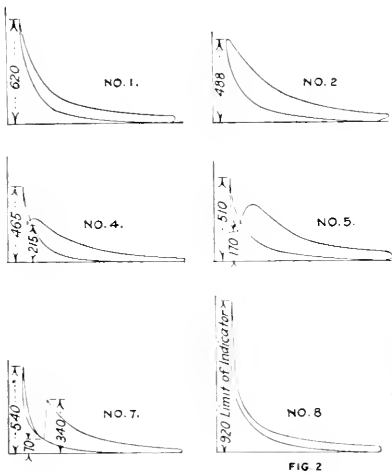

FIG. 2. DIAGRAMS TAKEN ON EXPERIMENTAL ENGINE

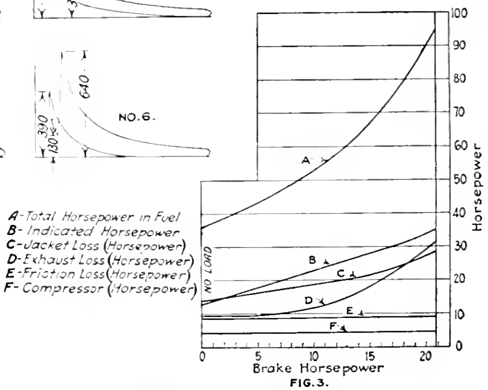

FIG. 3. VARIATION OF LOSSES WITH DIFFERENT LOADS

is cooled to the original temperature after having been compressed, it is brought back to the isothermal from which compression started.

This contention can be proved mathematically. The formula for work of expansion to the absolute zero of temperature and pressure is

$$W = PV \div (k - 1)$$

This formula considers a fixed quantity of air—that is, a certain weight. In the formula $PV = RT$, considering the same weight of air, P and V will be the same as in the formula for work. By substitution, the formula for work can be rewritten $W = RT \div (k - 1)$, where R and k are constants, and the only variable in the formula is T, the absolute temperature. This new formula will give the work of expansion for one pound of gas.

The above consideration of the injection air is simply to bring home the fact that a waste is being made of one-half of the available energy of the compressed air when this air is cooled to room temperature in place of being used at about 580 deg. F. If the injection air is used at this temperature, just one-half of the fuel to run the air compressor will be saved, and there will be no difference in the operation of the engine. Before this can be wisely done, however, there is need for redesigning of the fuel valve. It is the writer's opinion that the valve should be simplified even if the pump is complicated.

In regard to the danger in using air of this temperature there is this to say: Any explosion in the injection line will come from a quick opening of the air valve. If there is a pocket in the line where oil can settle and the air valve is suddenly opened with no pressure in the line, the body of oil will be dislodged from its pocket and shoved along ahead of the incoming high-pressure air, compressing the low-pressure

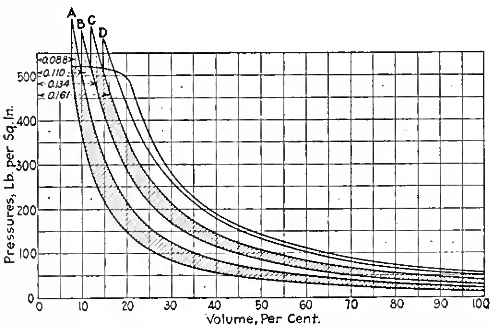

FIG. 4. SHOWING EFFECT OF SLOW FUEL INJECTION

air. If this action in the injection line takes place quickly, the body of oil will take the place of a piston and the action in the injection line will be the same as in the cylinder during the compression stroke. A temperature of ignition will be reached in the injection line regardless of the temperature of the injection air. In fact explosion is caused not by the injection air, but by the contents of the air line when the high-pressure air is turned on. It is possible to safeguard this type of engine from explosion in the injection line by a little care in the design of the piping arrangement, etc., and the exercise of due caution in operation.

The present instructions for the operation of Diesel engines state that the cooling water from the jacket of the fuel valve should be cold to the hand. The writer feels that the fuel valve can be designed so that it needs no jacket whatever. This may be objected to as an unsupported opinion, but it is based upon years of study along this line of work during which nothing has been found to oppose this idea and everything points to its possibility.

In closing, the writer's proposed thermo plant will be considered. Briefy stated, the starting medium is steam, generated in a special boiler. Before starting, the steam is admitted to the jackets of the engine, warming it to a point where starting steam can be used without excessive condensation. After the engine is running on oil the flow through the jackets is reversed, water from the bottom of the boiler enters the bottom of the jacket, and a mixture of steam and water comes from the top and is returned to the boiler. In this case combustion in the cylinder will not increase the temperature of the jacket water, but will transform it from water to steam at the same temperature. Also, the exhaust gases from the engine will pass around and through this boiler

before being rejected, and as much as possible of this waste heat will be converted into steam. The energy from the boiler will be used to run the auxiliaries and, if the idea is correct, to run a separate steam propelling plant. The exhaust from all steam units will be returned to a condenser, where at last the remaining heat units will be abandoned as unavailable energy.

OBITUARY

JOSEPH G. McCOLLUM

Joseph Grant McCollum, superintendent of construction of the Essex power station of the Public Service Electric Co., at Point-no-Point, on the Passaic River, died from pneumonia at the Newark (N. J.) Private Hospital, Jan. 13, at the age of 29.

He was graduated from Cornell University in the class of 1909. He was for a time with Westinghouse Church Kerr & Co. in New York, and early in 1914 removed to Newark, N. J., and became superintendent of construction at Burlington for the Public Service Electric Co. of New Jersey.

F. W. JENKINS

On Thursday, Jan. 14, 1915, Frank William Jenkins died at his home in Brooklyn, N. Y., from complications due to old age. He was widely known as an expert in hydraulics and was connected with the Henry R Worthington Pump Co. for over fifty years.

Mr. Jenkins was born in Hudson, N. Y., Feb. 26, 1832, moved to Brooklyn at the age of 14, and spent the remainder of his life there. Many inventions and improvements in steam pumps and hydraulic engineering are the products of his genius. He also occupied a high place in the civic and municipal life of the comunity in which he lived. Two daughters survive him.

PERSONALS

William Naylor, after a service of 44 years in the engineering department of Marshall Field & Co., has retired from his position as chief engineer. He was born in Lancashire, England, Jan. 4, 1833, was apprenticed at the age of 9 to the London & North Western R.R. shops at Leeds, and was promoted to engine runner at the age of 19. In 1859 he was driving the "Manchester-Liverpool Flyer," which occupation he left to come to America, arriving at New Orleans after a voyage of seven weeks. He worked at New Orleans, Jackson and Memphis for short periods and in 1860 settled in Mt. Carmel, Ill., and engaged in the lumber-sawing business. He moved to Warrensburg, Mo., in 1865, and in 1866 to Chicago, where he entered the employ of Field, Leiter & Co., now Marshall Field & Co., in 1871. He is father of Past-President Chas. Naylor, of the N. A. S. E., of which organization he is himself an active member, being treasurer of the Robert Fulton Association No. 28, of Illinois, and is known to, and esteemed by, almost everyone in Chicago who is in any way connected with power-plant engineering.

NEW PUBLICATIONS

OIL FUEL, ITS SUPPLY, COMPOSITION AND APPLICATION. By Edward Butler. Published by Charles Griffin & Co., Ltd., London, and J. B. Lippincott Co., Philadelphia, 1914. Size 5x7½ in.; 328 pages; illustrated.

After introductory chapters on the origin, production and economic aspects of oil fuel, the author reviews some of the early work with oil fuel, compares the steam-, air- and pressure-jet methods and then proceeds to descriptions of the burners in use today for steam boiler furnaces. Oil fuel for marine and locomotive purposes is dealt with at length and its use in metallurgical work is also considered. Very wisely, it would seem, no attempt has been made to touch upon the internal combustion engine, as this subject is so broad in itself that any treatment in a book of this kind would necessarily be incomplete.

THE ANALYSIS OF COAL WITH PHENOL AS A SOLVENT. By S. W. Parr and H. F. Hadley. Bulletin No. 76 of the University of Illinois. Paper; size, 6x9 in.; 41 pages, illustrated. Price, 25c.

As far back as 1851, experiments were made on coal for the purpose of dissolving those constituents of the coal which were soluble in certain chemicals, and from time to time different investigators have taken up the problem. The experiments by the authors of this bulletin have been made for the purpose of overcoming some of the objections to both the chemical and the proximate analysis.

It will be understood that the action of the chemical—phenol in this case—must be that of a true solvent and must not cause chemical changes either in its own structure or in that of the components of the coal. While there are several chemicals that will dissolve the solvent components of coal, phenol is best.

It does not seem that this method of coal analysis will be adopted generally in power plants, but our readers who are interested in that subject will find this bulletin well worth while.

STEAM CHARTS. By F. O. Ellenwood, Assistant Professor of Heat Power Engineering, Cornell University. Published by John Wiley & Sons, New York. Cloth, 7x9¾ in., 91 pages; 18 charts; 9 figures. Price, $1.

This book is intended to be of assistance to engineers and students when making calculations involving wet or superheated steam, and for that purpose the author has presented a set of charts convenient to handle and easy to read without extending the size of the charts beyond the dimensions of the page.

An introductory chapter sets forth the fundamental principles of pressure-volume and temperature-entropy diagrams, and another chapter is devoted to describing the preparation and use of the steam charts and a table of velocities, the scale of volumes being plotted from the values given by the steam tables of Marks and Davis.

A third introductory chapter defines atmospheric pressure and Baumétric corrections. There are an index chart, total, heat volume chart, external-work-volume chart, correction of mercury column for temperature and chart of correction of barometric readings due to change in elevation. There are also tables of correction of barometric readings and for capillarity, and tables of density of mercury and of theoretical velocities of steam expanding adiabatically in a frictionless nozzle.

Fifty illustrative problems are given with their solutions. These, together with the greater convenience of the charts over the large scale folders such as are usually employed for steam charts, render the task of making steam computation more inviting to the beginner and provide a work well adapted to the purposes of a handbook for engineers for data on the properties of steam and for checking methods of performing computations.

BUREAU OF STANDARDS PUBLICATIONS

Three instructive papers have recently been issued by the Bureau of Standards under title of "Measurement of Standards of Radiation in Absolute Value," "Various Modifications of Bismuth-Silver Thermopiles Having a Continuous Absorbing Surface," and "An Experimental Study of the Koepsel Permeameter," the last being an instrument for measuring the magnetic properties of iron and steel.

POWER

Vol. 41 NEW YORK, FEBRUARY 2, 1915 No. 5

The Leak

By R. T. Strohm

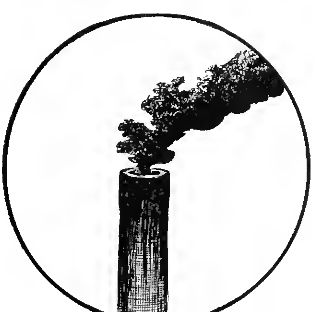
THE boss was good and proper mad, of that there was no doubt,
When he came in the other week to see the engineer.
He hardly got inside the door before we heard him shout
"Just look at this report on cost of power for the year!
The way you're running up expense has simply got to stop,
Or you'll be gallivanting 'round in search of pastures new.
Another year like this one was will make us close the shop.
Get busy, now, and find the leak—the thing is up to you!"

THE engineer was young and fresh, an overbearing snob,
Who always tried to make us feel that he was mighty wise;
So when we heard the sudden news that he might lose his job,
We nudged each other in the ribs and slyly winked our eyes.
For we were in the boiler room, to cart and heave the coal,
To clean the tubes and haul the ash, and tend the water, too;
And every mother's son of us, deep in his inmost soul,
Felt pretty sure that half the heat was going up the flue.

HE snooped around in every nook and tested all the traps,
To see that they were working well and steam could not get by;
He tinkered with the bearings and adjusted all the caps,
Believing that the friction loss was running rather high;

"The boss was good and proper mad"

"The engineer was young and fresh"



"Half the heat was going up the flue"

He packed the engines and the pumps to make them good and tight,
And then relined the shafting till it ran exactly true;
But we that fed the furnaces from early morn to night
Were puzzled why he never thought to test for CO_2.

HE polished all the pieces of his indicator kit
And took a set of cards from every engine on the floor;
He looked them over carefully and set the valves a bit,
And then he fixed the rig again and took a dozen more;
He overhauled the coverings on pipes conveying steam,
And every broken section was replaced at once with new;
He tried to lower running costs by every kind of scheme,
But never thought to make a test of what went up the flue.

HE fussed and fumed and stewed around about a week or so,
But still the coal-pile dwindled down alarmingly each day;
So finally we told him what we thought he'd like to know,
And said he'd better find just how much heat we threw away.
That hint was what he needed, for, instead of cutting loose,
He clinched his job still tighter, and he saved our bacon, too.
And thus he proved the adage that it's precious little use
To save around the engine while you're wasting up the flue.

Municipal Pumping Stations of Detroit

By Thomas Wilson

SYNOPSIS—Development of water-works from one unit in 1876 to ten units at present date, having a combined capacity of 267,000,000 gal. in 24 hr. New station containing three units just completed. Operating data and costs for the past year.

For 38 years Detroit's water-pumping station has been located in Waterworks Park at the eastern extremity of the city, between Jefferson Ave. and the river. Starting with one unit, the development to present capacity has been interesting. New units were installed as required until seven are now contained in the old station and three in a new building in which space has been provided for a total of six. Individually, each unit shows an increased duty over its predecessor, and collectively, the entire installation indicates the development in the art.

In the installation of large units Detroit has been a pioneer in pumping engines as well as in boilers, and it may be of interest to follow the plant through from the beginning. In 1876 a building large enough for two units was erected, and the first unit, a compound beam double-acting pumping engine having a capacity of 24,000,000 gal. per 24 hr., was installed. The cylinder dimensions were 42 and 84 by 40¼ by 72 in. In those days a compound engine was a novelty, and as the unit had almost double the capacity of any pump then in existence, it created wide interest and, like the Centennial engine, was one of the attractions in the engineering world. It showed a duty of 87,000,000 ft.-lb. on 100 lb. of coal, the steam pressure being 65 lb. gage and the speed 10½ r.p.m. It was the only pump of the kind ever built by the Detroit Locomotive Works. That it was of good design and well made is shown by the fact that it is still in active service.

A unit of similar design and of equal capacity and duty was installed in 1880. The dimensions were 46 and 84 by 41 by 72 in. Six years later another unit was required and the east end of the station was enlarged to make room for it. At this time Detroit's original pumping station was dismantled and as many parts as possible were saved for the new unit, which was to have a capacity of 30,000,000 gal. The pump thus had a capacity 25 per cent. greater than its predecessors, and was one of the "giants" of its day. It had compound steam cylinders and a water plunger of the same diameters as unit No. 2, but the stroke was 84 in. and the speed higher. The economy was also greater, as the pump showed a duty of 100,000,000 ft.-lb. In 1898 the high-pressure end was redsigned for a 35-in. high-pressure cylinder, so that the pump could utilize steam at 135 lb. pressure instead of 65 lb., the pressure formerly carried.

After an interval of seven years increasing demands called for a fourth unit, which was put in service in 1893. The west end of the station was enlarged to receive it. The pump was the first triple-expansion unit for the station, with cylinders 28, 48 and 74 by 36 by 60 in. It had a capacity of 24,000,000 gal. and was a duplicate of one pumping engine installed in Milwaukee and three in Chicago at the same time. Outside-packed plungers were another departure. A 30-day test by Professor Barrus on this unit showed a duty of about 130,000,000 ft.-lb., an increase in economy of 33⅓ per cent. over the most efficient of the compounds which had been previously installed.

Up to this time the pumps had been working against a head of 140 ft., or 60 lb. Need was felt for a higher pressure, so the next units were designed to operate against a head of 230 ft., or nearly 100 lb. pressure. The east end of the station was again enlarged, this time for three units. In 1900 two 25,000,000-gal. pumps were installed. They were triple-expansion units, 34, 62 and 92 by 36½ by 72 in., which on test showed a duty of 148,000,000 ft.-lb. These two units, as well as Nos. 3 and 4, operate on 135-lb. steam pressure. All up to this point had been equipped with jet condensers giving a vacuum of 26 in., the air pump being driven from the main shaft.

Fig. 1. New Pumping Station in Waterworks Park, Detroit

Eleven years passed before the seventh unit was needed. It was ordered in 1911 and was built and installed in the remarkable time of eight months after the contract was signed. The capacity was 25,000,000 gal. and the type vertical triple-expansion as before. The dimensions were 32, 60 and 90 by 37½ by 66 in. Since the last previous installation a surface condenser in the suction of the pump had become common practice, and was used in the present case. A surface of 2000 sq.ft. exposed to all of the water passing to the pump produced a vacuum of 28 in. and helped to boost the duty of this unit to 150,000,000 ft.-lb. and cut the steam consumption to 10.3 lb. per i.hp.-hr. This arrangement naturally eliminated the circulating pump.

Boiler Room

In the boiler room equal progress was made in the size and efficiency of the equipment. Old firebox marine and return-tubular boilers, hand-fired, have been replaced with water-tube boilers of horizontal and vertical types equipped with top feed or underfeed stokers. There is now a total of 15 boilers aggregating 4399 hp. There are four 225-hp. horizontal boilers on which the pressure has been cut to 110 lb., three 333-hp., four 225-hp. and four

400-hp. vertical boilers, all carrying a working pressure of 165 lb. The 400-hp. boilers were installed in 1913. Each has 4000 sq.ft. of heating surface and 64 (later reduced to 50) sq.ft. of inclined grate surface. The high ratio of 80 to 1 was made possible by the excellent quality of coal used, which is Meadow Brook run-of-mine averaging 14,300 B.t.u. per lb. and 6 to 7 per cent. ash. Four brick stacks for the 15 boilers supply natural draft. a common header tapped to each boiler. Feed-water regulators control the supply to the boilers, and as the pumps operate in unison with the main units, safety valves are installed on the discharge pipes to prevent excessive pressure and allow surplus water to flow back to the hotwell. Feed-water heaters are not used, as there is no auxiliary steam. This completes the equipment of the old station, which was given in some detail so that it might be known

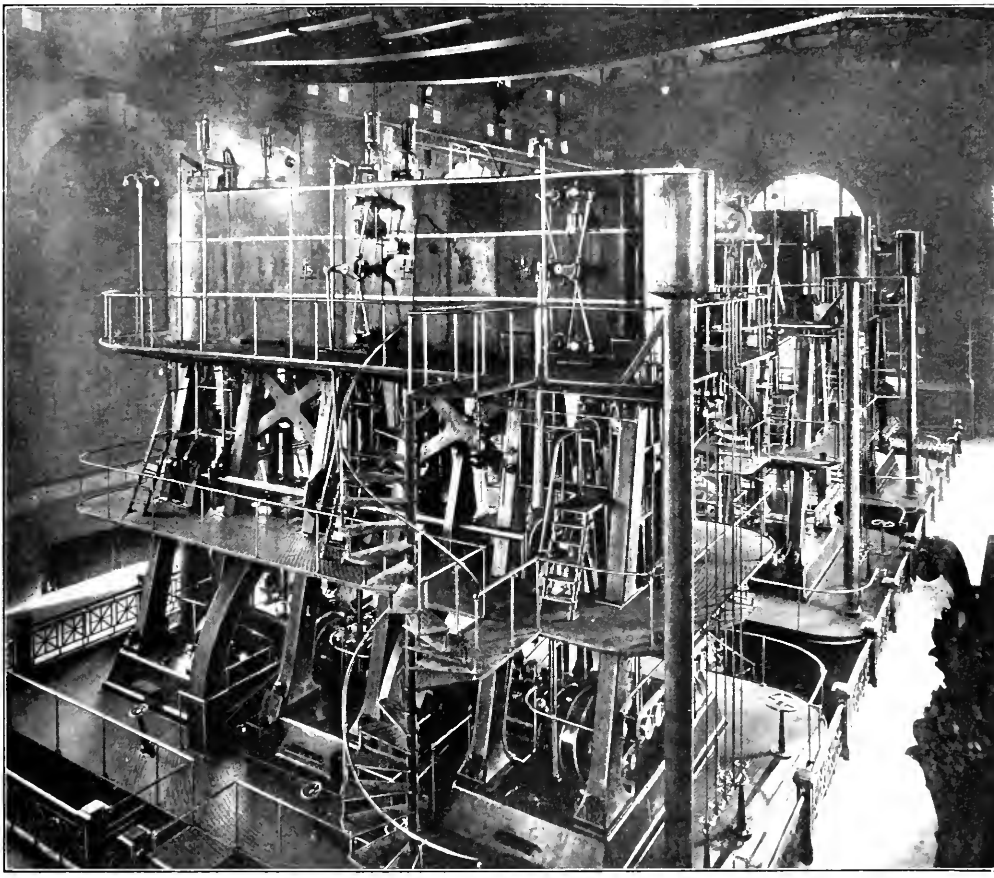


Fig. 2. Three 30,000,000-Gal. Pumping Engines Occupying Half the Station

Gages to measure the draft, a steam-flow meter and a CO_2 recorder make it possible to check results obtained from the boilers.

Fuel is obtained by boat during the navigation season. It is unloaded into a hopper, crushed, and conveyed to storage sheds of 12,000 tons capacity. Industrial cars carry the coal into the boiler room where, with the exception of the new boilers, it is shoveled into the magazines of the stokers. For the late addition a half-ton air hoist transfers the coal from car to stoker.

Water from the jet condensers and the steam jackets of the engine cylinders is discharged to hotwells at a temperature of 140 deg. and fed to the boilers by single-acting pumps operated from the walking beams or the main shafts of the first six units. The pumps discharge into from what type of machines the operating data presented later were obtained.

New Pumping Station

In 1909 the water commission broke ground for the new station which rapidly increasing demands made necessary. The building, which has just been completed, was planned for six units, being 300 ft. long and 75 ft. wide. It is one of the finest structures of its kind in the country. Concrete foundations, walls of cut stone and pressed brick, a marble entrance, large bronze doors, electroplated railings around the pits, massive lighting fixtures, slate and terrazo floors and white enamel brick walls in the basement are some of the features which helped to make the building cost half a million dollars.

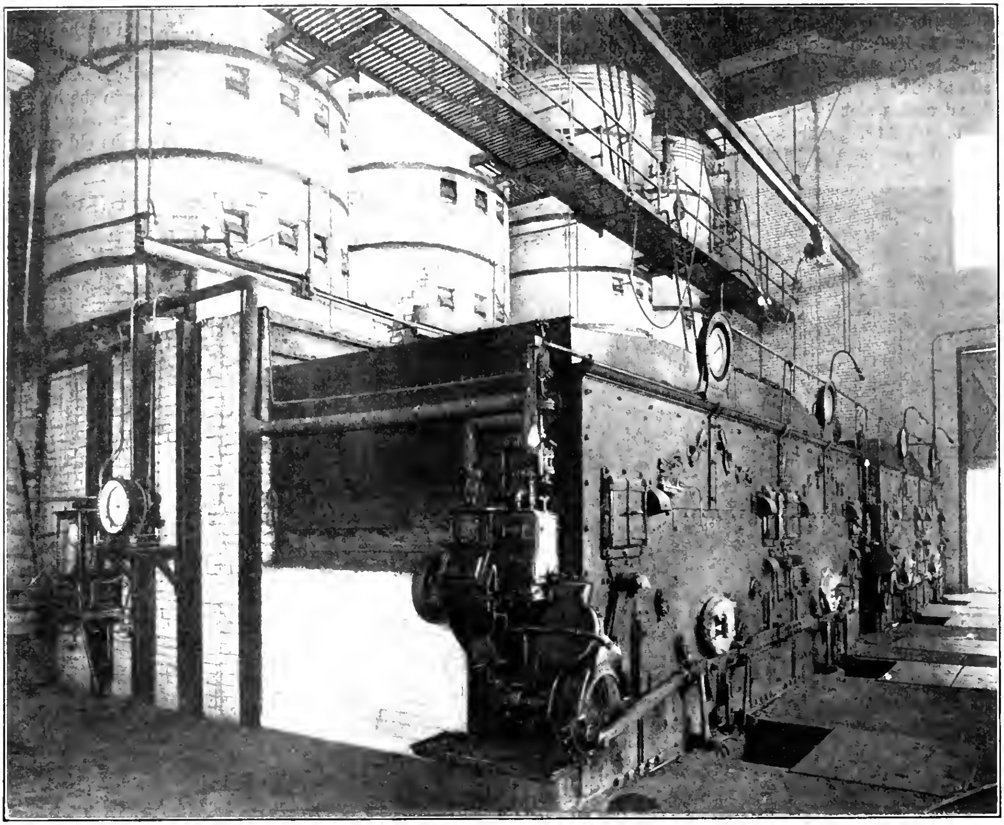

Fig. 3. Four 400-Hp. Vertical Water-Tube Boilers Installed in 1913

Three of the six units for this building have just been erected and put into service. All are triple-expansion engines of 30,000,000-gal. capacity, with cylinders 32, 60 and 90 by 39¾ by 66 in. The pumps are of the double-flow type and each has on the suction side a condenser having 2000 sq.ft. of surface. Hydraulically operated gate valves 48 in. in diameter are fitted to the suction and discharge pipes. Each pump weighs approximately 900 tons, of which 70 tons is accounted for by two 20-ft. flywheels. The hollow steel shaft is 22 in. in diameter. A feature is the making of the water ends entirely of cast steel. Extra strength was required, as the water is delivered directly to the mains, with no intervening reservoirs. No official tests have been conducted, but the duty guaranteed on 1000 lb. of saturated steam is 172,000,000 ft.-lb., and 180,000,000 ft.-lb. is expected by the builder. The cost of the pumping equipment was close to $3700 per million gallons of daily capacity.

PRINCIPAL EQUIPMENT OF DETROIT WATER-WORKS

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
1	Pumping engine	Compound, beam	42x84x40¼x72-in.	Main unit	Steam pressure 65 lb., head 60 lb.	Detroit Locomotive Works
1	Pumping engine	Compound, beam	46x84x44x72-in	Main unit	Steam pressure 65 lb., head 60 lb.	Riverside Engine Works
1	Pumping engine	Compound, beam	35x84x44x84-in.	Main unit	Steam pressure 135 lb., head 60 lb.	Riverside Engine Works
1	Pumping engine	Triple-expansion	28x48x74x36x60-in	Main unit	Steam pressure 135 lb., head 60 lb.	E. P. Allis & Co.
2	Pumping engines	Triple-expansion	34x62x92x36¾x72-in	Main unit	Steam pressure 135 lb., head 100 lb.	Allis-Chalmers Co.
1	Pumping engine	Triple-expansion	32x60x90x37½x66-in	Main unit	Steam pressure 165 lb., head 100 lb.	Allis-Chalmers Co.
3	Pumping engines	Triple-expansion	32x60x90x39¾x66-in	Main unit	Steam pressure 165 lb., head 100 lb.	Bethlehem Steel Co.
6	Condensers	Jet		Serving main units	26-in. vacuum	Same as pumping engines
6	Air pumps	3 single-acting, 3 double	Varying sizes	Serving jet condensers	Direct-connected—Speeds 12 to 21 r.p.m.	Same as pumping engines
4	Condensers	Surface	2000 sq.ft.	Serving main units	28-in. vacuum	3 Bethlehem engines—Worthington condenser; 1 Holly engine—Holly condenser
6	Pumps	Single-acting	Varying sizes	Boiler feed	Mechanically driven by main units	Same as main units
3	Boilers	Vertical water-tube	333 hp.	Generate steam	Steam pressure 165 lb., stokers	Wickes Boiler Co.
3	Stokers	Jones underfeed		Serving 333-hp. boilers		Under-Feed Stoker Co. of America
4	Boilers	Wood type	225 hp.	Generate steam	Steam pressure 110 lb., stokers	Wickes Boiler Co.
4	Stokers	Top feed		Serving wood boilers		Murphy Iron Works
4	Boilers	Vertical water-tube	225 hp.	Generate steam.	Steam pressure 165 lb., stokers	Wickes Boiler Co.
4	Stokers	Top feed		Serving 225-hp. boilers		Murphy Iron Works
4	Boilers	Vertical water-tube	400 hp.	Generate steam	Steam pressure 165 lb., stokers	Wickes Boiler Co.
4	Stokers	Top feed	50 sq.ft. grate	Serving 400-hp. boilers		Detroit Stoker Co.
1	Air hoist	Motor, air	5-ton	Serving 400-hp. boilers		Detroit Machine & Hoist Co.
2	Cranes	Travelling	30 and 20 tons	In new and old stations		Northern Engineering Works

Although an independent boiler room and coal-storing sheds are contemplated for the new station, at present steam is supplied from the boiler room of the older plant, the new 400-hp. boilers giving ample capacity; a total of 4399 boiler-horsepower in 15 boilers supplying 10 pumping engines having a combined capacity of 267,000,000 gal. in 24 hr. against a varying head running up to 100 lb. Thus, for a million gallons in 24 hr., 16.5 boiler-horsepower has been provided. Working on 8-hr. shifts, 65 men are employed for both stations.

Operating Data

Data available from the Board of Water Commissioners for the year ended June 30, 1914, are presented in the following: For the year the total water consumption was 40,724,947,672 gal. pumped to an estimated population of 652,000 against an average head of 53.2 lb. This reduces to an average daily consumption of 111,575,200 gal. and an average daily per capita of 171.4 gal. Of the total, 11,257,814,355 gal. was pumped on the high service against an average dynamic head of 63.7 lb., and on the low service 29,467,133,317 gal. against an average head of 47.4 lb. On Feb. 13, the maximum day, the pumpage was 145,607,536 gal., and on Dec. 25, the minimum day, 85,187,023 gal. For the high service the average daily was 30,843,327 gal. and for the low service 80,731,872 gal.

Each unit is equipped with a Venturi meter, which, on an average, reads to within 5 per cent. of the pump displacement. In the above figures an allowance of 6 per cent. slip was made for the three compounds and one triple-expansion engine and 5 per cent. on the other units.

During the year 46,874,865 lb. of Meadowbrook bituminous run-of-mine coal was burned. Including unloading from the boats, the price averaged $2.515 per ton. Per pound of coal 869 gal. was pumped against an average head of 53.2 lb. or 123.7 ft. The average duty per 100 lb. of coal was 88,906,868 ft.-lb. The pumping cost

COST OF PUMPING BASED ON STATION EXPENSES

Item	Amount per Year	Cost per Mil. Gal.	Cost per Mil. Gal. Raised 100 Ft.
Pay roll	$67,533.31	$1.66	$1.35
Fuel	59,103.57	1.45	1.18
Oil and waste	1,446.76	0.04	0.03
Supplies and repairs	4,359.97	0.11	0.09
Miscellaneous	3,556.77	0.08	0.07
Totals	$136,000.38	$3.34	$2.72

based on station expenses is given in the accompanying table. The total for the year is $136,000.38. This reduces to $2.72 per million gallons raised 100 ft. Figured on total maintenance, the cost per million gallons was $6.23.

Smith, Hinchman & Grylls, of Detroit, were the architects and engineers for the new station. Theodore A. Leisen is general superintendent of the Board of Water Commissioners and H. W. Gould engineer-in-charge of the pumping station. To both of these officials we are indebted for the information contained in this article.

The Constant-Current Transformer

By John A. Randolph

SYNOPSIS—Principles and construction of the constant-current transformer, with a diagram of its connection to arc-light circuits.

On all series arc systems it is important that the current be maintained constant irrespective of how many lights may be turned on or off. This is accomplished on direct-current systems by varying the voltage of a special generator assigned to each circuit. However, on alternating-current systems the arc lines are generally connected to busbars supplying other circuits, hence the maintenance of the constant current must be accomplished without affecting the generator pressure on the busbars. To secure this result, a special form of transformer is used. It is similar to the ordinary static transformer, the principal difference being that one of its sets of coils is movable.

Construction

The general construction is shown in Fig. 1. The transformer contains two coils, a primary and a secondary, one of which (in this case the primary) is stationary, the other being movable. The coils encircle the middle leg of a laminated iron core of the double magnetic-circuit type, the length of the core being sufficient to allow the secondary to move up and down through the required range. The secondary is suspended on either side from a rocker-arm attached to a shaft, which in turn is connected at its middle point to another arm extending oppositely to the other arms and which carries an adjustable weight. An oil-filled dashpot is also attached to the shaft for the purpose of steadying the movements of the shaft and its accessories.

Operation

In analyzing the operation, consider two simple closed coils of wire P and S placed side by side with axes coincident, as shown in Fig. 2. If a current is passed through

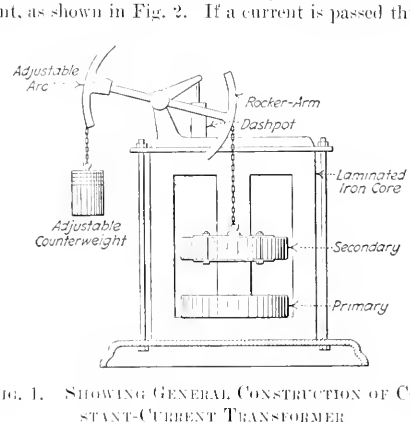

Fig. 1. Showing General Construction of Constant-Current Transformer

coil P, it will produce a magnetic field which will expand with the rise of the current. As these lines of force move outward they will be cut by the coil S. Now, according to the laws of electromagnetic induction, this cutting of lines of force will induce a current in the coil S, the direction of which will be opposite to that in coil P. This induced current will in turn set up a magnetic field of its own, but it will be opposite in polarity to that of coil P, owing to the opposite direction of the respective currents. A magnetic repulsion will therefore ensue between coils P and S. This action has been summarized in Lenz's law as follows: "In all cases of electromagnetic induction the reaction of the induced current is such as to tend to stop the motion which produces it." It is

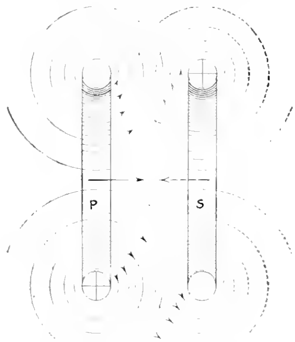

Fig. 2. Illustrating Principle of the Constant-Current Transformer

upon this principle that the operation of the constant-current transformer depends.

The counterweight in the two-coil type, shown in Fig. 1, is adjusted to exactly balance the weight of the secondary coil minus the repulsion, thereby rendering the transformer sensitive in its action and overcoming to a large extent the attraction of the force of gravity on the coil. The secondary coil is connected directly to the outgoing arc lines and the primary to the busbars. It can be said in general that the repulsion between the primary and the secondary will vary with the current in the latter. If, with the secondary coil in a given position, an additional number of lamps is turned on, the added series resistance will at once reduce the current for that particular instant. This will result in a decrease of the reaction of the secondary upon the primary, thereby allowing the secondary to fall nearer the primary, where the stronger field will induce the extra pressure necessary for maintaining a constant current in the secondary. The turning off of lamps will cause an instantaneous increase in the secondary current, which will increase the repulsion and cause the secondary to move to a weaker field, where the voltage will be lowered sufficiently to prevent any rise of current in the lamps that remain burning.

It will be observed in Fig. 1 that the arc on the end of the rocker-arm which carries the counterweight is adjustable. This is for the purpose of compensating for the difference in field strength in the various positions of the secondary. For instance, in a strong portion of the field, the difference between the weight of the secondary and the force of repulsion is less than in a weaker part of the field. Therefore, unless the counterweight were adjusted to balance this added weight in the weaker field, a stronger current would be necessary in the secondary to shift the latter to a position of equilibrium than would be required in the stronger field. The constancy of the current in the arc circuit would therefore be destroyed. However, by the adjustment of the arc from which the counterweight is suspended, the latter is caused to pull more heavily on the secondary in the weaker parts of the field, thereby enabling the secondary to maintain a constant-current value.

Three-Coil Type

As the capacity of the transformer increases, the number of ampere-turns in the primary and the secondary must also increase. Therefore, if only two coils were used, this would result in bulky windings and accessories which it would be difficult to handle and which would be likely, on account of their inertia, to lack the proper sensitiveness in operation. To obviate these difficulties three or four coils are used instead of two. In the three-coil type one primary and two secondaries are used, as in Fig. 3. Large pulleys are used instead of levers for the chain connections to the counterweights. The primary is stationary and is placed between the two secondaries, which are movable. Each secondary has two pulleys and a counterweight of its own and is entirely independent of the other in its action. Therefore, the repulsion and the distance between coil S_1 and the primary may be widely different from that between coil S_2 and the primary. Arc circuits may therefore be operated on the two coils in entire independence of each other. To increase the current in coil S_1, the external resistance remaining the same, the weight W_1 is reduced, allowing the coil by means of gravity to move nearer the primary. On the other hand, to increase the current in coil S_2, the counterweight W_2 must be increased in order to overcome the force of gravity and raise the coil to a position nearer the primary.

Four-Coil Type

In this transformer the primary and secondary are each composed of two coils, both coils of one set, either

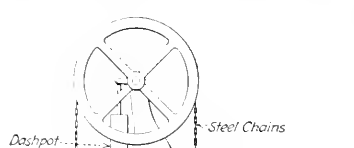

Fig. 3. Three-Coil Type

primary or secondary, being movable. In Fig. 4 is shown the arrangement of coils where the secondary is movable. The two primary coils are fixed at the extremities of the middle leg of the laminated iron core, the secondaries being free to move up and down in the intervening space. A repulsion between the primary and the secondary causes the two coils of the latter element to move toward the center of the core, thereby approaching each other. The movable coils are balanced against one another on two double levers, A and B, one end of lever A being connected to coil S_1 and the other to coil S_2. Likewise, lever B is connected to the other sides of coils S_1 and S_2. With this arrangement the secondaries will exactly balance each other when no external force is applied. This equilibrium, however, is destroyed as soon as a force of repulsion is set up between primary and secondary. To counterbalance this repulsion and regulate the movements of the secondaries, a counterweight is attached to the lever system. This has a tendency to bring the primary and the secondary coils together and is set to counterbalance the repulsion for a given current. As in the case of the two-coil transformer, the counterweight is supported on an adjustable arc to compensate for the difference in field strength in the various parts of the magnetic circuit.

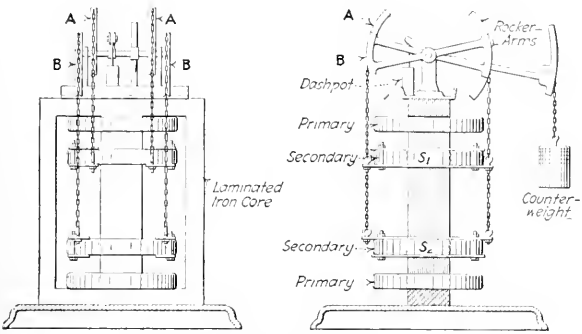

Fig. 4. Arrangement of Four-Coil Type with Movable Secondaries

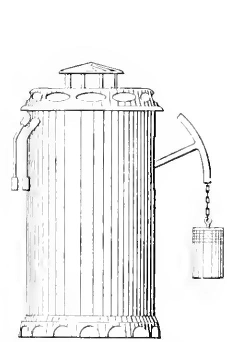

Fig. 5. Casing of Air-Cooled Transformer

Installation and Connections

Constant-current transformers are made in both the air-cooled and the oil-cooled types. When of the former pattern, all the parts except the counterweight are inclosed in a suitable sheet-iron case, as shown in Fig. 5, with liberal openings at the top to provide the necessary ventilation. Large openings are also left in the bedplate for the same purpose. In the oil-cooled type all the interior parts are placed in a tank and covered with oil, its external appearance being similar to that of the ordinary oil-cooled static transformer.

A diagram of connections commonly followed in the use of the constant-current transformer on three-phase systems is shown in Fig. 6. In the case shown the transformers are of the larger type containing two primaries and two secondaries, and the windings are connected for full load. However, it is sometimes desired to operate on partial loads, under which conditions, owing to the inductance of the primary coils, the power factor would be considerably reduced were the full winding used. To obviate this difficulty and thus maintain the efficiency of the system, taps are provided on the primary whereby part of the winding may be cut out, thus reducing the inductance and raising the power factor. Taps are also generally provided in the secondary coils for the same reason.

For opening and closing the primary circuit, either plug switches or oil switches may be used, but it is common practice to use the latter because of greater convenience in operation and the fact that they will open automatically if a sudden abnormal load is thrown on the transformer through a short-circuit, a ground, a lightning discharge or other disturbance. This tripping of the switch is accomplished by a relay which receives its

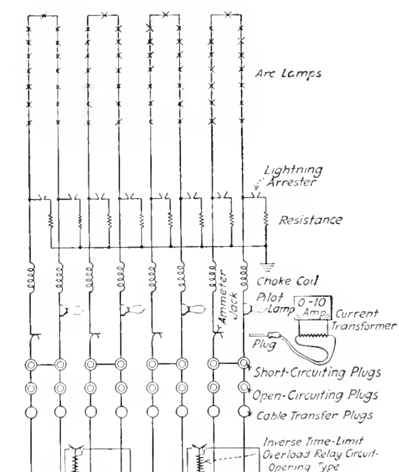

Fig. 6. Typical Diagram of Connections for Constant-Current Transformers

excitation from a current transformer in one of the primary leads.

Cable transfer plugs are provided in the secondary lines for the purpose of transferring the load on any line to another circuit. This provides a convenient flexibility in the system in case of repairs and other contingencies. The open-circuiting plugs are for the purpose of disconnecting the various circuits from their respective transformers. The short-circuiting plugs enable one of the two circuits of each transformer to be disconnected from the system without affecting the operation of the other.

An ammeter is provided on the arc panel to give current readings on the various circuits. To enable the customary low-voltage switchboard ammeter to be used, a current transformer is placed between the ammeter and the line, thereby preventing the high voltages of the line from coming in direct contact with the ammeter. The transfer of the instrument from line to line is accomplished by means of a plug attached to a flexible cord. The plug is inserted into a jack or receptacle attached to one leg of the respective circuits. As an additional means for providing current indications, a pilot lamp is connected in series with each circuit. This furnishes an approximate indication when the ammeter is disconnected.

Choke coils are placed in the various lines for the purpose of forcing lightning discharges to jump to ground through the lightning arresters, thus protecting the station apparatus.

It will be observed that larger wire is used on the primary side of the transformer than on the secondary. This is because on the heavier loads the primary, owing to its constant voltage, may be taking a heavier current than the secondary whose current never varies and is usually about ten amperes.

The efficiency of the constant-current transformer, when operating under full load, ranges from 94 per cent. in the smaller sizes to 96 per cent. in those of larger capacity.

⁂

Examining the Examiner

In connection with the selection and appointment of the members of the Steam Engineers' and Boiler Operators' Licensing Bureau recently authorized by the State of New Jersey, the impression has been created that the questions asked by the Civil Service Commission of candidates to membership on the Board of Examiners were abstruse and technical to such a degree that no practical engineer could be expected to answer them. We have obtained from the Board the list of questions used at the examination which has been most discussed. Here they are. Is there a question in the list which one who aspires to be a state examiner of engineers should not be able to answer?

GENERAL QUESTIONS

A. State your experience, giving a complete record of where you have been working the last ten years; stating the size and make of each engine and boiler that you had under your jurisdiction, also giving name of the man, with his title, to whom you reported.

B. Write out five questions which you would suggest as desirable to use in examining a candidate for a first-class engineer's license.

C. Describe fully what you believe would be a correct method to use in forming different grades for engineers' and firemen's licenses.

Note: Candidates may ask examiner for explanation of any question that is not understood.

WRITTEN TECHNICAL QUESTIONS

1. Show by a sketch how a (one) steam main should be arranged in a boiler room in which there are two 200-hp., 160-lb. pressure boilers and two 100-hp. 100-lb. pressure boilers, so that at times all boilers might be put in service at 90-lb. pressure, or, each may be used at its respective pressure. Indicate all valves, reliefs, safetys, etc.

2. Calculate the horsepower of a boiler plant that burns 35 lb. of coal per square foot of grate per hour under boilers containing 10,000 sq.ft. of heating surface. Ratio of heating surface to grate surface = 50:1. Heat units in coal = 15,000 B.t.u. per pound. Efficiency of burning coal in boiler = 60 per cent.

3. Show by a sketch a triple-riveted butt-strap joint, and explain why longitudinal seams are butt-jointed and girth seams are lap-jointed.

4. A flat plate, 16x12 in. is held against a tank by four 1-in. bolts; what is the safe pressure to use in the tank, assuming factor of safety 5, tensile strength 50,000 and diameter root of thread = ¾ in.?

5. Show the arrangement of tubes, doors, etc., indicating the location of grate, smoke flue and baffles, for
   (a) Babcock & Wilcox cross-drum boiler
   (b) Stirling boiler
   (c) Heine boiler
   (d) Horizontal return-tubular boiler

6. (a) How many square feet of grate should there be for a 500-hp. boiler burning soft coal?
   (b) How large a piston should there be in an engine to develop 500 hp., if the mean effective pressure is 100 lb. and the piston speed is 250 ft. per min.?

7. If the eccentric of an engine is set so that it has an angle of advance of 28 deg., and if it is desirable to change the direction of rotation of engine, exactly how many degrees would you move the eccentric and in which direction, so that the angle of advance would still be 28 deg.?

8. How could you increase the operating speed of a flyball governing Corliss engine and yet have the "cutoff" the same?

9. If a cross-compound engine was out of adjustment how would you proceed to correct the steam distribution, so that equal work would be done on both cylinders?

10. Explain in detail how you would proceed to erect a girder-frame engine so that it would be level, true and aligned up to connect to a flange on a shaft already installed.

11. (a) What is meant by "clearance" of an engine?
    (b) How could you determine the location of the piston in respect to the ends of the cylinder, without removing the heads?
    (c) At which end of the stroke should the greater distance to the cylinder head be allowed? Why?

12. Show by a sketch how the exhaust-steam piping should be arranged for an engine operating with a surface condenser, indicating all valves, reliefs, etc.

Note: An examiner was present during the examination to explain any question that was not understood by candidates.

ORAL QUESTIONS

The candidate upon finishing the above set of questions will be examined orally on practical questions submitted to him in the engine and boiler room.

The candidate may answer the questions orally, or by demonstration.

Note: The general questions asked the last candidates were in connection with the following:

Cross-Compound Corliss Engine with Flyball Governor

1. Trace path of steam through the engine.
2. Explain the use of pipe pointed out (atmospheric relief pipe for high-pressure cylinder).
3. Examine, and explain completely the action of the engine governor.
4. Explain why the engine would not speed up if the governor belt broke
5. Explain the use and principle of operation of the dashpot.

High-Speed Vertical Compound Engine, Double Acting

6. Examine, and state type of engine.

Single-Cylinder Horizontal Engine, with Inertia Governor

7. Explain operation of the governor on the engine shown.

Vacuum Pump

8. Examine, and state what the piece of apparatus pointed out is used for.

Worthington Surface Condenser

9 Examine, and state what the piece of apparatus pointed out is used for.

Open-Type Feed-Water Heater

10. Examine, and state what the piece of apparatus pointed out is used for.

11. Is the heater shown an open or closed type?

Forced-Draft Apparatus (Engine and Centrifugal Fan)

12. Explain the use of the apparatus pointed out.

13. Does the engine have a lighter load with the forced-draft slides entirely closed, or with them entirely open?

Pressurlokd Water Gage

This water glass is so designed that the boiler pressure is used to lock the registering glass, which prevents the glass from flying should it break, and also prevents the escape of hot water and steam. A sectional view is shown in Fig. 1.

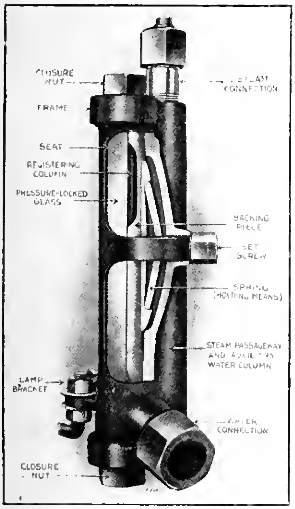

Fig. 1. Details of Pressurlokd Water Gage

The outfit consists of a metal-gage frame in which the registering glass *A*, Fig. 2, is held in place by a metal-sealed joint *C* to the seat *H*, by a back piece *N* and a holding spring *I*. The interior parts are held in place by a setscrew *L* which, when screwed down to its copper sealing washer, puts the proper tension on the spring. This tension, supplemented by the steam pressure at the points *D*, holds the backing piece and metal-incased glass to its seat on the inside of the frame, thus pressure-packing the metal-sealed joint. The steam pressure around the sides *EEK* and on the ends of the metal-incased glass locks the glass. Should the glass crack, the external pressure on the side and ends presses the shattered pieces closer together, which prevents leakage and the flying of glass.

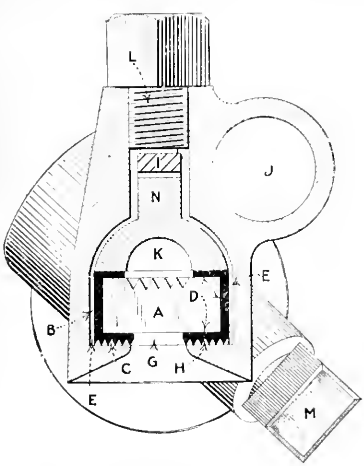

Fig. 2. Cross-Section of the Gage

The registering glass is incased with a sealing metal *B*, with the exception of the sight opening in front and the reflex part at the back. The metal frame seats on the serrated front *C* of the metal casing around the sight opening *G* inside of the frame. The spring which holds the glass to its seat permits it to expand and contract on its seat, thus relieving it of strains.

The space *K* back of the glass communicates with the water space *J*, and to the boiler through water and steam passageways. The steam and water connections to the boiler are straightway and, as no separate water column is used with the glass, straightway valves are used in the connections. Each valve is fitted with a semaphore handle, which shows whether the valve is open or closed. *M* is a cleaning plug.

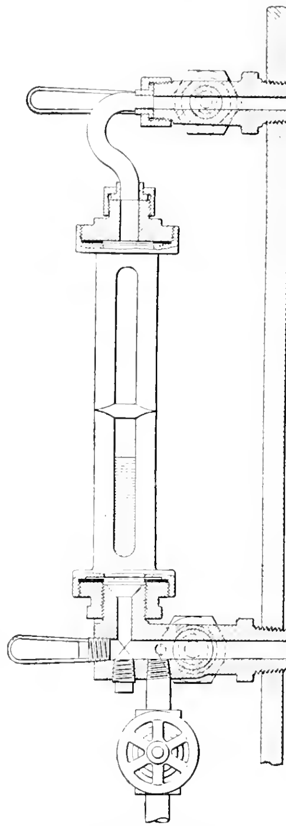

Fig. 3. Universal Gage for Any Boiler

The universal type of water glass, designed for any type of stationary boiler, is shown in Fig. 3. It contains the features of the locomotive type (Fig. 1) and is provided with a separate steam passageway, no water-column reservoir being used.

In case the glass breaks, the closures at the top and bottom of the frame are unscrewed, the setscrew is released and the old glass removed. When the new glass is inserted the setscrew is turned to its seat, copper gaskets inserted and the closures replaced.

These water gages are manufactured by the Prince-Groff Co., 50 Church St., New York City.

In "The Year's Review," published in our issue of Jan. 5, we failed to mention that the first unaflow engine built in this country under Professor Stumpf's patents and under the supervision of his American representatives, was erected at Auburn, N. Y., by the Ames Iron Works. We are glad to learn that the success of this first engine has led to numerous orders, and hope soon to be able to describe a considerable installation.

Power Requirements of Ammonia Compressors

By W. N. McKee

SYNOPSIS—An explanation of the use of charts for determining the power requirements of ammonia compressors for different suction and discharge pressures.

The power required to drive ammonia compressors is a constantly varying quantity due to the many operating conditions possible with such machines. Likewise, the amount of ammonia gas which it is necessary to circulate to produce certain amounts of refrigeration may vary in equally wide ranges.

The engineer who keeps records of costs in the operation of the plant has been compelled to go through a tedious routine of figures to maintain his daily records. This process becomes a burden when the engineer has a number of plants in various parts of the country. These plants must necessarily be operating under widely varying conditions which different climatic conditions make inevitable. To meet these conditions and include the greater number of variables, Charts I and II have been prepared and used by the writer in records covering the operation of a number of refrigerating plants.

Chart I is based on a table in a paper read by Thomas Shipley before the 1906 meeting of the American Society of Refrigerating Engineers. It shows "the minimum theoretical power utilized in a compressor to compress sufficient ammonia gas which, when liquefied at the pressure stated, will, upon being evaporated from the temperature corresponding to the given pressure to the temperature corresponding to the pressure in the evaporating system, do the same amount of work (have the

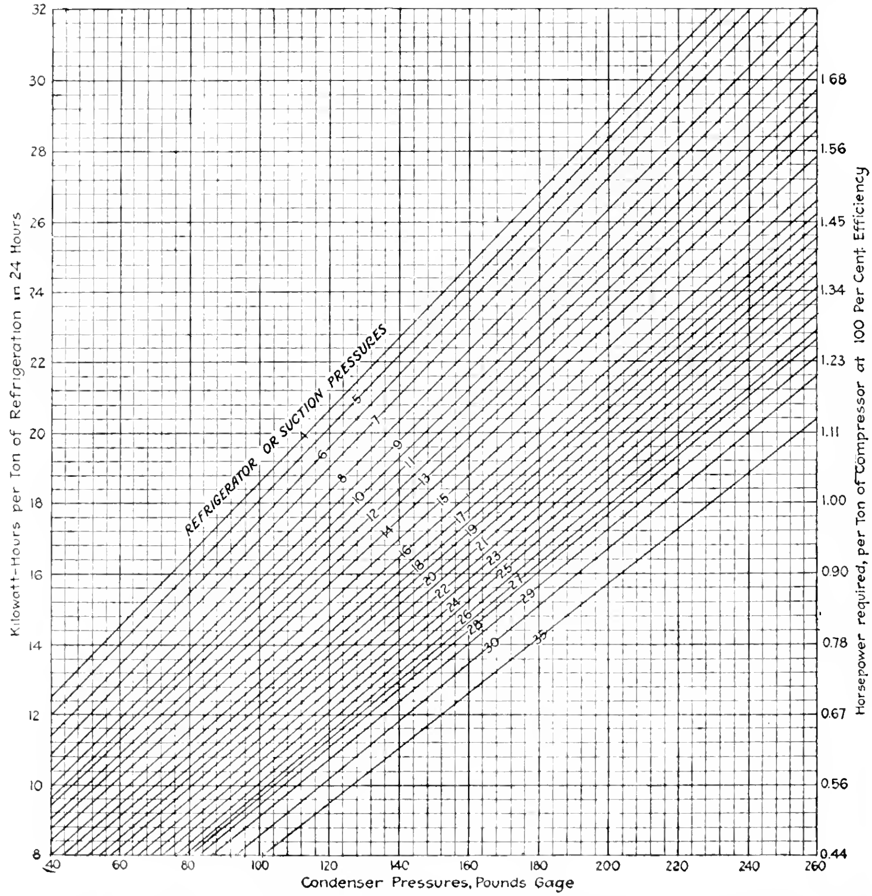

Chart I. Power Required per Ton Refrigeration for Various Suction and Condenser Pressures same cooling effect) as is done in the melting of one ton of ice." The kilowatt-hours, if the compressor is motor driven, to fulfill above conditions in a twenty-four hour period, is shown on the right, and the horsepower required is given on the left-hand margin. In each case the volumetric efficiency of the compressor and the efficiency of the motor are assumed as 100 per cent.

Chart II is to be used for closely estimating the work of the compressor or the amount of refrigeration produced over any period when the capacity and volumetric efficiency of the compressor are known.

pressor efficiency it will require 1.11 hp. per ton of refrigeration. Assuming 80 per cent. volumetric efficiency, then 1.11 divided by 0.80 and 15 per cent. added for friction load, gives nearly 1.6 hp. per ton refrigeration.

To the left it will be found that it requires 20 kw.-hr. per ton refrigeration in twenty-four hours at 100 per cent volumetric efficiency of the compressor. Then 20 divided by 0.80 volumetric efficiency and 15 per cent. added for friction, dividing this figure by 0.90 (approximate motor efficiency) gives 31.94 kw. per ton of refrigeration in twenty-four hours. The total current consumed,

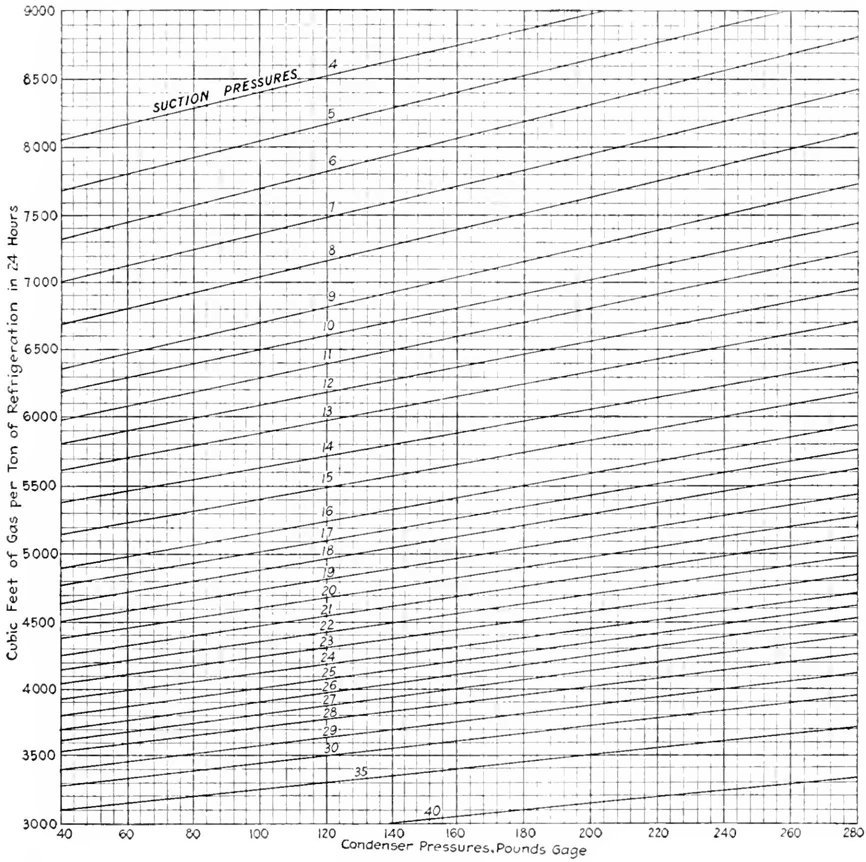

Chart II. Volumes of Gas per Ton Refrigeration for Various Suction and Condenser Pressures

This refrigeration as given is expressed in tons per twenty four hours. In the use of Chart I, take as an example an average condenser pressure of 180 lb. gage, average suction pressure, 16 lb. gage, to find the horsepower of the motor or engine required to drive a 100-ton compressor, also the current consumption on a twenty-four-hour load at the given suction and condenser pressures, follow the line for 180 lb. condenser pressure up, until it meets the 16-lb. suction-pressure line, and then along on the horizontal line to the right for the horsepower to drive and to the left for kilowatt-hours per ton for twenty-four hours. At 100 per cent. com-

31.94 times 100 (rating of the compressor) gives 3191 kw.-hr.

In the use of Chart II, it is necessary to know the capacity of the compressor over some definite period. If the machine starts and stops frequently or is of the automatic type without attendance, a revolution counter should be attached by which the capacity will be known over any period regardless of frequent stops.

As Chart II gives the number of cubic feet of gas required at 100 per cent. efficiency, it will be necessary to find the actual displacement of the compressor at the operating pressures for the proper period of time or number of revolutions. It is advisable to bring the displacement of the compressors to the same condition as stated in the chart, or 100 per cent. for a definite time, and thus obtain results by one division or multiplication.

The power required to drive small ammonia compressors of the single-acting type where the condenser pressures are not known but are for average refrigeration will be approximately as follows:

Capacity Tons	Horsepower Required	Capacity Tons	Horsepower Required
1	2	8	14
2	3½	9	15
3	5	10	17
4	7	15	25
5	8½		

In the table a friction load of 15 per cent. has been assumed. This would be the average for medium to large engine-driven units. For smaller units and belt drive the friction load may run greater, although the worst condition is seldom over 20 per cent.

If the ammonia liquid is cooled below the temperature corresponding to the condenser pressure, the tonnage will be increased thereby, but as this is not a usual operating condition it has not been included in the charts. The standard conditions have been assumed in which a ton of refrigeration is equivalent to the circulation of 26.7 lb. of anhydrous ammonia per hour at 15.67 lb. above the atmosphere, condensing pressure taken at 185 lb. gage pressure.

Tom Hunter, Hoisting Engineer

By Warren O. Rogers

SYNOPSIS—We visit an uptodate power plant and Hunter discusses high- and low-priced machinery; he points out that cheap units are uneconomical in operation. Some examples of wasteful pumps and fan engines are given as well as the reason for their condition.

The next morning after our visit to Scalp Level I was up and ready for another tramp before Hunter put in an appearance. When we started out for the day, we headed for No. 35 colliery of the Berwind-White Coal Mining Co., at Windber, Penn. Here we found two 100-kw., three-phase, 25-cycle, 6600-volt turbo-generators running at 1500 r.p.m. There was also a cross-compound engine-driven unit, the generator having the same phase, cycles and voltage as the turbine generators. Beside this equipment and the motor- and engine-driven exciter units, there were two 225-hp. motor-generator sets delivering alternating current, Fig. 1. M. J. Gross, the engineer of the plant, told us that the electrical energy was transmitted to eight substations and then transformed to 550 volts direct current for use in the mines. Steam for the plant was generated by twelve 250-hp. water-tube boilers equipped with mechanical stokers.

Here was a plant as uptodate as the one we had visited the day before. That both were owned by the one company was a striking indication to me that the central station did not cut much ice with these operators; that they found it economical to generate their energy on the ground where it was to be used.

"How is it that this company has built such substantial power plants while others appear to have been built apparently for short occupancy?" I asked, at the same time yanking Hunter out of the way of an electric locomotive drawing a train of empty coal cars into the mine

Hunter calmly proceeded to count the cars as they rumbled past—an even hundred, I believe—before he turned to answer my question.

"That is business," said he. "These mines are a long way from a central station in the first place; in the second, it will be a good many years before the mines will be worked out. For these reasons it is advisable to put up a substantial building to house the generating units. If the mines were to give out within the next few years, inexpensive buildings would have been the proper structures to have put up. The machinery, however, should be of the best, for when the present mine workings are abandoned, the machinery can be moved to a new site for further use."

"Well, that's clear enough, but with high-priced machinery the fixed charges will be high, while if the machinery is low in cost they will be correspondingly low."

"Right you are, but don't forget that low-priced machinery makes high operating costs. A cheap engine will generally consume an excessive amount of steam,

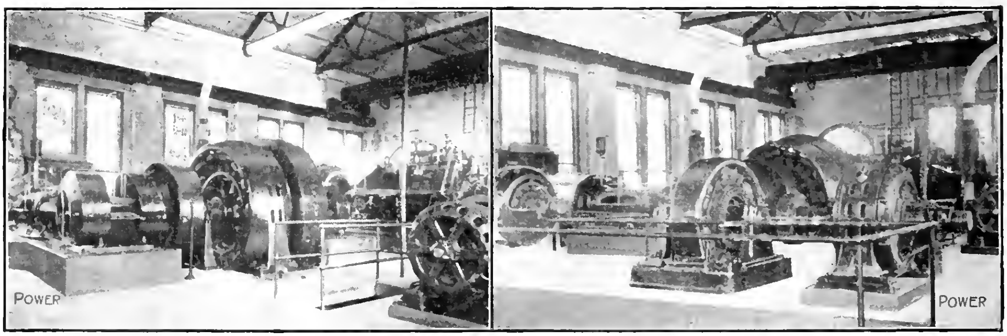

Fig. 1. Power Plant from Which No. 35 Colliery Is Operated

which means that an increased boiler capacity must be had over what would be required with an economical engine plant; this, of course, would lower the saving made on the price of the engine.

"My contention is that cheap machinery means high maintenance costs, let alone the losses occasioned by frequent shut-downs.

"When these units were put in," and Hunter motioned toward the power plant, "they were selected, no doubt, after the question of first cost and operating costs had been considered in conjunction with the load that could be expected during the year. The result was a plant containing expensive machinery and reduced fixed charges, low steam consumption, small repair bills and satisfactory operation. The opposite could be expected with low-grade apparatus."

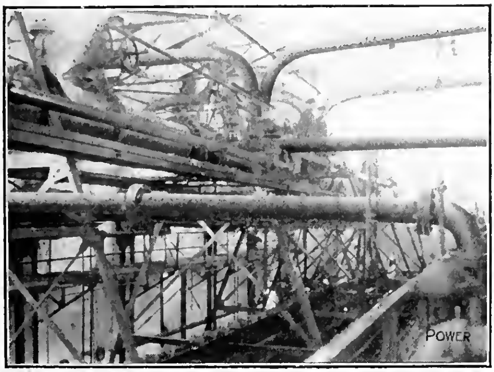

FIG. 2. THE WASTE OF STEAM IN THE AVERAGE MINE PLANT IS DUE LARGELY TO BARE PIPES, LEAKING JOINTS AND WORN ENGINE VALVES AND CYLINDERS

"You would recommend direct-connected units in preference to belted generators, I suppose?"

"I certainly would, because with direct-connected units all troubles from belts slipping, belt repair, etc., are out of the way, less floor area is required, and a smaller building can be used, which means a lower first cost."

"The fact that the general arrangement of the plant is simple, without any attempt at frills, should help with the first cost and with that of maintenance."

"Now you're talking! While simplicity does not mean cutting out necessary apparatus, there is no sense in putting in lines of piping to provide for a breakdown that in practice seldom comes. A steam plant should be designed to avoid as much as possible all chances of breakdowns, and, therefore, the best of material should be used at all points, for one breakdown caused by faulty material will offset the cost of the best many times over. Did you notice how the coal is delivered to the boilers?"

I confessed I had not.

"I'm surprised, because the delivery of coal to a boiler plant is of importance. This arrangement here is about as simple as it can be. Coal fresh from the mine is taken to the boiler house in the mine cars and, after passing through a coal crusher, is delivered to the coal bin above the stoking aisle in the boiler house. Of course, this is an exception, because but few steam plants are situated to take advantage of a drift or a slope level with the boiler-house coal bunkers."

"When you speak of simplicity of design don't you favor cross-connections, so that where several engines have their batteries of boilers they can be arranged to operate with another battery?"

"Now, don't make a mistake; I haven't said any such thing. In fact, interconnections between boilers and engines should be so arranged that any boiler or set of boilers can be used with any engine. The idea is that this arrangement gives the engineer an opportunity to make repairs to any set of engines or boilers without interfering with those in operation.

"With some arrangements of pipe lines there is no certainty that a supply of steam will be had for the fan engines, pumps and hoisting engines in case a boiler tube should burst. One safeguard against the stoppage of the steam supply is to equip each boiler with a nonreturn valve. Then if a tube does fail, putting one boiler out of service, the others will supply enough steam to operate the mine. If an accident serious enough to wreck the boiler plant occurs, then the best protected piping would be of no avail."

"I'll tell you, Hunter, I think the piping between the boilers and engines should be short, and provision made to take care of expansion in all high-pressure steam lines. For the life of me, I can't see how many steam lines could be any shorter than they are, although they may be several hundreds of feet long."

"Unless the mine is equipped with electric drive there is no way to get rid of long pipe lines, and unless properly drained there will be trouble when the water reaches the engines in large quantities, as there is danger of its doing, and wrecking the engine. On the other hand, if the water of condensation gets back into the main line there is danger of bursting the fittings by water-hammer. Not only should the pipe lines be drained, but the valves should be placed so that there will be no pockets of water when the valve is closed."

"The idea is that the pocket of water would go to the engine in a slug when the valve was opened?"

"You've hit it exactly! It is easy to collect such water in traps and return it to the boilers."

During the conversation we had made our way toward a fan house in which was a motor-driven fan. The absence of leaky pipe joints, piston packing and pounding engine was noticeable. Furthermore, the room was clean and free from the mass of grease and general filth so often found.

"This is a good object lesson in favor of electric drive," observed Hunter; "everything neat and clean, no vibrating steam pipes and other annoyances."

"Some steam lines do vibrate; how would you prevent it?"

"Putting in a receiver near the fan engine will frequently stop vibration if the receiver is of sufficient size to supply the engine with steam without materially lowering the pressure in the receiver. This would allow of a practically continuous flow of steam to the engine from the boiler and relieve the pipe of pulsation.

"The waste of steam about the average mine power plant is frightful, due to bare pipes (Fig. 2), leaking valves and worn cylinders. When there are apparently not enough boilers, more are put in; this is generally a waste of time and money. It would be more to the point to put all the engines and pumps in first-class condition, thus consuming a minimum of steam. Then the existing boiler plant would be sufficient for, if not in excess of, the steaming capacity required."

"You don't seem to have a high opinion of the steam equipment of some mines," I remarked as we left the fan house and started toward the street-car tracks in the town.

"Do you know that there are pumps operating in mines on a 24-hr. run which have been in use thirty or forty years and consuming—well, I wouldn't want to say right out, but 160 lb. of steam per water-horsepower would not be too high a figure.

"What can be expected when a pump is operated for long periods and not shut down until something happens? When repairs are being made, nobody thinks of making the pump run more economically; the one idea is to get it back in service as soon as possible, and but little attention is given to the condition of the cylinders, pistons, valves, etc. It's no wonder that steam is wasted.

"The same neglect is found with fan engines. They run day and night, seven days a week, and there is but little opportunity to overhaul them. I have known of fan engines that used about 80 lb. of steam per indicated horsepower-hour when half of that amount would have been excessive.

"The great trouble is that many mine operators conduct their business with the idea of getting a maximum coal output and pay little, if any, attention to the machinery that makes this output possible."

That afternoon we packed our grips and made for Pottstown, where, we were informed, there were several interesting collieries.

The Diesel Principle Applied to Small Engines

SYNOPSIS—This engine, of German design, is of the high-compression, double-piston type and embodies simplicity as well as compactness. With a direct-connected generator it is made in sizes of 10 to 40 kw.

A successful attempt to adapt the Diesel principle to the small oil engine has been made by the Allgemeine Elektricitäts Gesellschaft, of Berlin, which is now putting out direct-connected generating sets, in the two-cylinder model, with capacities of 10 to 40 kw. The engine is of the double-piston, two-cycle type, employing 420- to 570-lb. compression and a fuel-injection pressure of approximately 850 lb. In order to insure reliability in the hands of unskilled attendants, simplicity, accessibility and interchangeability of parts have been made an important feature in the design, and compactness is further increased by having the end of the crank case terminate in a flange to which is connected the stator of the generator.

Referring to Fig. 7, the compressor is seen to be mounted in line with the working cylinders and is driven from the main crankshaft. It comprises a two-stage injection pump E and a scavenging pump P. The latter is double-acting and is regulated by a rotary slide valve mounted on the vertical intermediate shaft. The upper part of the crank case forms a scavenging air reservoir L, into which project the lower ends of the cylinders. These are provided with scavenging ports, so that the air follows the most direct path. The relative locations of the pump P and the reservoir L do away with the necessity for intermediate piping. The injection pump is fitted with ring plate valves.

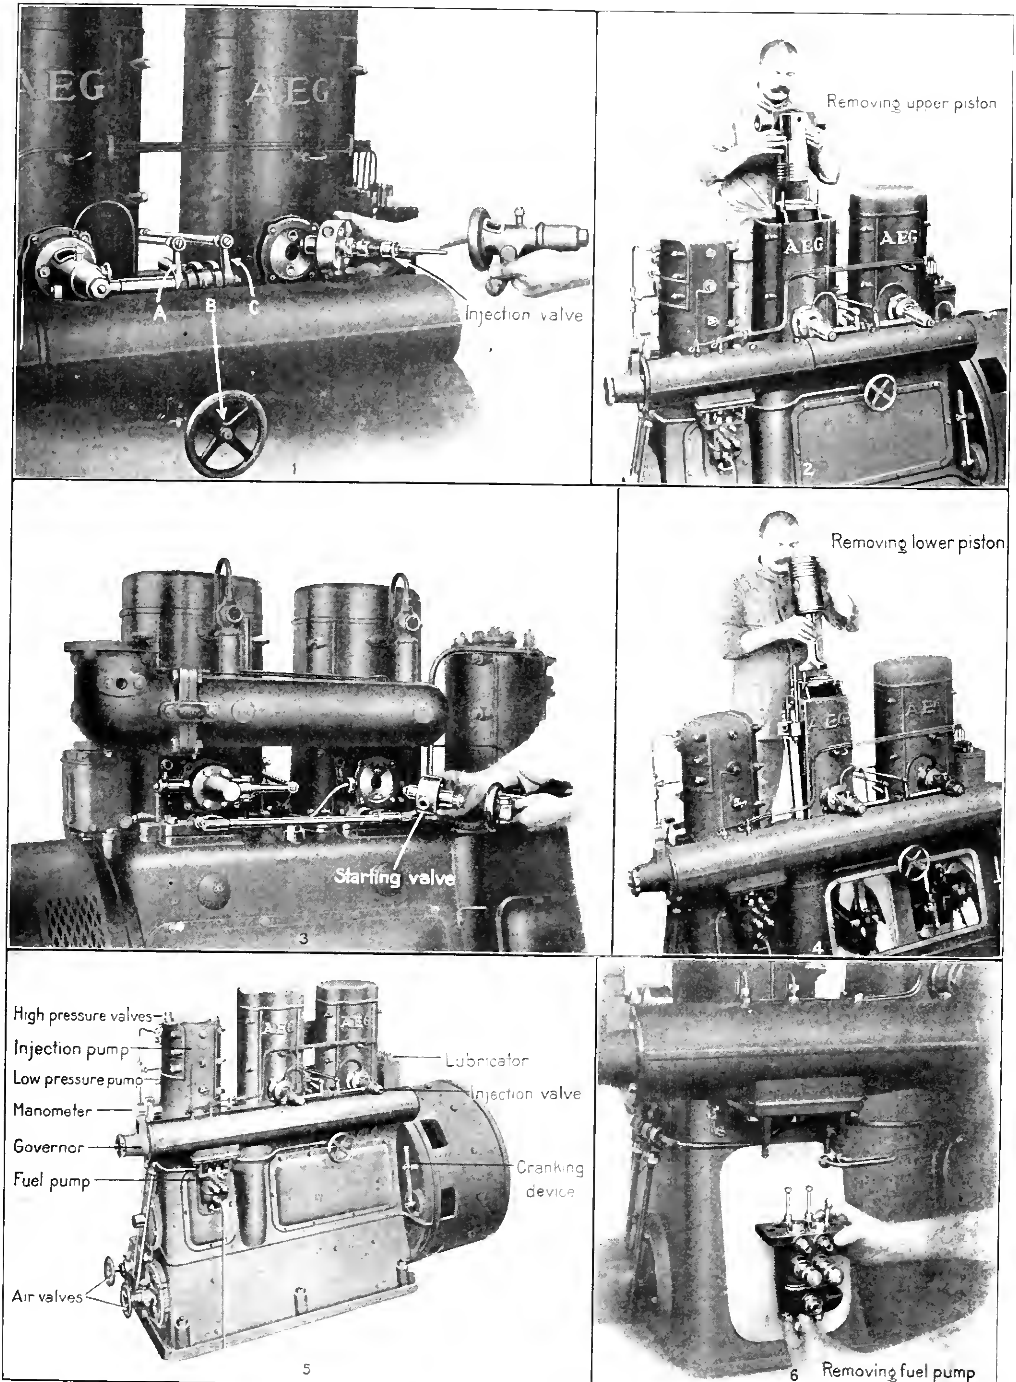
The air for starting and for fuel injection is stored in the cylinder F, located with the lubricating receptacles S in the under-frame of the engine. This not only provides a more convenient arrangement, but also allows the numerous valves for starting and fuel injection to be replaced by a common distributor, which carries a manometer (see Fig. 5) and a safety valve.

Amply dimensioned hand openings are provided, permitting convenient inspection and removal of parts. The driving gear is provided with forced lubrication, the oil being led to the bearings through passages in the casting and then distributed through recesses in the crankshaft to the pivots of the connecting-rods and the suspension rods, finally rising further through pipes to the piston pins. Nonreturn valves prevent the oil from running into the pipes when the engine is at rest, and a hand pump permits the pipes to be filled or washed out while the engine is idle. In the larger sizes the pistons are oil cooled. In this case the oil, which is supplied by a gear pump, flows to the lower pistons through jointed pipes and to the upper pistons through conical pipes, finally discharging through funnels.

A special point has been made of rendering the piston easily demountable. In about 10 minutes after stopping, the upper piston can be removed, and in another 10 minutes the lower piston can be taken out. These operations are shown in Figs. 2 and 4. There are no pipes to be disconnected, no valves to be removed, and no covers, tightened by packing, to be unbolted.

The crankshaft is driven by worm gearing through a vertical intermediate shaft, which can be removed bodily with the bearings and wheels after loosening a few bolts. The governor, mounted at the front end of the camshaft, works directly onto the fuel pump by means of an adjusting rod sliding in a slot on the camshaft. This does away with any external lever transmission. The handwheel shown is for adjusting the speed, which can be read from a tachometer placed above it.

Some difficulty was experienced in designing the fuel pump for the small engine, especially in connection with the regulation of the quantity of fuel, which in many cases amounts to only a few drops. As the same amount of work is done in one cylinder of the new engine as in two cylinders of the single-piston type, however, the quantity of fuel per cylinder is doubled, and its regulation is thus simplified. It is effected by the movement of a cam acting on the suction valve. The starting valves are controlled mechanically by means of cams from the



Figs. 1 to 6. Showing Engine and Generator Complete and the Ease with Which Parts May Be Removed camshaft. The driving lever *A* (Fig. 1) for the starting valves and the lever for the injection valve are arranged eccentrically, so as to bring them into operation alternately by switching over a lever. For starting, therefore, it suffices to open the air admission by means of the handwheel *B*, and to throw over the hand lever. These starting valves are accessible and can be exchanged in a few minutes. The injection valves for admitting the fuel into the working cylinder are placed opposite the starting valves, and the needle is likewise moved by means of a disk from the same camshaft. If it should prove necessary to repack an injection-valve needle, the entire

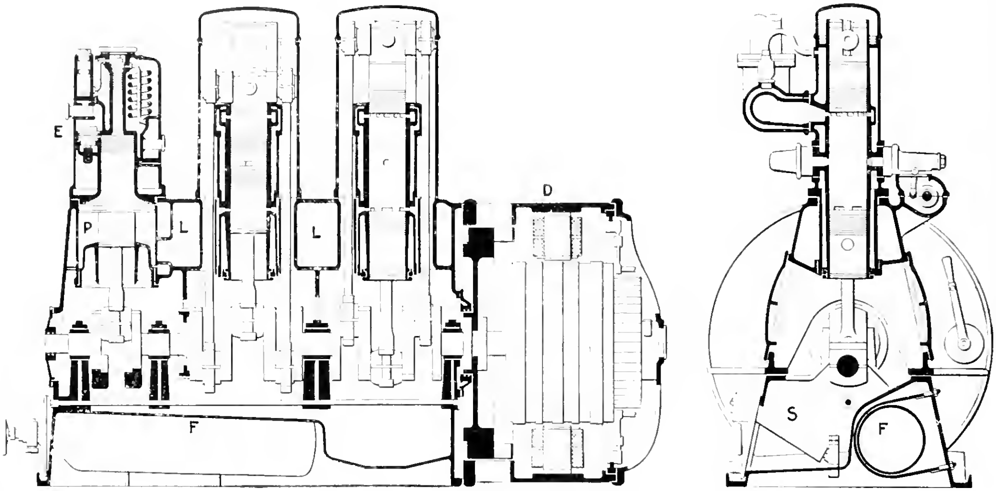


Fig. 7. Longitudinal and End Sections through Engine

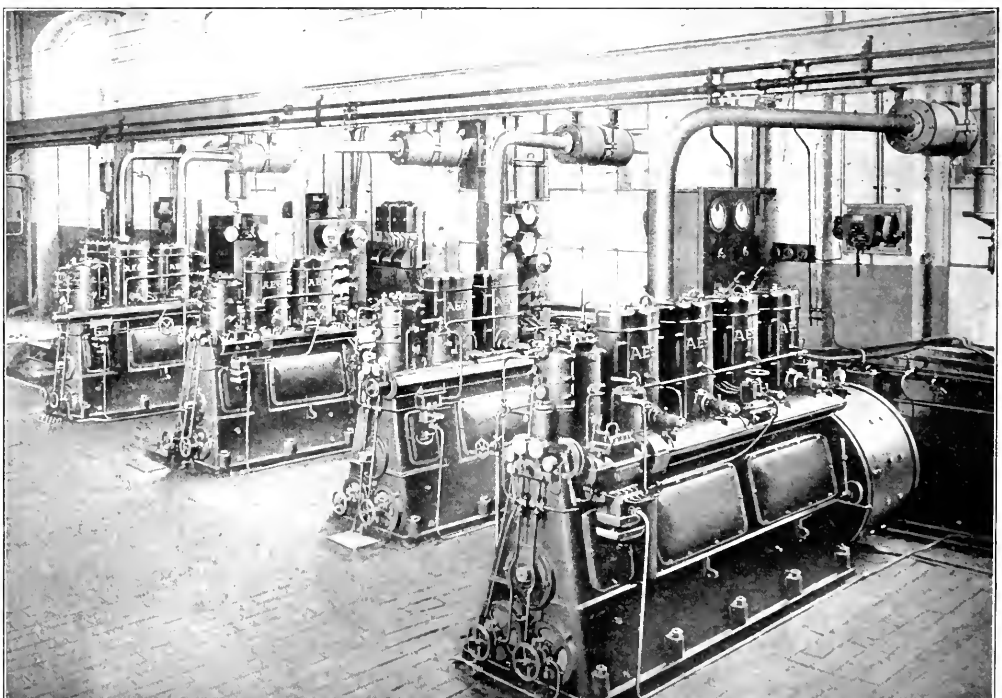

Fig. 8. Engines Set Up for Testing at A. E. G. Works

valve can be taken out after the engine has been shut down, and a spare one put in its place; this takes about 15 min. The adjustment of the play between the cams and camshaft and the roller of the driving lever, and therefore the exact timing for the opening of the needle, is carried out by means of calibrated disks placed beneath the needle.

These engines are built for a speed of 500 r.p.m., at which they develop their normal output.

Coal, the Big Item

The largest single item in the operating costs of any steam power plant is coal. In most plants the purchase of coal is a matter of careful consideration, and in the larger ones it is usually bought under specifications. Once the coal is in the bunkers, this careful consideration stops and the actual burning of the coal is very rarely given more than a passing thought, as long as the steam pressure is kept up. Of course, there are some plants where this does not apply, but in the majority it does.

The men employed are paid the lowest possible living wage and are chosen more on the basis of the wages they will work for than the results they are able to produce. The man who burns the coal can easily vary the efficiency of the boiler by 10 to 15 per cent., or the heat absorbed by 15 to 20 per cent., yet he is at the bottom of the payroll.

No revolutionary advancement has been made in power plants recently, and the increased efficiency is accomplished only by taking each process separately and bringing it up to the highest standard. It would therefore seem wise, in attempting to increase the overall efficiency of a plant, to start with the item that represents the largest expenditure and work down the list.

In office-building plants the cost of coal represents some 35 to 40 per cent. of the total expenses and boiler-room labor 12 to 15 per cent. In big plants the cost of coal is 50 to 55 per cent. and the boiler-room labor 7 to 8 per cent. Take a concrete case of a certain office building in New York City that employs two firemen at $600 a year each. Their coal costs approximately $10,000 a year. If we assume that the boiler efficiency is 60 per cent., and that by paying $900 a year men could be obtained who would operate the boilers at an efficiency of 70 per cent., it would be a paying investment. The increase in wages is $600 a year. The increase in boiler efficiency amounts to a reduction in coal burned of 14.3 per cent., or $1430. The net result is $830 to the good by the change—not a matter of philanthropy.

Any plant owner can figure out for himself what a small increase in the boiler efficiency will amount to in dollars and cents, and may find it profitable. The efficiency of the boilers may be increased in several ways, but first, proper equipment must be furnished. Every boiler plant should be equipped with a draft gage, stack thermometer and means for determining the CO_2. The cost of this whole equipment need not exceed $100, which would be repaid in a very short time.

Then the firemen should be taught the use of this apparatus to determine the proper method of handling the fires to secure the highest efficiency. A bonus system for savings over a certain amount would probably be productive of the best results. If the firemen are able to save the plant money by their efforts, they should logically be entitled to a part of it.

Dayton Power Pump

The Dayton Pump & Manufacturing Co., of Dayton, Ohio, is placing on the market a new power-driven

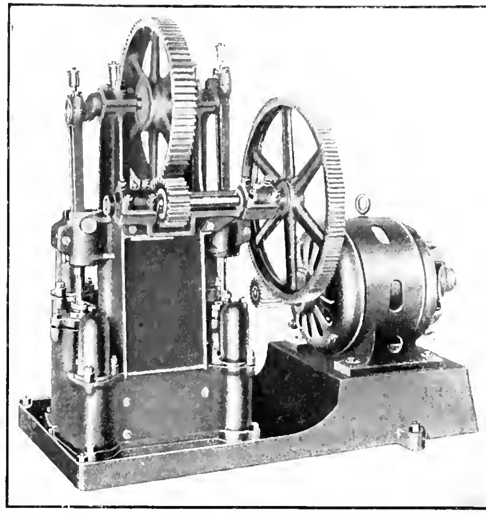

Fig. 1. Motor-Driven Duplex Double-Acting Pump

pump, Fig. 1, of the duplex double-acting type. Being double acting on both sides, four impulses are imparted for every revolution of the cranks, and a steady stream

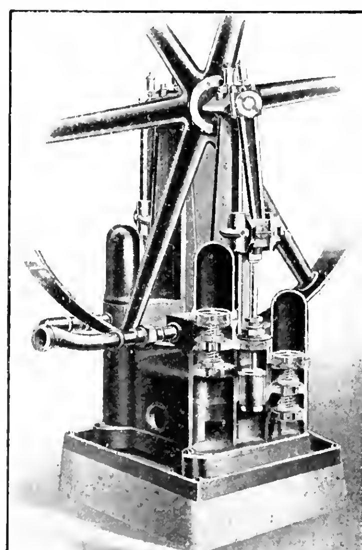

Fig. 2. View Exposing Valve and Pulsation Chambers

is discharged. The cranks are set at 90 deg., so that when one piston is moving at its highest speed and delivering its greatest amount of water, the other piston is moving at its lowest speed and delivering a proportionately smaller amount of water. In this way the flow and torque are equalized, so that a minimum expenditure of power per cubic foot of displacement results.

An unusual feature is an air chamber over each valve chamber, and in addition, a large air chamber forms part of the body of the pump immediately under the gears. As a result of these five chambers there is no perceptible wave line to the discharge, which is practically as steady as the outflow from a centrifugal pump. The arrangement of plunger and valves is shown in Fig. 2, a sectional view of the pulley-driven pump. The new motor-driven pump is made for pressures up to 100 lb. and is designed primarily for house service.

Chimneys for Havana, Cuba, Power Plant

The accompanying illustration shows the five chimneys constructed by the Weber Chimney Co. for the Havana Railway, Light & Power Co., Havana, Cuba.

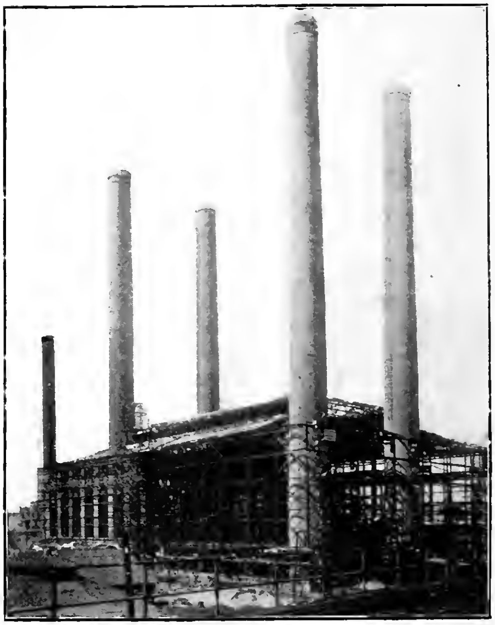
In 1910 the company built a cylindrical chimney 200 ft. high by 10 ft. diameter, of reinforced concrete. After it had been in use approximately three years, a consolidation of the Havana Railway, Light & Power Co. and the Havana Gas Co. necessitated the construction of a large central station, which was started early in 1913. An order was placed for four coniform reinforced-concrete chimneys, each 275 ft. high and 14 ft. inside diameter at the top. Six months from the date of starting work these were completed.

The chimneys rest on individual foundations 32 ft. square and 6 ft. 6 in. thick, supported by piles. In the lower part of the foundation are four layers of steel. The bottom layers run diagonally to the sides and consist of ¾-in. round bars at 8-in. centers; the two upper layers are placed from 4 to 6 in. above the diagonal net and about 8 in. from the bottom of the foundation, and run parallel to the sides. The vertical bars in the shaft run into, and anchor beneath, the horizontal steel reinforcement in the foundation, providing anchorage for the chimney shaft.

The outside diameter at the base of the shaft of each chimney is 20 ft. 6½ in., tapering to an outside diameter of 15 ft. at the top. The wall thickness of the shaft at the foundation is 19 in., tapering to 6 in. at the top. There are two hundred ¾-in. round vertical bars in the shaft, extending to a height of 22 ft. above the top of the foundation, where the number is reduced to 132 for the next 20-ft. section, decreasing uniformly to the top, where there are sixteen ⅝-in. round vertical bars in the upper 30 ft. of the chimneys. The smoke openings (7 ft. 2 in. wide by 14 ft. 2 in. high) which received the breeching from the boilers are 56 ft. above the foundation and are 20 per cent. larger than the area of the chimney at the top. There are two opposite openings in each chimney, and a baffle wall is built in the center of the chimney, starting 2 ft. below the bottom of the openings and extending to a point 3 ft. above the top.

There is a reinforced-concrete lining 58 ft. 6 in. high, starting at a point 4 ft. below the opening. The lining is reinforced vertically and horizontally by sixteen ½-in. round vertical bars, evenly spaced, and by horizontal rings at 14-in. centers encircling the vertical members; these take up the shearing stresses caused by the wind and temperature. The lining is carried on a corbel supported by the outer wall of the chimney. All vertical steel in the shaft is calculated to take up stresses produced by a wind velocity of 100 miles per hour.

The chimneys are inside of the power house, and in order to utilize the space two storage rooms were provided in each. A floor was placed at an elevation of 18 ft. above the foundation, and an opening provided so that this part of the chimney is accessible. At 36 ft. above the



Reinforced-Concrete Chimneys for the Havana Power Plant

foundation is another floor and storage room. A ladder is provided on each chimney, running from the top of the chimney to the roof of the building.

The present boiler installation consists of 24 water-tube boilers, rated at 650 hp. each, a total of 15,600 hp.; provision has been made for eight additional stoker-fired boilers. Three turbine generators of 10,000 kw. are operating at present, with provision for an additional unit.

The Action of Ice and Common Salt (sodium chloride) is to lower the mixture temperature below 32 deg. The depression of temperature depends mainly on the proportion of salt used, and partly on the rate at which heat is supplied from the outside. The following table gives the approximate temperatures resulting from the use of different proportions of salt and ice:

Per Cent. of Salt in Mixture	Temp. of Mixture, Deg. F.
5	26.6
10	19.9
15	11.8
20	1.6

The minimum temperature obtainable with ice and salt is about —7.5 deg. F., this temperature being given by a 24 per cent. mixture.

Editorials

Fuel Economics

The slogan, "Made in America," is aimed to incite domestic industries and manufactures. As a result many new factories will be built in the near future and probably many old plants will be remodeled to meet increased demands and manufacture new lines. All of these factories will require power, which will benefit the central stations and also be the occasion for many new isolated plants—some large and some small. To manufacture economically, cheap power will be required, will be absolutely necessary, and though the "Made in America" indorsement may secure many sales at this time, when serious foreign competition is not felt, the time will come when only the American producer who is manufacturing economically and efficiently will be able to hold his own.

Even in an efficiently operated plant, from twelve and one-half to fifty per cent. of the cost of power is found in the coal bill, the large power house operating on the lower unit cost. Coal bills must then be kept down, and to do this only the economical coal must be burned, the coal that will evaporate the most water for a given outlay. This does not mean the best coal procurable nor yet the cheapest; it means the most economical, for efficiency in combustion is almost entirely a matter of correct grate and combustion-chamber design and care in firing, conditions that may be relatively realized with the same results when using a low-grade coal as when using the more easily consumed coals of high heating value.

The price of coal varies to a great extent in different localities, and coals vary among themselves in heating value and in ash and refuse contents. The heat units in the coal increase its value but not proportionately, for the ash and refuse contents not only add expense by entailing definite outlays for their disposal, but also have the tendency to reduce boiler efficiencies. Of two grades of coal of equal heating value, the one with the lower proportion of ash and refuse will develop the greater boiler efficiency—grates and combustion chambers being equally well proportioned for their respective grades of coal and equally good attention paid to the firing of the boiler. The detracting effect of increased ash and refuse contents of a coal is not as great ordinarily as the beneficial effect of an increase in heating value of the fuel, the diluents forming but a comparatively small proportion of the coal, unless it happens to be a very inferior grade. Heat units per pound generally govern the price of the coal, but the price in no way fixes its true economic value, for the increase in cost of high-grade coals is much more rapid than the increase in their heating value.

As a general rule, where coal is relatively cheap—near the source of supply, for instance—more heat units are purchased for the dollar when buying a low-grade coal. Where coals are expensive, on the other hand, the heat units sold for a dollar are more nearly the same for coals of various grades, as in such localities the coal has to carry a burden of freight and delivery charges that are not proportioned to its heating value but are unduly severe on the poorer coals, notwithstanding that freight rates are usually somewhat lower on poor fuels. Where coals are cheap, the most economical grade to use is the poorest grade that can be efficiently burned on properly proportioned grates, etc.; while in sections of the country where coals command high prices, better grades can be economically used.

With the constantly increasing price of coals, one other general rule tends toward economical choice of fuel for an efficient power house, which is that in cases where two grades of coal do not vary greatly in economic value—fuel cost per boiler horsepower—it is usually advisable to adopt the poorer grade even when the net fuel cost is slightly greater than that of the higher-grade coal. The fuel cost of the more economical and higher-grade coal increases more rapidly for an increase in tonnage cost of fuel than is true in the case of the poorer coal, so that only a little of the inevitable increase in the price of all coals will throw the economic balance in favor of the inferior coal and any further general increase in cost of coals will steadily increase the relative economy of the fuel of less heating value—the saving increasing progressively.

The Archaic Boiler Horsepower

We are glad to see our friends of *The Locomotive* place the stamp of disapproval on the horsepower as a unit of boiler capacity (see page 175). In 1876 a committee of eminent engineers appointed to conduct a competitive test of the boilers at the Centennial Exposition decided upon the rate of evaporation of 30 pounds per hour from feed water of 100 degrees Fahrenheit and at 70 pounds gage pressure (barometer unknown) as equivalent to one horsepower, this being considered about the rate at which a boiler would have to steam per horsepower developed by the average engine of that time, under average conditions.

At the time and at the best it was only the crudest kind of an attempt to correlate the capacity of the boiler and that of the engine, for there were then many engines which required less than 30 pounds of steam per hour per horsepower. Today, with boilers evaporating two or four times as much water per square foot of heating surface and engines requiring only one-half as much steam per horsepower, there is a wide and variable discrepancy between the horsepower of the boiler as determined by the Centennial standard and that of the engine or turbine which it can supply with steam.

How should boilers be bought, sold, and classified—by the amount of steam which they can make per unit of time, or by the number of square feet of heating surface which they contain, or how? The horsepower rating is supposed to be a statement of the rate at which the boiler can make steam, but is in the awkward unit of 34.5 pounds per hour at the standard condition of "from and at 212 degrees." If one wants a boiler which will make the equivalent of 3000 pounds of steam per hour from and at 212 degrees, he says: "3000 ÷ 34.5 = 90, about. Give me a 100-horsepower boiler."

And then the boiler maker says: "Ten square feet per horsepower—give him 1000 square feet of heating surface." So the thing gets down to a heating-surface basis after all, notwithstanding the fact that the evaporation per square foot of heating surface may vary from 2 to 10 pounds, according to the amount of grate surface supplied with it and the rate at which the coal is burned.

Another basis for rating is the amount of heat which the boiler can absorb per hour. To evaporate 34.5 pounds of water from and at 212 degrees requires 34.5 × 970.4 = 33,478.8 B.t.u. A kilowatt is equivalent to, say 3415 such units per hour. Messrs. H. G. Stott and Haylett O'Neill suggest that the capacity to absorb 34,150 B.t.u. per hour be taken as the unit of boiler capacity, and that this unit be called a "myriawatt," signifying 10,000 watts.

We do not see that this improves matters much. There is no such definite relation between the kilowatt and the number of pounds of steam that it takes to make one, as to warrant the use of an awkward five-place divisor, and it simply means tricking out the old boiler-horsepower in a new regalia of metric trappings and continuing it upon the stage.

Should we "get the hook" for it? If so, when we are describing a plant with four 300-horsepower boilers, shall we say "four boilers of 3000 square feet of heating surface each," "four boilers capable of evaporating 9000 pounds of water per hour each"—or what?

The Practical Man's Boiler Test

Two methods of conducting boiler tests are now generally accepted—one according to the short code of the A. S. M. E. and the other based on the more elaborate standard code. The first contains about forty items, readings or calculations for which are necessary, and the complete code contains over one hundred. Condensed and standardized as are the calculations and complete as is the information gained by following these codes, a boiler test is not simple, but requires considerable preparation and care and consumes much time. Furthermore, when accomplished, the test is rarely typical of actual operating conditions. As a means of establishing a record, or standard, to be striven for by the operating force it is exceedingly valuable, but as a reliable record of efficiency of average operation and a true gage of the economy of the plant, it leaves much to be desired. What is required is a continuous record to show the true efficiency of the plant at all times, a "practical man's boiler test," and a test that the boiler operators can easily comprehend—a test with the results continually before the fireman.

It is neither fair to the boiler-room force nor conducive to the best results to blame it for wastes after they have occurred—especially after they have been going on for some time. The time to call attention to them is while they are occurring. The boilermen should know the instant that the boilers commence falling below requirements, and this can be realized only when simple and continuous records are provided for their frequent inspection.

The apparatus required is neither very complicated nor complex. All that is needed are some automatic device for recording the amount of water fed to the boiler and means of weighing the coal as fired. Automatic firing simplifies the keeping of records of fuel consumed, but even when hand firing is employed, satisfactory records can be kept by weighing the fuel—practice will soon enable a competent fireman to accurately gage his fuel consumption in reference to his boiler feed. Pounds of water evaporated per pound of fuel is all that really matters, and the greater this ratio the better the boiler efficiency. Automatically recording pyrometers, CO_2 recorders and temperature records of feed, etc., all assist in discovering the reasons for falling off of boiler efficiency, but the vital records are those of fuel consumed and water evaporated while maintaining steam pressure.

Careful boiler tests should be made from time to time, but more to fix the standard of operation for the boilermen than for any other reason. The "practical man's boiler test" should be a continuous operation in any boiler plant making claim to efficient operation. It alone can lead to economic operation, it alone is fair to the boilerman, and it alone shows whether the fires are kept in good condition and how carefully and systematically the heating surfaces are freed from soot, etc.

The Loafing (?) Engineer

When we say "loafing," we have in mind the man whom the employer generally finds sitting in the old easy-chair reading a technical or trade journal or just smoking his pipe. Of course, everything is clean about the plant and the machinery is running smoothly, but there can sometimes be detected in the employer's face a look of dissatisfaction. He is paying his engineer a good salary and cannot see that the latter is doing any work and seems to think that he is not getting value received for his money, for a cheaper man could hold down the "Old Armchair" just as well.

This is a view taken by a great many employers and is altogether wrong. The very fact that the engineer finds time to "loaf" and that the owner is not annoyed by frequent shutdowns should be sufficient to convince him that the engineer is a good man and has his department in perfect order. Look out for the engineer that is constantly rushing wildly about with greasy clothes and smutty face and a handful of tools, for unless his plant is dying of old age, there is something wrong with the man.

The employer who wants a man to build boxes, mow the lawn, look after the roofs and a few other "little things" to keep busy, is not looking for an engineer and will seldom get one, and when something unforeseen and real annoying, like a wrecked engine or bagged boilers, happens, he generally gets about as much sympathy as he deserves.

"Some Original Ideas"

When we called for accounts of stupidity, in our issue before the last, under the heading, "Just for Fun," we started something, for we have had a deluge of them. Evidently, nearly everyone has a stock of such stories up his sleeve. We can use but a few of the best, as we said, but if our readers do not mind sending them in, in spite of a long chance that they may not be printed, we do not mind reading them over to see if they are available.

Correspondence

Live-Steam Ash Ejector

In the issue of Dec. 22, page 889, E. H. Clark asks what the trouble is with the ash ejector. I believe if he will increase his steam line to 1½ or 2 in., and then, instead of a bell nozzle, use a throttling nozzle having a diameter not over ⅝ in., he will have no further trouble with the construction as shown in the illustration referred to.

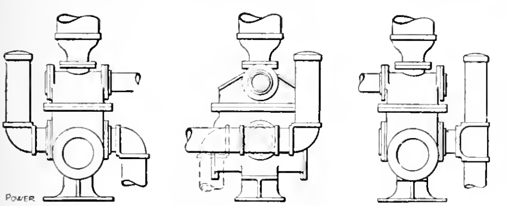
The nozzle should be about even with the back edge of the hopper opening. The ejector will probably work a little better if the end of the 6-in. pipe is left open where the live-steam pipe enters. If closed at all, the area should equal an opening 3½ or 4 in. diameter.

F. F. JORGENSON.

Gillespie, Ill.

Pumping Hot Water

It is surprising how many have trouble when trying to pump water at 210 deg. F. or over. To do this successfully, the pump should be able to deliver the maximum quantity of water at slow speed and the water-supply should be at least 30 in. over the discharge valves, for the reason that if a vacuum is created in the suction pipe, some of the water will flash into steam and fill the water cylinder with vapor. Although it takes 212 deg. F. to boil water under atmospheric pressure, or 14.7 pounds, in a vacuum it will boil at a much lower temperature.



FORMS OF AIR CHAMBERS FOR SUCTION PIPES

It is a good idea to place an air chamber in the suction pipe, as shown in the illustration. The discharge air chamber should be kept three-quarters filled with air; a glass gage will show the water level at a glance. Should the air get away, the chamber can be recharged by admitting air into the suction line.

A sight-feed lubricator should be connected to the steam pipe above the throttle valve, but a mechanical lubricator may be connected below the throttle valve if desired. If an automatic governor valve is used it should be placed above the throttle valve, but a chronometer governor valve should be placed below the throttle and the oil should pass through them in either case.

It pays to use good packing, which should be soaked in warm water before being put in the piston: the joints should not be in line or the packing follower-bound. It is unnecessary to subject the rod packing to great pressure; it is better to repack than to continue to tighten the gland. It will be found with these precautions that hot water is no more difficult to pump than cold.

THOMAS J. ROGERS.

Jersey City, N. J.

Proper Location of Overflow

In a vacuum steam-heating system that requires no jet water at the vacuum pump, the air-separating tank should not be equipped with such auxiliary appliances as a float-controlled inlet and outlet valve, gage-glass, overflow pipe and handhole. A large tank, with these appliances, is necessary only where jet water is used, because the operator may use more jet water than is required for boiler feed, causing it to flow through the heater into the sewer. This would tax the heater beyond its proper capacity and reduce the temperature of the boiler feed. Therefore, an automatic valve is placed between the tank and heater, so that the tank will overflow to the sewer and not flood the heater when excessive jet water is used.

New York City.

Concrete as a Furnace Lining*

Our experience with concrete as a furnace lining with underfeed stokers was not satisfactory. The concrete was made of cement and gravel which ranged in size from sharp sand to pebbles the size of a hen's egg in proportions of about 1 : 4. The old firebrick side walls were taken out, the walls cleaned and thoroughly wet, the concrete was poured in place in forms, in the usual manner, and allowed to dry several weeks before the boiler was put into service. As a means of comparison, another furnace was relined with firebrick at the same time. These furnaces are subjected to hard service, and the clinkers stick to the side walls so that it is necessary to use a sledge and chisel bar to remove them, and more damage is done in this way than by the fire. The concrete walls did not stand as well as the firebrick and the clinkers gave about the same amount of trouble.

Concrete has one important advantage, however, in that it is less expensive to put in, but even if allowed to become thoroughly dry, and heated up slowly, it will give some trouble from cracking and falling out, although this may be prevented by reinforcing it with expanded metal or rods. In our case it was tied in one place only, and perhaps more experience would have produced better results. Oyster shells used as a flux prevented clinkers sticking to the walls to a great extent. Two or three scoops of these shells were thrown in next to the walls on each side after cleaning the fire. I believe that it was the lime in these shells that did the work, and crushed limestone would probably do the same.

*See also page 840, Dec. 15, 1914; page 62, Jan. 12, 1915, and page 131, Jan. 26, 1915.

I find that there is a great difference in firebrick and fireclay, and also in the workmen that build the walls. It is customary in our plant to have this work done by contract, with a guarantee that the work will last one year. One contractor had to rebuild his walls twice during the year, and another put in a wall that was not tied to the outside wall, and it fell out in less than a month. A third put in a wall that did not require any repairs during the year. Good material should be used, and it is essential that it be tied solidly to the outer wall at every fifth course by a header tied into the outside wall, and if subjected to hard usage the headers should be placed every third or fourth course. The fireclay should be made very thin and the least possible amount used. The brick should be dipped in it and rubbed to a tight fit to make a firm bed, so that there is no chance for the mortar to chink out and let the brick fall down. In arches the proper wedge and skew brick should be used to get the proper arc with a full bearing the entire length of the brick without resorting to fireclay to do it.

Safety in Handling Refrigerants

An editorial in the Dec. 15 issue comments on New York City's refrigerant regulations. The regulations appear in the same issue as does comment on them by members of the American Society of Refrigerating Engineers.

There should be, as the editorial points out, widely adopted rules for the safe operation of refrigeration machines, as there are for boilers and steam-driven machinery. In this city (Chicago) the laws governing steam apparatus are strict, but nothing is said of high-pressure gases or air.

As the water here is exceptionally good for making raw water ice, there are many motor-driven ice machines, and some of them are operated by men who are not licensed engineers. For the heating system in such plants low-pressure steam or hot water can be used, so that the board of examining engineers has as yet nothing to do with them. Surely there is danger in these motor-driven ice plants even though there are no high-pressure steam boilers. Such plants are often located in thickly settled residential neighborhoods, close to schools and churches.

The license law should cover all apparatus carrying pressure, whether steam, gas or air. Regular inspection should be made and none but competent men allowed to operate. There is without doubt less chance of dangerously high condenser pressure with a motor-driven unit than with steam drive. Increased pressure will cause the circuit-breaker to trip or a fuse to blow, whereas a steam engine will keep going until something gives way. But again, circuit-breakers may be tampered with or even blocked in and heavy fuses used by some who do not realize the danger.

Pop safety valves are good in some ways, but sometimes they are both a nuisance and a danger. It is, as Mr. Fairbanks remarked (Dec. 15 issue, p. 866), almost impossible to get an ammonia safety valve that does not leak. When once it opens it seldom seats tight again until it has been taken apart and cleaned of the grayish powdery sediment which has collected. Rather than shut a compressor down in a rush season, many engineers will plug the valve so as not to lose the ammonia.

If the outlet of the safety valve is piped into the suction side of the compressor, it might leak a little all the time and so cut down the efficiency of the machine. Again, if the outlet is piped into water or to a high point above the building, there can easily be a constant loss of ammonia. In one plant the safety-valve outlets of a number of ammonia compressors were piped into a header, and this extended high above the building. The continual loss of ammonia was finally traced to this manner of connection, and the header was done away with and the valves allowed to discharge into the engine room. This often proved a source of annoyance when starting up a compressor which had been down so long that liquid had collected in the discharge line. The valves nearly always opened until the discharge line had become cleared of liquid. In the case of a large direct-expansion system, when a small slug of liquid was pulled into the compressors the valves would often open. In another plant two different suction pressures were carried on several compressors. When one compressor could be spared from the high back pressure, it would be changed over to the low, and often while this change was being made there was loss of ammonia and inconvenience to the men owing to the pop valves opening.

In the foregoing cases the safety valves were a nuisance and were really not necessary. Whether or not a pop valve is the proper thing on an ammonia compressor is a question hard to decide. These valves will relieve a compressor or condenser of over-pressure, it is true, but most engineers will know of the increasing pressure without having the engine room filled with suffocating gas or losing much ammonia. The sound of the machine, whether motor or steam driven, will be warning enough to any competent man. An engineer should be near enough to hear his machinery, or if he should have to go away he should have a man in the engine room who knows enough to shut down in case of accident.

There are not many things liable to happen that will cause a sudden rise in the condenser pressure. Shutting off the water from the ammonia condenser will not cause so sudden an increase of pressure that there is not plenty of time to slow down or stop the compressor.

Any cross-connection between a hot and cold water-supply should not be allowed on pumps supplying a condenser with water. Such a connection can and has caused trouble, but with proper inspectors such cases would be few. Another cause could be the breaking of the suction line. This would allow the compressor to draw in much air, but with an operator within hearing distance he would have plenty of time to shut down. One other cause of dangerous pressure—and in this case I do not believe a safety valve would do much good—is the sudden closing of a valve on the discharge line between the compressor and condenser. This can hardly happen unless an angle or globe valve had been put in the discharge line with the pressure side of the disk toward the condenser. In that case the disk might come off and suddenly close the discharge; the shock would rupture something. But as in other cases proper inspection would minimize the chance of such a condition.

If a safety valve opened directly into a small engine room, the charge of ammonia would probably be lost as it would be impossible for a man to shut down the machine unless provided with a helmet. A positive device for shutting down the compressor when the discharge pressure reaches a predetermined point is safer. Such devices are in use in some places and work well. Each has a connection from the discharge line to the engine governor, and when the pressure goes to the point at which this control is set the governor acts and the engine is shut down as if the governor belt broke. Such a device can be tried daily or weekly and kept in proper working condition. A safety valve on an ammonia line or container cannot be tried occasionally like one on a steam boiler, to guard against its sticking when needed.

Proper check valves should be placed in both suction and discharge lines of compressors so that in case of a bursting cylinder the gas will be shut off. It is seldom that a serious accident occurs from over-pressure during the operation of an ammonia compressor. When the pressure gets too high it will blow out a gasket in the system or perhaps split a pipe in the condenser. What really causes serious accidents is the dropping of a broken suction valve into the cylinder or something breaking on the piston which will knock out a compressor head. Fortunately, this does not happen often.

Internal explosion in the discharge receivers and the oil separators occurs from permanent gases or inferior lubricating oil which becomes ignited when a high discharge temperature is maintained. The proper oil and care in keeping noncondensable gases out of the system and a correct discharge temperature will do away with the possibility of such explosions.

It is common practice in most new installations to test the high-pressure side with air at 300 lb. and the low-pressure with 150 lb. air pressure, and once a year in old plants after the winter overhauling. This is particularly dangerous in motor-driven compressors where the speed is constant. The air discharged by the compressor reaches a dangerous temperature when the gases from the oil and ammonia mix with it. As several bad ruptures have resulted from this cause, the use of a small unit built for testing purposes should be insisted on and the temperature of the system kept low to insure safety.

Another noticeable neglect in the ammonia system is the lack of suitable hangers for coils and pipe work. In direct-expansion systems the coils on the walls and ceilings of some rooms become so heavy with frost that the hangers give way and allow the coils to fall and break. This can also happen on suction lines not covered and allowed to accumulate frost. There should be proper means of supporting all coils and lines, and care should be taken for the regular removal of frost.

Electrically operated valves are valuable in most plants. In case of accident the machines could be shut down and the ammonia cut off from a point outside the building by means of switches. Discharging ammonia into water or into the atmosphere in case of accident has its dangers in a large plant unless there is a river or lake nearby. Some other way of disposing of a large charge of ammonia must be found.

The adoption by the City of New York of a set of rules for the safe operation and proper inspection of all machinery handling high pressure should be and most likely will be the beginning of improvements in the ice-machine business. Competent men to operate and inspect the plants would make them safe.

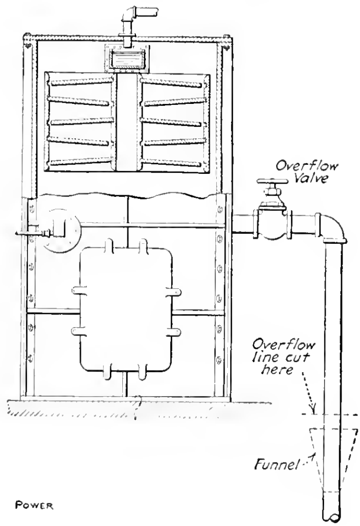
Chicago, Ill. A. G. Solomon.

Saving in the Pump Room

The idea that the greatest possibilities for improvement in economy are to be found in the boiler room seems to be generally accepted. This story, however, is to show that leaks of some magnitude may be found in the pump room.

On taking charge of the plant, the new chief had certain suspicions as to the cause of the low feed-water temperature. As soon as possible he placed a recording thermometer in the feed line. The first chart confirmed his suspicions and an investigation disclosed several interesting items. The feed-water heater was of the open type, to which condensate from various heaters, driers, etc., was returned.

The overflow pipe was connected without an opening and concealed the excessive waste of water. The new chief cut the pipe and put in a funnel (shown by dotted lines in



Overflow Changed

the illustration) and it was observed that for a time a stream of hot water would pour from the overflow—then the makeup valve would open wide. It was evident that water was coming back in slugs, showing that the receiver capacity of the heater was not sufficient for these conditions. Much hot water was being wasted to the sewer at times and a large quantity of cold makeup water was called for at others.

More capacity was at hand in the shape of an old receiver, which had been used up to the time the heater was put in. It was still connected up for an emergency so that it was only necessary to combine the two and maintain a constant level in the heater and waste no hot water through the overflow.

The makeup valve was moved from the heater to the receiver and set to operate only when that vessel was nearly empty. At first it was needed, but now it has almost gone out of use. The main bearings of the big engine were water-cooled. This water had formerly been wasted to the sump pit and then lifted to the drain by an ejector. The chief piped this, together with the jacket water, from the air compressor to the receiver. This nearly equals the amount of makeup water needed.

The average temperature from a week's charts among the first was 140 deg., and from the latest it was 212 deg. These two sets were turned over to the manager, together with a statement of the monthly coal bill. Where the coal formerly cost in excess of $3000, there was now a saving of about $200. As a saving it interested the manager and he actually offered the chief words of praise —but nothing more.

Separator Drain as Steam Supply to Pump

I read in Power, Dec. 22, page 890, of using a steam-separator drain as a supply line for a pump. This is very good as regards the engine, but how about the pump?

I think a much better way would be to repair the trap or install one that would work, rather than run this wet steam to the pump, for if only one pump is on the line, and that is shut down while the engine is running, all the condensation must go through the engine. As water is bad for an engine cylinder, as every engineer knows, will it not do damage to the pump also? The pump is one type of engine.

I have seen plants where every precaution was taken to insure dry steam for the engines, yet all the steam for auxiliaries was taken from the lowest point in the steam main without a separator. There was much complaint about the amount of oil required by these pumps. A pump is a wasteful thing at best, and I cannot see where there is any economy in supplying it with wet steam. If there is some good reason for this I would be glad to learn of it.

Who Gets the Promotion?

The Foreword in the issue of Dec. 15 is indeed a problem if sentiment is allowed to enter into it, assuming that the promotion is to be to that of chief engineer and the three candidates to be watch engineers. Only one candidate has made any special effort to fit himself for the position and is therefore entitled to it on a strictly business basis.

The one on the left is popular with his mates, a hustler, observing and is liked by the manager, and expects to slide into the job. Being popular with a number of men is no guaranty that he can handle those same men. He will not be taken very seriously, and if he changes his attitude to one of authority they will resent it. Being a hustler is not an essential quality in a chief engineer. His task is to devise ways and means to operate the plant economically and efficiently. His observations are of little value if he lacks the technical knowledge to decide their true significance. The manager has no right to consider his likes or dislikes.

The center candidate is steady, sober and honest, which is probably the reason he has seen long service. Seniority without any indication of ability is no reason for promotion. He has made no effort to fit himself for a better position, therefore has no right to expect promotion. Lacking in ambition, it is not reasonable to suppose he will make an efficient chief. He hopes to fall into the position.

The candidate on the right is qualified in every way, and being a student will be progressive. He, however, is grouchy and will probably have labor trouble; but if the manager understands the principles of coöperation he can explain to this man the effects of grouchiness on the men under him. It is only reasonable to suppose that a man who has the ambition and perseverance to fit himself for the job in every other way will also overcome this fault when he is made to see how objectionable it is. He is the only man who deserves the position; he is trying to climb into it.

S. H. Farnsworth.

Chicago, Ill.

[The foregoing assumes one change is to be made; eliminating a fatal error and substituting a desideratum. Suppose the others to be similarly treated?—Editor.]

Substitute for "Kilowatt-Hour" Suggested

Electricity as sold is usually dependent upon two factors—the full or maximum demand and the extent or hours of use of the demand.

The demand is the force applied in doing work, and the electrical unit for measuring force is the kilowatt. It is thus described in the A. I. E. E. Electrical Standards:

"Electrical power, which is the rate at which energy is being transformed in a circuit, is expressed by the product of the instantaneous values of electromotive force and current in the circuit. The practical unit is the kilowatt, which is 1000 times the watt."

The amount of force or energy expended in doing work is the product of the average force applied and the duration of time during which the force is applied. The electrical unit is the kilowatt-hour, described as follows:

"The amount of electrical energy transformed in a circuit is measured by the product of the power and the time. The practical unit is the joule, which is equal to one watt-second, the watt-hour and the kilowatt-hour."

It may be found convenient in the sale of electric power to charge on the basis of the kilowatt demand alone, the energy in kilowatt-hours consumed alone, or by a combination of the two methods. Nontechnical men who, through the nature of their business, happen to deal with electrical matters often confuse these terms. The kilowatt and the kilowatt-hour, while directly related, have a different significance, and the oversight or unintentional dropping of the suffix "hour" may create a serious and perhaps costly misunderstanding.

For the best interest of the electrical business it seems that an appropriate substitute for the term kilowatt-hour is highly desirable, and it is fitting that the units of quantity of energy be designated as "kelvins," in distinction of the memorable work of Lord Kelvin. This thought had its inception at the last International Electrical Congress and was at that time recommended for adoption and, not unlike the appeal for the substitution of the term myriawatt for boiler-horsepower (although of a somewhat different application), should receive the indorsement and support of the entire electrical industry.

Engineers' Study Course

Heat-Engine Cycles

The series of thermal and mechanical operations through which the working medium of a heat engine passes is called its cycle. The actual cycle of any working engine has back of it an ideal scheme of operation under which the greatest possible proportion of heat could be converted into work. Between ideal and actual performance there is a gap due to secondary losses resulting from imperfections of the real machine.

The essential parts of the ideal cycles of the common types of engine, with both steam and gas as working mediums, are as follows:

1. Reception of heat at high temperature or over a high range of temperature.
2. Lowering of temperature by adiabatic expansion, in which no heat is given to or taken from the substance, so that it performs work at the expense of its initial store of heat energy.
3. Rejection of heat at low temperature or over a low range of temperature.
4. Raising of temperature to the starting point by adiabatic compression, in which the work done upon the substance adds itself to the initial store of heat energy.

Looking at the matter from the side of thermal action, the simplest case is that in which heat reception occurs at some uniform high temperature and heat rejection at some uniform low temperature. The resulting combination of two isothermal (constant temperature) and two adiabatic (no heat transfer) operations constitutes the well known Carnot cycle, which is, thermally, the simplest possible scheme of working. If T_1 is the absolute temperature of heat reception and T_2 the absolute temperature of heat rejection, the efficiency in heat conversion is

$$E = \frac{T_1 - T_2}{T_1}$$

This means that the quantities of heat received, converted, and rejected are respectively proportional to T_1, $T_1 - T_2$ and T_2.

Fig. 1 is a true representation, laid out to scale, of the performance of one pound of air as medium in a Carnot cycle, when working from 2000 to 1000 deg. abs. F., or from 1540 to 540 deg. F. The pressure limits are from 450 to 15 lb. abs. per sq.in. The purpose in giving it is to show how utterly impractical this cycle is as an underlying scheme for a gas engine. The faults are, first, a very weak variation of pressure from the beginning of the stroke at A to the end of the stroke at C; secondly and especially, the vertical narrowness of the inclosed diagram $ABCDA$ coupled with the high total pressures prevailing, as measured above the base line OV. The small mean effective pressure will require a large cylinder for a given power, and the big total pressures will call for a strong and heavy machine and will cause large losses of power through machine friction. Further and finally, isothermal operations could not well be secured with any scheme of internal combustion. The alternative of treating a gaseous medium like the water in a boiler, and supplying heat through a metal wall from an external furnace, has been tried out in the hot-air engines. While not impossible, this plan is of little value practically.

But with steam, as laid out in Fig. 2, the Carnot cycle becomes of distinctly usable form. This is because constant pressure goes with constant temperature in the isothermal operations of evaporation and condensation. The description of Fig. 2 is as follows:

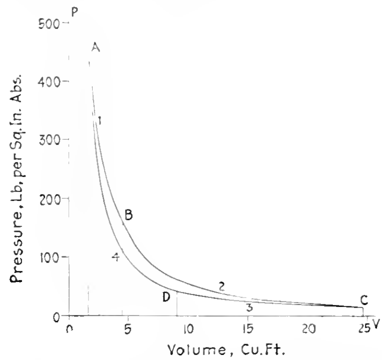

Fig. 1. Carnot Cycle for One Pound of Air

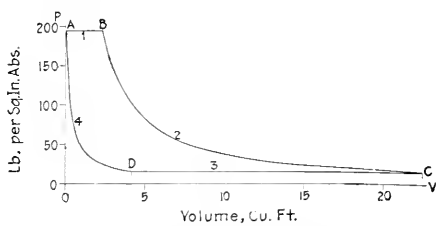

Fig. 2. Carnot Cycle for One Pound of Dry Saturated Steam

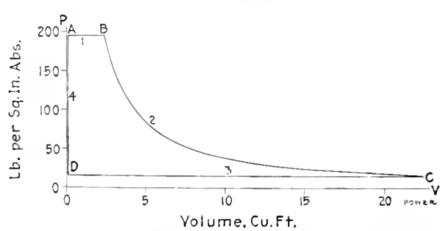

Fig. 3. Rankine Cycle for One Pound of Steam from Fig. 2.

At A is represented the volume of one pound of water at steam pressure and temperature. Line AB represents the vaporization of this water and the admission into the cylinder of the full volume of steam formed.

With ideal action there would be no loss of heat or pressure in the steam pipe or engine valve and no abstraction of heat by the cylinder walls. Of course, no material exists of which the thermally neutral cylinder requisite for such action could be made.

Curve *BC* shows adiabatic expansion carried down to exhaust pressure and temperature at *C*. This continues to require the imaginary nonconducting cylinder. To supply heat for work done there is progressive condensation of steam along line *BC*.

Line *CD* represents not so much the expulsion of exhaust steam from the cylinder as the decrease of volume by condensation. This condensation is stopped at such a point *D* that adiabatic compression of the whole charge of the water-steam mixture will bring it to the initial state at *A*.

Now the real cycle of the steam plant conforms to this scheme as closely as actual conditions and materials will let it, with but one exception. This one essential departure lies in the absence of any attempt to raise the feed water to steam temperature by adiabatic compression. Instead, the steam is all condensed, and the resulting water or an equivalent fresh supply is pumped into the boiler.

Modified thus by the omission of adiabatic compression, the Carnot cycle of Fig. 2 becomes the Rankine cycle of Fig. 3. This is the ideal scheme of working which lies back of the actual performance of the steam plant with either piston engine or steam turbine. Such an engine as the direct-acting steam pump falls far short of the ideal output of work per pound of steam. Good plants range from 65 to 75 per cent. of ideal performance.

Working according to the Rankine cycle, an ideal steam plant would get more work from a pound of steam than if on the Carnot cycle, hence would require fewer pounds of steam per horsepower-hour. But the heat required to make a pound of steam increases more rapidly than the work output, so that the Rankine-cycle efficiency is lower.

It is to be borne in mind that the line *AD* at the left-hand edge of Fig. 3 is not identical with the axis line *OP*. The distance between them is the volume of the pound of water, and operation No. 4 is performed by the feed pump. Of course, this operation no longer conforms to the general description in paragraph 2.

Turning now to internal-combustion engines, the cycle most used is represented in Fig. 4. This is in true proportions for certain assumed data, with one pound of gas mixture. The dotted outline shows approximate dimensions of the real diagram. Heat reception takes place with rise of temperature from *A* to *B*, heat rejection with fall of temperature from *C* to *D*. Operations 2 and 4 are adiabatic expansion and compression, as heretofore. In the actual engine the heating at constant volume is pretty well realized. The would-be adiabatic operations are strongly modified by cylinder-wall action, which is strengthened by the water jacket. The ideal cooling at constant volume from *C* to *D* is approximated in mechanical effect by actual exhaust, no matter just how the heat in the exhaust gases is really dissipated into the atmosphere.

The Brayton cycle, Fig. 5, in which heating and cooling take place under constant pressure, is of little practical interest as regards use in piston engines. It is, however, the cycle of nearly all the attempted gas-turbine plants. In the latter there are necessarily two distinct pieces of apparatus—the compressor, whose operation is represented by diagram *DAEFD*, and the turbine, with diagram *EBCFE*.

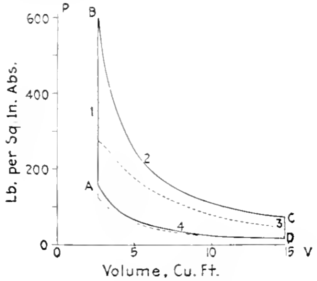

Fig. 4. Ideal Otto Cycle

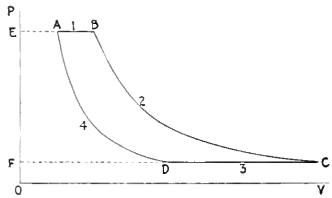

Fig. 5. Brayton Cycle, Used in Gas Turbines

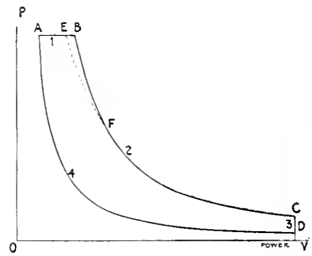

Fig. 6. Diesel Cycle

The Diesel cycle, Fig. 6, calls for little comment. Its heat reception is nearly at constant pressure, although a short isothermal section *EF* is sometimes assumed as a part of the ideal diagram.

The ideal cycle, with its output and efficiency, is not nearly so much used as a standard of comparison for the gas engine as it is for the steam plant. One reason is that it is a much larger task to calculate, exactly, the dimensions of an ideal gas cycle than those of the Rankine steam cycle. Roughly, if T_1 is the average absolute temperature during heat reception *AB*, and T_2 the average temperature during heat rejection *CD*, the efficiency is, as per the Carnot cycle,

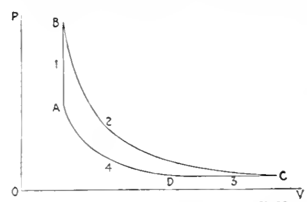

Fig. 7. Cycle of Explosive Gas Turbine

$$E = \frac{T_1 - T_2}{T_1}$$

But this is only a rough approximation; and a large amount of mathematical work is needed to get an exact value.

In the way of a comparison among these cycles, one important point will now be noted. From the side of the machine (as against that of thermal action) that cycle is best and easiest to apply effectively in which the least amount of work must be expended in getting the medium up to its high pressure at the beginning of the working stroke—at *A* in all except Fig. 4, and in this figure at *B*. The steam-engine cycle, Fig. 3, shows up best in this respect, although its apparent advantage is partly neutralized by compression in the cylinder. The latter is not an essential part of the cycle, but one of the secondary sources of loss, like cylinder-wall action, etc.

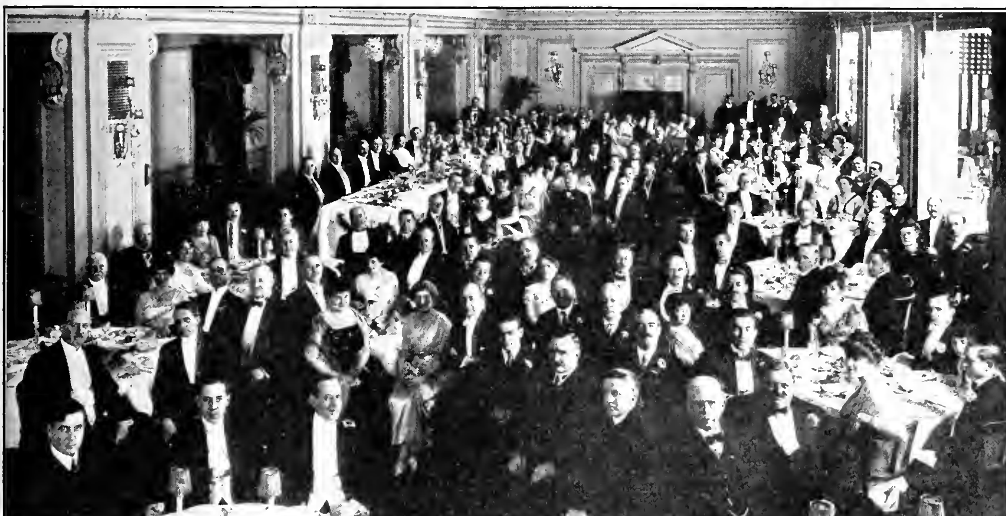
As between gas-engine cycles, the two-part operation *DAB* in Fig. 4 is better than compression clear up to the highest pressure along the curve *DA* in Fig. 5 or *DA* in Fig. 6.

The Diesel engine has advantages which overcome the handicap of excessive compression work. But this handicap is a serious matter indeed for the gas turbine, and one of the chief reasons for its lack of success. It is because of the smaller amount of compression work that the explosive cycle, driving by puffs, has been employed, as in the Holzwarth turbine (POWER, Feb. 9, 1912, p. 191). This cycle is outlined in Fig 7, and the constant-pressure line *CD*, as in Fig. 5 also, has the practical significance that there is a longer range of expansion than of compression.

American Society of Heating and Ventilating Engineers

The twenty-first annual meeting of the American Society of Heating and Ventilating Engineers, held Jan. 19-22, at the Engineering Societies Building, West 39th St., New York City, was attended by 200 to 300 members and guests, and the attractive program which had been announced was carried out in nearly every detail.

At the business session, held Wednesday afternoon, Jan. 20, reports of the secretary, treasurer and council were received and indicated that steady progress had been made in the special field of the Society and that the ambition to increase its membership to one thousand was not without substantial encouragement.



ANNUAL DINNER OF AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

PRESIDENT'S ADDRESS

In his annual address, Samuel R. Lewis, the retiring president of the Society, urged upon the members the advantages of following up the actual operation of heating and ventilating plants, especially those of their own design, as information thus gained is highly beneficial in broadening out personal experience and in establishing the relative merits of different systems. Continuing, he said:

When the designing engineer has more to do with the operation of the plants he designs, there will be an improvement in design. I speak from experience, and believe that this opinion will be shared by others who have had like experience.

An examination of the Society's proceedings discloses many descriptions of new plants, but little information as to their operation or as to the costs of installation or maintenance.

I venture, therefore, to present an analysis of some data. In 1912 two large factory buildings were erected, one in Toledo and one in Detroit, and both were designed by the same architects. The writer designed the heating equipment for both plants.

The character of the construction is identical. There are no basements, but there are some tunnels provided under the first floors for air ducts, service pipes, wiring, etc. The buildings are of reinforced-concrete construction, with solid concrete floors, mushroom type, and 12-in. brick curtain walls. The glass is set in tight, steel frames extending practically from floor to ceiling and from column to column. The ratio of glass to exposed wall is approximately three to one. The roof is of concrete-slab construction, with a cinder fill and tar above.

The Toledo building is heated and ventilated by an all-indirect system, equipped with automatic temperature and humidity control, the humidifying being by means of steam jets. There is no direct radiation whatever, except in a few toilet and service rooms.

The Detroit building is heated entirely by direct radiation, about one-half of the radiation being placed on the side walls and one-half on the ceiling. Great care was taken, however, in placing the radiation on the side walls to provide for a liberal circulation of air behind it. The Detroit building has no automatic temperature control, although good hand regulation is obtainable by shutting off parts of the radiation.

Each plant is equipped with an efficient two-pipe vacuum system. The Toledo plant is unique in its design to the extent that the blast-heating surface is arranged at the bases of the vertical flues and so proportioned that much the same effect is obtained every day as would be obtained by having direct radiators in the various rooms, since gravity indirect heating is always in effect whenever there is any steam in the radiation. The theory in the design was that the Toledo plant should be economical, comparing with direct radiation by reason of this gravity effect, while not open to the objections inherent in direct radiation when placed against the outside walls. These objections are that the direct radiation interferes with the benches of the workmen, causes local overheating, and is not economical of fuel, since there is an opportunity for a large amount of radiant heat to directly enter the outside wall without appreciably affecting the temperature of the room. The air is handled by steam power, and the cost of air handling is included in the fuel cost.

The Detroit plant, with its direct radiation, is, of course, heated whenever supplied with steam. In March, 1914, information was received from the owners to the effect that the heating plants had proven adequate and satisfactory.

A careful record was kept of the fuel consumed during the season of 1913-14. The following data will serve for comparison:

	Toledo With Ventilation	Detroit No Ventilation
Exposed glass surface	39,520 sq.ft.	13,980 sq.ft.
Exposed wall surface	7,904 sq.ft.	2,796 sq.ft.
Exposed concrete-column surface	7,680 sq.ft.	3,600 sq.ft.
Exposed roof surface	45,880 sq.ft.	29,358 sq.ft.
Exposed ground-floor surface	45,880 sq.ft.	29,358 sq.ft.
Contents	2,460,500 cu.ft.	704,592 cu.ft.
Floor area	178,800 sq.ft.	56,955 sq.ft.
Blast radiation	12,983 sq.ft.	
Direct radiation	negligible	8,905 sq.ft.
Air delivered per minute	138,000 cu.ft.	
Boiler capacity	500 hp.	125 hp.
Cost of coal per season	$3,009.00	$952.00
Fuel cost for heating and ventilating per 1000 cu.ft. of contents per season	$1.22	$1.35
Same per thousand sq.ft. of floor space per season	$16.82	$16.73

So far the evidence is favorable to a blast system as indicating that a large, well built factory building can be heated and ventilated with an efficient, all-indirect plant at less cost per thousand cubic feet of space per season and for nearly the same cost per thousand square feet of floor space per season, as the other can be only heated by plain direct radiation.

The economy of the Toledo plant lies in the form of the building; that is, the Detroit building, being but two stories high, loses heat through the floor of the first floor and through the ceiling of the second floor, whereas the Toledo building, being four stories high, has two intermediate stories which only lose heat around their sides. For this reason there is advantage sufficient in the instance under consideration to make a favorable showing for the blast system.

REPORTS OF COMMITTEES

The report of the committee appointed January, 1914, "to prepare a set of minimum ventilation requirements for public and semipublic buildings which the Society can recommend for legislation," was received with interest.

General Statement of the Committee on Compulsory Ventilation

A correct interpretation of the experimental work which has been carried on in the last few years, relating to ventilation practice, forces certain conclusions:

A. The necessity for adequate ventilation has been emphasized, although the relative importance of certain factors has changed.

B. A high temperature, especially if associated with a high relative humidity, is injurious.

C. The proper relation between air temperature and relative humidity should be emphasized.

D. Air movement in contact with the body materially assists normal heat dissipation.

E. Air supply free from dust, bacteria and other contaminations is important.

In making recommendations for compulsory ventilation laws it is believed that the importance of the following requirements has been amply demonstrated:

1. A minimum allotment per person of floor and air space, based upon the nature of occupancy.

2. A quantitative minimum air-supply requirement.

3. A carbon-dioxide test for determining the quantity of air supply and its distribution.

4. A temperature-range limitation.

5. The removal from the air of injurious substances arising from manufacturing processes or other causes.

6. Air-exhaust requirements for special service rooms (toilets, locker rooms, etc.).

7. Definite requirements regarding the drawing, filing and approving of plans for both new and existing buildings in which ventilating equipments are to be installed or changes in the equipment made.

8. Ample authority to enforce the law without recourse to civil action, and with sufficient operative and financial assistance to care for the clerical, field and technical details incurred by such enforcement.

9. The official body charged with the enforcement of such laws shall have authority to promulgate specific rules and regulations covering details of installation and operation not included in the law. Such rules and regulations must not conflict with the full intent and meaning of the law. (A few such rules are appended to the report.)

The committee decided that it would be impracticable to attempt to draft a model ventilation law with the necessary legal phraseology, as this would require the assistance of an attorney, and would, moreover, call for an extensive building classification which could not be satisfactorily used in the various states, cities or towns where building laws and regulations based on other classifications are now in force. The committee submitted, first (under Section I), the specific report covering general suggestions for minimum heating and ventilation requirements that are applicable to all classes of buildings, and secondly (under Sections II, III and IV), separate sets of more definite requirements for schools and colleges, factories and theaters.

Sections II, III and IV cover three very important classes of buildings which are often the subject of separate legislation. Many other classes of buildings, such as department stores, hospitals and similar institutions, churches, restaurants, police stations, jails, bakeries, laundries, etc., for which the requirements for heating and ventilation are covered by careful interpretation and use of Section I, would be benefited by separate sets of requirements. It was also pointed out that suggestions from the Society, covering practical requirements for the heating and ventilation of street cars and some other public conveyances, are desirable, and that the report could be considerably enlarged to cover these subjects.

The committee strongly urged that educational and coöperative methods of improving heating, ventilation and sanitation conditions be studied, and used as far as possible in addition to compulsory methods.

Various members of the Society and others had assisted in the compilation of these recommendations, and the information had been cheerfully given when available. The committee also reported that acknowledgments were especially due to investigations and recent committee reports concerning the work in New York City and to the ventilation code and experience in the City of Chicago.

The General Suggestions, Section I, of the Committee's Report, applicable to all classes of buildings, to be provided and maintained during occupancy in all rooms and all inclosed spaces in all classes of buildings, are summarized as follows:

Article I—Space per Occupant (minimum requirement)—

Schools and colleges—class, study, lecture and recitation rooms, floor area per occupant in sq.ft.	15
Schools and colleges—class, study, lecture and recitation rooms, cubic space per occupant (volume divided by number of persons) in cu.ft.	180
Primary schools—class and study rooms (pupils under 8 years of age), floor area per occupant in sq.ft.	12.5
Primary schools—class and study rooms (pupils under 8 years of age), cubic space per occupant in cu.ft.	150
Theaters, auditoriums and courtrooms, floor area per occupant in sq.ft.	6
Theaters, auditoriums and courtrooms, cubic space per occupant in cu.ft.	90
Factories, manual-training rooms and other workrooms—floor area per occupant in sq.ft.	25
Factories, manual-training rooms and other workrooms—cubic space per occupant in cu.ft.	250

Minimum space conditions in all classes of buildings or rooms not tabulated shall be reasonable and practical and shall meet the approval of the Department of Health.

Article II—Air Supply (minimum requirement)—

Sufficient outdoor air shall be provided for all occupied rooms or inclosed spaces at all times during occupancy, as may be necessary to meet the requirements of Articles I to XI, inclusive.

The supply of outdoor air for the following classes of rooms shall be positive and based on a minimum quantity of cu.ft. per occupant per hour as tabulated:

Class, study, lecture and recitation rooms in all schools and colleges, cu.ft. per occupant per hour	1800
Courtrooms and auditoriums	1500
Theaters	1200
Factories, manual-training rooms and other workrooms	1500

All air supply for ventilation must be from an uncontaminated source of air from which the dust or other impurities shall be sufficiently removed by washing or otherwise.

Article III—Air Distribution—

The distribution and temperature of the air supply for ventilation shall be so arranged as to maintain the temperature requirement, as stated in Article IV, without uncomfortable drafts, or any draft lower than 60 deg. F., and as a test of proper supply and distribution it shall be required that the CO_2 content shall not at any time exceed 10 parts in each 10,000 parts of air, based upon tests taken in a zone from 3 to 6 ft. above the floor line in the occupied spaces. This requirement may be modified by the properly constituted authority as applying to breweries, water-charging rooms or other rooms where carbon dioxide is liberated in manufacturing processes.

Note—While carbon dioxide in the air, in reasonable quantities, is not considered injurious to health, its presence in occupied rooms is an acccurate measure of the air supply and distribution if no other source of carbon dioxide is present except the occupants of the room.

Article IV—Temperatures—

The temperature of the air in occupied rooms in all classes of buildings, during the periods of occupancy, shall be not less than 60 deg. F., nor more than 72 deg. F., except when the outside temperature is sufficiently high that artificial heating in the building is not required, this requirement not to apply to foundries, boiler or engine rooms, or special rooms in which other temperatures are required or advisable.

Articles V to XIV provide suggestions pertaining to regulations on the subjects of sources of heat; removal of dust, fumes, gases, vapors, odors, fibers or other impurities; prevention of excessive temperature and humidity; ventilation of special-service rooms; ventilation of toilet rooms; ventilation of cellars, basements and spaces under buildings; authorization to require special ventilation; filing of plans; investment of officials with the right to inspect premises; authorization of officials to close premises after noncompliance with regulations and due notice.

A report was submitted by the committees on the Development of Heating and Ventilating Industrial Buildings, and progress was reported by other standing committees.

In a brief paper presented by A. M. Feldman on an experiment with ozone as an adjunct to artificial ventilation at Mt. Sinai Hospital, New York City, the author recited details of experiments and observations upon which he unhesitatingly recommended the use of ozone as an efficient deodorant, which he believed was beneficial in general improvement of air conditions when properly used, and harmless in physiological effects.

The observations of the author precipitated some discussion of the old question of whether the action of ozone was a destruction of baneful conditions or a mere masking of odors. Dr. M. W. Franklin ably described experiments made by him which demonstrated by comparatively simple chemical processes and analyses that compounds consisting of most disagreeable and deleterious exhalation are so broken up by ozone as to be destroyed and not merely compensated.

A well illustrated paper was presented by D. D. Kimball, author of Part I, and George T. Palmer, chief of investigating staff, author of Part II, on "Results of Physiological and Psychological Observations during the First Year's Experiments" by members of the New York State Commission on Ventilation. The investigation was made possible through the generosity of Mrs. Elizabeth Milbank Anderson, who gave to the Association for Improving the Conditions of the Poor of New York the sum of $550,000 for various phases of social investigation, $50,000 of which is to be expended in an investigation of the problems of ventilation.

This commission, consisting of Professors C. E. A. Winslow, F. S. Lee, E. L. Thorndike, E. B. Phelps, Dr. James A. Miller and D. D. Kimball, was organized early in the summer of 1913, and steps were immediately taken to provide a laboratory equipment for the conduct of the studies and the experiments. The experimental plant was installed in rooms of the biological laboratories of the College of the City of New York. It was aimed to provide atmospheric conditions with temperatures from that existing out of doors or less up to 100 deg. F. in zero weather, with humidities varying from the saturation point to practically nothing. The illustrations and descriptions of the apparatus and methods employed for creating the desired conditions, selection of subjects, tests and data are all of highest scientific interest to physiologists, employers, heating and ventilating engineers, and the public generally, in determining the influences of different air conditions and advantages of controlled systems of ventilation.

In the first experiment, the efficiency in mental work of four subjects, young men about 18 years of age, students of the College of the City of New York, was compared in five different atmospheric environments, viz.: 68 deg. F. and 50 per cent. relative humidity with ample air supply (about 45 cu.ft. per min. per person); and the same temperature and humidity, no air supply (i.e., a stagnant condition); 86 deg. F. and 80 per cent. relative humidity with ample air supply, and also with no air supply; and 86 deg. F., 80 per cent. humidity, no air supply (a stagnant condition but with small electric fans blowing air on the faces of the subjects).

The experiments were thus planned to give information on the subjects' efficiency in (1) a hot moist room as compared with a cool room, (2) a room with ample supply of fresh outdoor air as compared with a room in which no air at all was supplied, and (3) a hot moist room where relief was afforded by the moving air from electric fans. The relative effects were determined by (1) measurement of mental accomplishments, (2) measurement of physiological responses and (3) recording the opinion of the subject as to state of comfort.

In addition to the above six, other sets of tests were conducted, with conditions varied to correspond with extreme conditions of outdoor and indoor atmosphere during the warmest season of the year.

The results of each series of experiments bring out strongly the fact that temperature, and not chemical composition of the air, exerts the greater influence on the physiological responses and that no distinct differences exist between fresh and stagnant air, as far as pulse and blood pressure are concerned; that more food is eaten at the lower temperatures, and the increased consumption on the days with air supply is even more striking; that when the subjects were urged in their work, about one-third more was done at 68 deg. than at 86 deg. F.; that no falling off of judgment was indicated by exposure to the hot conditions, the slightly better score even favoring the warm days and the days with air supply; that room temperature fails to influence mental efficiency, although the feelings of the subject differ materially, favoring the lower temperature. The results also showed that while high temperature and even 75 deg. measurably affected certain physiological reactions of the body, mental processes were not impaired. In fact, with the same relative humidity (1) the 75-deg. condition is somewhat preferable for tasks involving deep concentration, such as mental multiplication; (2) the 68-deg. condition is slightly more desirable for combined mental and motor tasks such as typewriting; (3) that the difference between the two temperatures is practically negligible for maximum effort tests involving mental processes similar to those used in additions of columns of figures, and that there is no choice between these two variables so far as the physical comfort of the subject is concerned.

Application of the inclination-to-do-work test to physical studies was instituted to analyze the effects of the 68-deg. and 75-deg. temperatures and the importance of air supply. These tests consisted of (a) accomplishment of voluntary physical work, (b) variations in appetite, (c) effect of extreme exertion on rate of pulse recovery, and (d) effect on various physiological responses. The results of the work tests show that when left free to occupy their time either at work or rest, the subjects performed 15 per cent. more work at 68 deg. than at 85 deg., and that 2 per cent. more work was done when air was supplied.

In their summary of results the authors state that it is difficult at this time to arrive at any sweeping conclusions as to the importance of different ventilation factors. The influences of humidity have not been studied at all to date. The first year's work of the commission has, however, developed these facts:

1. Temperature within the range from 86 deg. to 68 deg. F. has a marked effect on certain physiological responses.

2. Stagnant air, lacking a definite disagreeable odor but containing all the products of the exhaled breath, including carbon dioxide in excess of 30 parts per 10,000, is objectionable in a manner as yet unknown but demonstrated by a lessened desire for food, but otherwise shows no debilitating effect on the mental process nor on the various physiological reactions which have been studied in these experiments.

ELECTION OF OFFICERS

Officers for the year 1915, as reported by the nominating committee, were elected as follows: President, Dwight D. Kimball, New York; first vice-president, Harry M. Hart, Chicago; second vice-president, Frank T. Chapman, New York; treasurer, Homer Addams, New York. Managers—Frank Irving Cooper, Boston; Dr. E. Vernon Hill, Chicago; W. M. Kingsbury, Cleveland; Samuel R. Lewis, Chicago; Frank G. McCann, New York; J. T. J. Mellon, Philadelphia; Henry C. Meyer, Jr., New York; Arthur K. Ohmes, New York.

The first paper considered at the evening session of Jan. 20 had for its subject "The Centrifugal Fan," by Frank L. Busey, and had been prepared for presentation before the Society just previous to the death of its author. The paper was read by W. H. Carrier, who stated that a very considerable portion of the data consisted of results of the author's personal investigations. (Most of the leading features of the paper are given by the author in an article by him, which was published in the Aug. 11, 1914, issue of "Power," pp. 200-204.) Several members spoke in the highest terms eulogistic of the author's attainments and the work which he did as a valuable member of the Society. The paper was ordered to be printed in the "Transactions," and by a rising vote of all present the thanks of the Society were tendered to Mrs. Busey for her act of providing the Society with the manuscript.

A paper on "Engine Condensation," by Perry West, elicited a spirited discussion, in which several members took issue with the author's deductions leading to the statement:

> It will be seen from the foregoing that in passing high-pressure steam from a boiler through a system of piping and thence through a reciprocating engine, a considerable heat loss is encountered, which usually results in a considerable percentage of condensation in the exhaust. I should say that with simple engines this would run between 15 per cent. and 20 per cent. This means, of course, that there is never as much steam available for the heating system as is started with at the boiler, but just this amount of condensation. Besides this, the steam is in a very moist condition, due to the presence of this water.

David Moffat Myers, the author of the succeeding paper, presented by discussion and in his paper, "The Heating Value of Exhaust Steam," statements and conclusions which were considerably at variance with the deductions of Mr. West, claiming that the latter's method of estimating heat remaining in the exhaust of an engine were unwieldy, and when estimates are based on data which have been established for the thermal efficiencies of engines, the average of Mr. West's estimates for the heat loss of simple engines would be found about 8 per cent too high.

"A Study of Heating and Ventilating Conditions of a Large Office Building" was the subject of a paper presented jointly by C. E. A. Winslow and G. F. Maglott, in which the authors call attention to the facts that the progress of the art of heating and ventilation has been seriously retarded by the gap which, unfortunately, often exists between design and operation. Excellently planned systems may fail on account of changes in conditions of occupation or carelessness in upkeep and management; while on the other hand, operation sometimes reveals shortcomings in design which should be instructive in the planning of future installations. Careful studies of actual results obtained are none too common. The authors present such a study of a large business office building in New York City, heated in the main by direct steam radiation, with certain rooms on the lower floors in part indirectly heated by plenum air supply.

A scientific investigation showed, as all too often is the case, that both the heating and the ventilating systems had been allowed to fall into such disrepair and to become so ill adjusted to present needs as to fall far short of realizing the purposes for which they were designed. It is just such conditions as these which constantly bring discredit upon the art of heating and ventilation, and they are conditions which can only be brought to light by comprehensive engineering and sanitary study of actual operation.

Other papers presented and discussed were: "Studies in Air Cleanliness," by G. C. and M. C. Whipple; "Problem of City Dust," by R. P. Bolton; "Cinder Removal from the Flue Gases of Power Plants," by C. B. Grady; "Recirculation of Air in a Minneapolis School Room," by Frederic Bass; "Comparative Tests of Various Types of Exhaust Ventilators for Sleeping Cars," by Dr. T. R. Crowder; "Ventilation of Industrial Plants," by T. Graham-Rogers, M. D.; "Test of a Cast-Iron Sectional Down-Draft Boiler," by C. A. Fuller; "Crude Oil Fuel," by H. S. Haley; "Some Phases of Room Heating by Means of Gas Burning Appliances," by George S. Barrows; "Rational Methods Applied to the Design of Warm Air Heating Systems," by Roy E. Lynd; "Tests on Threading Steel and Wrought-Iron Pipe," by C. G. Dunnells; "Capacities of Steam Pipes at Different Pressures," by James S. Otis.

ENTERTAINMENT

The entertainment committee provided a program for out-of-town members and guests, which included social sessions, shopping tours for the ladies, theater parties and visits to points of interest. The annual dinner, which was held at the Hotel McAlpin on the evening of Thursday, Jan. 21, was attended by nearly 200 members and guests and proved to be one of the most enjoyable events in the history of the Society.

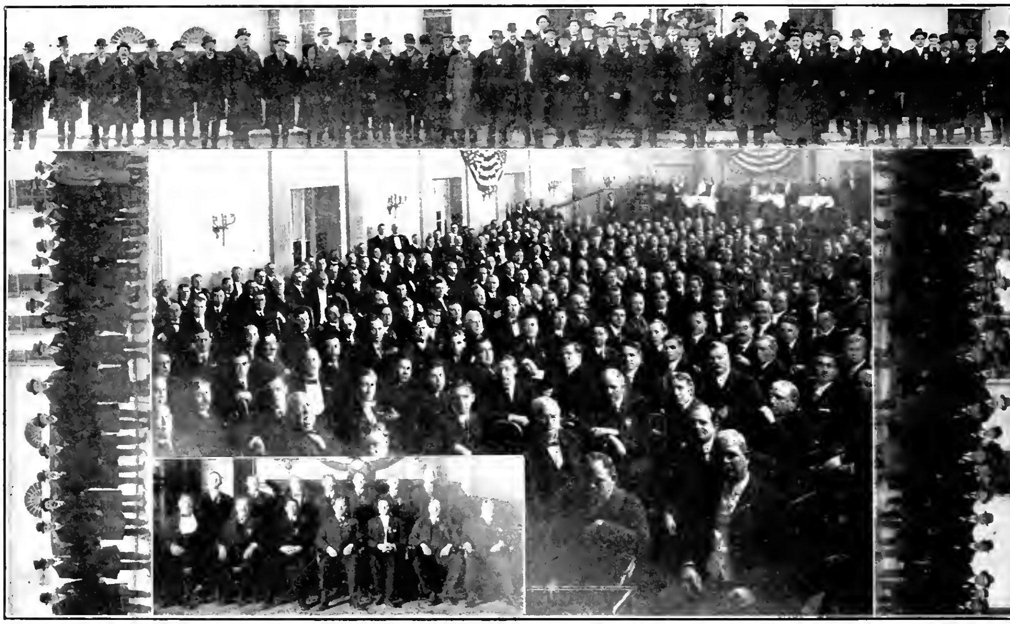
National Marine Engineers' Convention

The National Marine Engineers' Beneficial Association of the United States of America convened in its fortieth annual session on Monday, Jan. 18, at 10 a.m., at the Raleigh Hotel, Washington, D. C. The following officers occupied their respective chairs: William F. Yates, president; George H. Bowen, second vice-president; Charles N. Vosburgh, third vice-president; George A. Grubb, secretary; Albert L. Jones, treasurer.

The several daily sessions of the delegates were from 9:30 a.m. to 1:30 p.m. There were present 60 delegates, representing 115 votes from all of the large lake and river cities of the United States. The financial report showed the organization to be in a prosperous condition. Many matters of special interest to the association were discussed and disposed of with harmony and dispatch.

On Thursday morning an adjournment was taken by the delegates to permit of the convention visiting the White House to be presented to President Woodrow Wilson. There was a theater party on Monday evening to Keith's Vaudeville House for everybody, and on Wednesday evening there was one exclusively for the ladies. The smoker on Thursday night tendered to the engineers by the Supplymen was the big event of the convention, and was heartily enjoyed by all. Fully 400 delegates and invited guests assembled in the ballroom of the Raleigh, where the "New York Bunch" of entertainers made things lively, and kept the audience in good humor for the entire evening. Good things to smoke and drink were served plentifully.

At the session on Wednesday morning the following national officers were elected: A. Bruce Gibson, president, San Francisco, Calif.; E. M. Roberts, first vice-president, New York City; C. N. Vosburgh, second vice-president, New Orleans, La.;



THE MARINE ENGINEERS' BENEFICIAL ASSOCIATION'S FORTIETH CONVENTION

Group outside the White House after being received by the President—The new National Officers—The Smoker at the Raleigh Hotel

William C. Wilson, third vice-president, Philadelphia, Penn.; George A. Grubb, secretary, Chicago, Ill.; Albert L. Jones, treasurer, Detroit, Mich.

The advisory board includes: Thomas L. Delahunty, New York City; George H. Willey, Boston, Mass., and Robert L. Goelet, Norfolk, Va.

The trustees of the "American Marine Engineering" comprise Clinton E. Thurston, Norfolk, Va.; Joseph G. Myers, Charleston, S. C., and William Murray, New York City.

The forty-first annual convention will meet at Washington, D C., the week beginning Jan. 17, 1916.

General Electric Co. Exhibit for Panama-Pacific Exposition

The exhibit of the General Electric Co. in the Transportation Building at the Panama-Pacific International Exposition will comprise electric locomotives for various classes of service, including steam-railroad electrification, railway motors and all kinds of apparatus and accessories for electric railways, signal accessory electric devices, electric apparatus and equipment for railway shops, electric illumination for cars and shops, etc.

One of the electric locomotives is one of four recently built for the Butte, Anaconda & Pacific R.R. and is a duplicate of the original 17 units put into service in 1913. These are the first 2400-volt, direct-current electric locomotives ever built. Each unit weighs 80 tons, and two are coupled together for freight service hauling trains of 4600 tons at 16 miles per hour up a 0.3 per cent. grade, and at 21 miles per hour on level track. Two passenger locomotives, operating as single units on this system, are geared for a max'mum speed of 45 miles per hour on level track.

Down with the Archaic Boiler Horsepower

We are rapidly drawing away from the horsepower method of rating boilers. This has come about through the working of two different tendencies, both of which diminish the value of such a statement of boiler capacity. In the first place, there no longer exists any particular equality between the horsepower of a boiler and the amount of engine power which it may be expected to serve, although at the time of the adoption of the present unit, in 1876, it was given a value about equal to the average steam consumption per horsepower of the engines exhibited at the Centennial Exposition, on the assumption that this would approximate average conditions at that time. Modern engines have so far improved in economy that it is now possible for one boiler horsepower to serve from two to three engine horsepower of connected load under favorable circumstances. There is, moreover, another influence at work to lessen the value of the horsepower rating—namely, the growing demand for greater and greater boiler output per unit of heating surface—so that it is no longer a matter of special novelty to read test returns of boilers in regular operation at upward of 200 per cent. of what a few years ago would have been considered a proper performance.

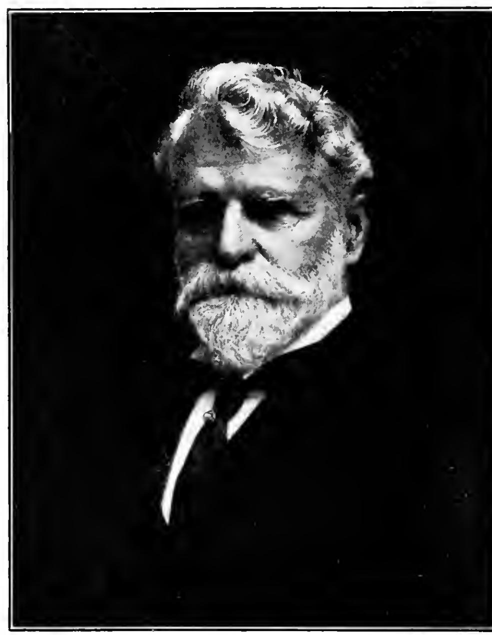
The result of these two changes in power-plant economics is to make it more and more necessary to plan boiler plants on a heating surface and not a horsepower basis. The designing engineer first determines the rate at which he expects to be able to work his heating surface, with the character of coal, draft, setting, etc., which he expects to utilize; that is, he sets a figure for the amount of water which he may expect to evaporate on each square foot of heating surface in the particular plant he has in mind. It is then only necessary to add the combined water rates of the different steam-consuming devices and divide by the evaporative rate to arrive at the total heating surface, which he can divide among the proper number of boilers.

When an essentially nontechnical buyer of boilers is obtaining competitive bids from boiler makers, he is apt to think and talk in terms of dollars per 100 or 150 (or some other number) horsepower. He naturally assumes that this is a proper basis upon which comparisons may be made. He will of course be disappointed if, having purchased the boiler from the lowest bidder, he finds to his surprise that this builder has bid on a boiler rated at 10 sq.ft. to the horsepower, while perhaps his engineer in deciding on the necessary size has calculated on 12 sq.ft. to the horsepower rating. This is very confusing to the owner who is not an engineer or who is not familiar with the diversity which exists among boiler makers as to the proper rate of evaporation to use as the foundation for a catalog rating. It is not at all uncommon for the condition outlined above to come about, resulting in the purchase of a boiler 20 per cent. smaller than either the buyer or his engineer desired.—"The Locomotive."

The Engineering Foundation

The ceremonies inaugurating the Engineering Foundation were held Wednesday, Jan. 27, at 8:30 p.m., in the auditorium of the Engineering Societies Building in New York City. The name, The Engineering Foundation, has been given to a fund "to be devoted to the advancement of the engineering arts and sciences in all their branches, to the greatest good of the engineering profession and to the benefit of mankind." The administration of this fund will be intrusted to the Engineering Foundation Board elected by the trustees of the United Engineering Society, the holding corporation of the Engineering Societies Building, and composed of eleven members, two each from the American Society of Civil Engineers, the American Society of Mechanical Engineers, the American Institute of Mining Engineers and the American Institute of Electrical Engineers, two members chosen at large, and the president of the United Engineering Society, ex-officio.

Gano Dunn, president of the United Engineering Society and past-president of the American Institute of Electrical



Ambrose Swasey

Engineers, presided, and announced for the first time the name of the donor of the initial gift of $200,000—Ambrose Swasey, who is widely known as a member of the firm of Warner & Swasey, of Cleveland, Ohio, prominent machine-tool builders and the foremost builders of telescopes in the world. Among the instruments which they have designed are the famous Lick, Yerkes and United States Naval Observatory telescopes, as well as the 72-in. reflecting telescope for the Canadian Government, which is now under construction. In addition to his engineering achievements, Mr. Swasey is known for his practical efforts toward scientific education and the advancement of the profession. His gift for the establishment of The Engineering Foundation is in line with these undertakings, which may be destined to outlast his fame as an engineer.

In response to the ovation given Mr. Swasey at this time, he arose and made an acknowledgment of his appreciation of the spirit in which the announcement had been received. Other speakers of the evening were: Dr. Henry S. Pritchett, president of the Foundation for the Advancement of Teaching. Dr. Robert W. Hunt, past-president of the American Institute of Mining Engineers, Charles MacDonald, past-president of the American Society of Civil Engineers; and Dr. Alexander C. Humphreys, past-president of the American Society of Mechanical Engineers.

Following the ceremony a reception to Mr. Swasey was held at the platform of the auditorium. A testimonial dinner to him was given on the preceding evening by the president and board of trustees of the United Engineering Society, at which speeches were made by leading engineers representing the civil, mining, mechanical and electrical branches of the profession, which helped to further cement the close relationship existing and gave promise of hearty cooperation in the future on all matters affecting the profession in general.

Rolling-Mill Engine Wrecked

Early in January the compound condensing engine driving a train of hot rolls at one of the plants of the American Sheet and Tin Plate Co., at Chester, W. Va. (near East Liverpool, Ohio), was badly wrecked, caused by the breaking of the strap on the crosshead end of the connecting-rod.

When freed from the rod the crosshead and low-pressure piston were driven through the low-pressure cylinder, breaking it beyond repair, also the distance piece between the high- and low-pressure cylinders. The high-pressure cylinder was not so severely damaged, because the studs which held it to the bedplate gave way and allowed the cylinder to recede. It was torn from the bedplate and its steam connections at the throttle and receiver pipe.

The engine was built by C. & G. Cooper and had been in use about 14 years. It was 26&54x60-in. and ran at 65 r.p.m., carrying a 22-ft. flywheel weighing about 60 tons, and was geared to a shaft driving six hot mills. A steam pressure of 140 lb. was carried, exhausting into a Worthington condenser.

Fortunately, no one was injured, but the mill will be shut down for fully four weeks, during which time about 500 men will be idle. Our representative was, unfortunately, unable to procure photographs, as the work of clearing away the wreckage and reconstructing the engine was begun at once and all haste was made to get the mill in operation again.

PERSONALS

F. W. Rose, of the firm of Rose & Harris, engineers, Auditorium Building, Minneapolis, has been elected secretary and treasurer of the Minnesota section of the American Society of Mechanical Engineers.

Errett L. Callahan, for the past six years manager of the new business department of H. M. Byllesby & Co., Chicago, Ill., has resigned that position to become Chicago district manager for the Westinghouse Lamp Co.

David A. Wright, for several years with the Yale & Towne Manufacturing Co., of New York, as district manager in the West, has engaged in business for himself as manufacturers' agent, at 149 South Dearborn St., Chicago, Ill. He is specializing on labor-saving and pneumatic machinery, cranes, hoists and trolley systems.

E. P. Roberts, commissioner of smoke abatement, Cleveland, Ohio, has tendered his resignation, to take effect Feb. 1, and will resume business as a consulting engineer, with temporary address 2053 East Ninety-sixth St., Cleveland. In addition to general power-plant engineering as heretofore, he will make a specialty of smoke abatement.

Dr. Edward Weston, of Newark, N. J., has been presented with the ninth impression of the Perkin medal, given for distinguished service in chemistry and electrochemistry. The ceremony took place on Jan. 22, at the Chemists' Club, Dr. G. W. Thompson presiding. The medal was presented by Doctor Chandler, senior past-president of the Society of Chemical Industry, after briefly reviewing the career of the recipient.

ENGINEERING AFFAIRS

The Western Society of Engineers, Chicago, has elected the following officers for the year 1915: President, W. B. Jackson; first vice-president, Ernest McCullough; second-vice president, Charles B. Burdick, third vice-president, P. B. Woodworth; treasurer, C. R. Dart, trustees, F. E. Davidson (one year), H. S. Baker (two years), O. P. Chamberlain (3 years).

Railroad Night for Chicago Section A. S. M. E.—Jan. 8 was railroad night for the Chicago section of the American Society of Mechanical Engineers. As usual, it was a dinner meeting held in the Louis XVI room of the Hotel La Salle. There was a large attendance and a number of able speakers. S. G. Neiler presided. The subjects discussed were: The Locomotive Superheater, Locomotive Stokers, and Railway Economics. The subject first named was introduced by R. M. Ostermann, of the Locomotive Superheater Co. C. F. Street, president of the Locomotive Stoker Co., gave some statistics on the cost of operation when using stokers and outlined the advance that had been made in this field. Railway Economics was discussed at length by W. A. Smith, president of the "Railway Review."

Technology Clubs Convention—The Technology Clubs Associated, an organization of former students of the Massachusetts Institute of Technology, will hold a reunion in Pittsburgh Feb. 19 and 20, at the invitation of the Pittsburgh Association. The main features will be: Class luncheons the first day; course luncheons the second day where discussion of the various curriculums will be undertaken and where graduates, in the light of their later experiences, will be invited to criticize their own courses of instruction; and the banquet Saturday evening, when addresses will be given by President Richard C. Maclaurin and probably President A. Lawrence Lowell, and two other speakers of international prominence whose names are to be announced later. All alumni and former students of the institute are invited.

International Engineering Congress—The American Society of Mechanical Engineers has issued a circular letter to its membership, urging individuals to subscribe to the International Engineering Congress to be held in San Francisco in connection with the Panama-Pacific International Exposition, Sept. 20 to 25, 1915. As one of the five national societies in the hands of the representatives of each of which the Congress is placed, it is urged by the mechanical engineering society that its members should feel responsibility and give their fullest support to the Congress. The fee for membersnip is $5, which entitles a member to the index volume which covers general proceedings, indexes and digests, and any one of nine other volumes which are published or to be published, as follows: Vol. 1, The Panama Canal; Vol. 2, Waterways and Irrigation; Vol. 3, Railways; Vol. 4, Municipal Engineering; Vol. 5, Materials of Engineering Construction; Vols. 6 and 7, Mechanical and Electrical Engineering; Vol. 8, Mining Engineering and Metallurgy; Vol. 9, Naval Architecture and Marine Engineering; Vol. 10, Miscellaneous.

TRADE CATALOGS

Skinner Engine Co., Erie, Penn. Catalog. Universal Unaflow engine. Illustrated, 28 pp., 8½x11 in.

The Emerson Electric Mfg. Co., St. Louis, Mo. Catalog No. 6700. Electric fans. Illustrated, 48 pp., 7x10 in.

Kennedy Valve Mfg. Co., Elmira, N. Y. Catalog. Gate, globe, angle, radiator and corner valves. Illustrated, 124 pp., 6x9 in.

B. F. Sturtevant Co., Hyde Park, Mass. General Catalog No. 195. Fans, exhausters, blowers, engines, steam turbines, etc. Illustrated, 116 pp., 6½x9 in.

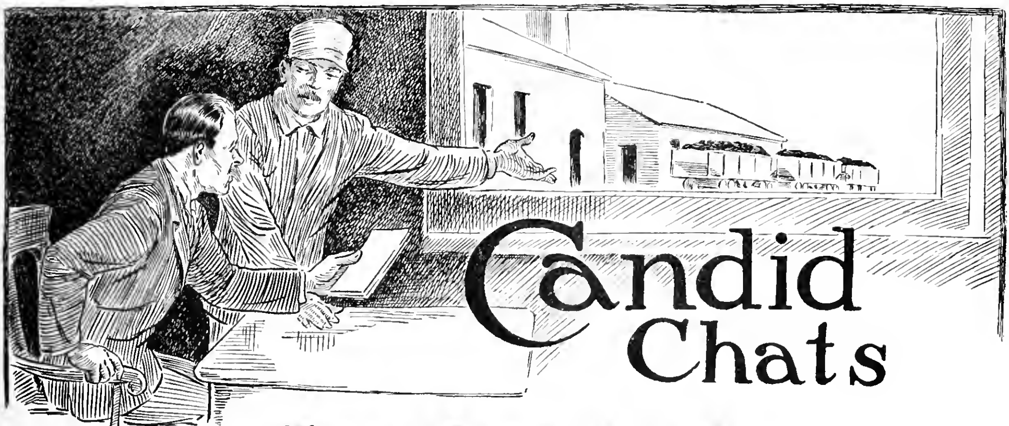
Armstrong Cork & Insulation Co., Pittsburgh, Penn. Booklet. "Permanent Fortifications." Nonpareil corkboard insulation. Illustrated, 8 pp., 3½x6 in.

CONTRACTS TO BE LET

TREASURY DEPARTMENT, Supervising Architect's Office, Washington, D. C., January 5, 1915—Plans and specifications are now approaching completion for a central heating, lighting and power plant, to be erected in this city under the direction of this office. These plans and specifications will be ready for delivery on or after January 15. Bids may be submitted for the entire work or for any one of the following sections: Power plant building complete, with steel stacks; boilers; generating apparatus; pumping equipment; condensers; coal and ash handling apparatus; steam and water piping; switching gear; tunnels; substation apparatus, etc. Prospective bidders should immediately submit to this office applications for plans and specifications, stating the portions of the work upon which they desire to bid. If it appears that the applicant is in a position to bid on all of the work in any one of the sections of the project, or upon the entire work, the plans and specifications will be forwarded. No plans or specifications will be furnished sub-bidders or others not in a position to submit a bid on all of the work comprised in at least one section. The Department will be able to allow only about 15 days for the preparation of estimates. At the time plans and specifications are forwarded to bidders the date for the opening of bids will be stated, and this date will not be extended. O. WENDEROTH, Supervising Architect.

POWER

Vol. 41 NEW YORK, FEBRUARY 9, 1915 No. 6



Too Much Coal

Here is an amusing yet pathetic story which you'll appreciate all the more if you know of a similar case

THE plant is the ordinary large, industrial kind where much low-pressure steam is used for manufacturing purposes. The management—the president and the usual outfit—is representative of the average.

The new chief engineer was engaged on a salary and percentage-of-saving basis. Of course, the first thing he did was to return to the boiler the many pounds of 210 deg. F. condensate allowed to merrily flow to the sump and sewer. Winter was coming on, and one need not be a college professor to know that changes in pipe sizes and arrangements and the installation of a few traps on the heating system would make the coal man feel badly.

The volume of business was fairly constant, and had been for years, so the coal was bought by contract and supplied in unvarying amounts as regularly as you get sleepy between 2 and 3 a.m. when you are on the 12-to-8 watch. The coal was stored in a large low building and had to be trimmed considerably to fill it. Soon the effect of the changes in the uses of steam and the disposition of condensate was made apparent by the full coal cars on the siding and the labor necessary to trim coal in the storage bin. The amount of coal on hand was becoming a veritable nuisance!

The chief asked the manager to have the supply stopped for a while. This was a new one on the manager; the engineer's complaint had always been the other way, and the manager did not understand. Couldn't the engineer find room for it somewhere? The quantity received was as usual, and he could prove it by comparing the monthly statements. The mills ran full time; the winter was just as cold as previous ones, if not colder. He glanced at the calendar to make sure it was Feb. 1 instead of Apr. 1, and finally walked to the window to see that string of cars. Yes, the coal was there! Ah! he had it; the coal was not being used!

The engineer suggested that they compare the weekly coal consumption reports. Yes, the manager was right; the coal was not being used as formerly. The reports showed that up to date about one hundred tons less coal had been used these last winter months than for the corresponding months of previous years.

What does this case show? Here is an actual, honest-to-goodness example of the amount of worth-while attention some concerns pay to the power plant.

And the engineer was engaged on a percentage-of-saving basis, too!

It shows that the engineer must keep duplicate reports and, above all, see to it that the management really studies them and is given every opportunity to know what their proper interpretation means in its relation to the chief engineer and the cost of manufacture.

This engineer had applied himself to the task of reducing costs and improving service, had stayed up late nights outlining necessary alterations to this end—he was making good! And he was getting no more moral credit than the man who would have used the 100 tons and saved disturbing the manager. Things would have gone this way until the books were examined to determine how much in percentage-of-saving was due the engineer.

Seattle Municipal Lighting Plant

By W. L. Kidston

SYNOPSIS—This plant will assist in carrying the winter peak loads of the Cedar Falls (Wash.) hydro-electric plant. A steam pressure of 200 lb. is carried on the three boilers, with 125-deg. superheat. The turbo-generator is of 7500-kw. capacity. The boiler furnaces are designed for burning fuel oil or coal with mechanical stokers, which can easily be put in place.

The new steam-generating station of the Seattle (Wash.) municipal system, known as the Lake Union auxiliary, has a continuous capacity of 9375 kw. and will be used by the lighting department to help the main hydro-electric station at Cedar Falls over the heavy winter peaks and to take its full capacity load in case of accident to the water-power station or transmission lines. The steam plant is near the geographic center of the city, on the east shore of Lake Union It will be accessible from Puget Sound and Lake Washington through the Lake Washington canal, and by land it can be reached by the Lake Union belt-line railway and by the tracks of the local traction company.

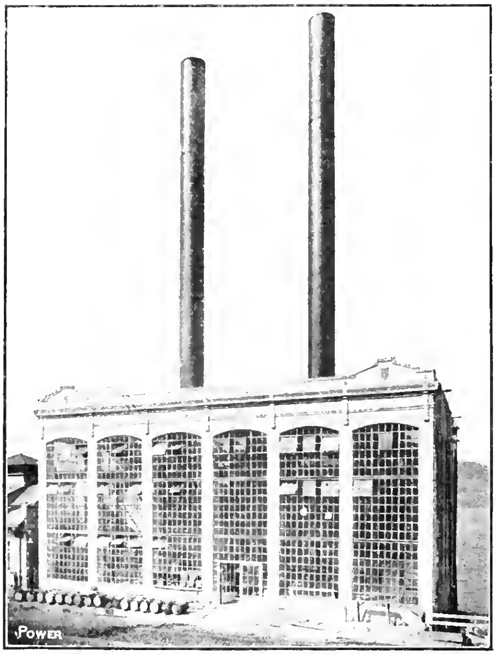


Fig. 1. New Seattle Generating Station

The building (Fig. 1), built of reinforced concrete, is 90x100 ft. and 57 ft. from the basement floor to the cornice and was begun on Apr. 25 of last year. It was designed and built by the Department of Buildings of the city of Seattle. The foundation is on piles. The basement floor is 18 ft. below the level of East Lake Ave., and a concrete retaining wall containing 800 cu.yd. was built to support the street and protect the structure from possible slides from the hill beyond. Steel sash is used throughout the building, and as the space between columns is glazed, ample light is secured. A 25-ton crane with a 30-ft. span serves the turbine room.

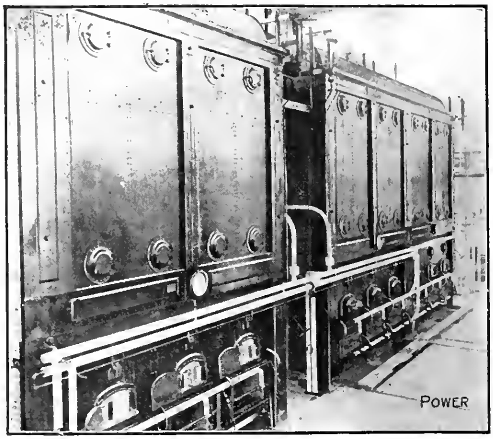

Fig. 2. Three Water-Tube Boilers with 8230-Sq.Ft. Heating Surface

The plant contains three water-tube boilers (Fig. 2), each having 8230 sq.ft. of heating surface, which will supply steam at 200 lb. pressure and 125 deg. superheat to the 7500-kw. turbo-generator set (Fig. 3). The boilers are on the street floor at the west side of the building, with the firing aisle next to the lake. They are equipped for burning oil, but the settings are arranged for stokers and ash hoppers, so that a change may be made to coal burning at any time by inserting the stokers, the tracks for which are in place. The basement under the boilers is planned to accommodate the ash-handling cars. Provision is made for a fourth boiler. The boilers are guar-

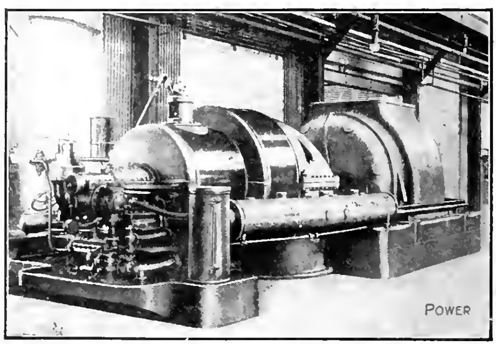

Fig. 3. The 7500-Kw. Turbo-Generator Unit

anteed for 77 per cent. efficiency at full load and to operate satisfactorily at 180 per cent. continuous overload. Two steel stacks, 90 in. diameter, designed for coal burning, extend 170 ft. above the boiler-room floor, each to care for two boilers.

Two steel oil-storage tanks, 11 ft. and 20 ft. long, of 15,000 gal. capacity each, are buried just outside the boiler room on the south side of the building. Both tanks have domes 4 ft. in diameter and 4 ft. high, with screw covers and steel ladders to permit of inspection. This capacity per tank is the largest allowed by the city ordinance. As the tanks are adjacent to the building, it was necessary to bury them, and a concrete wall was built, separating and inclosing them. The space around the tanks was then filled with earth to a depth of 4 ft. above the top of the shells. Six-inch connections to the domes are used for filling the tanks and connections of the same size on the under side join with an 8-in. suction header, to which the two motor-driven storage pumps, each with a capacity of 16,000 gal. per hour, are connected. This header runs out to the lake for use in unloading oil-tank cars or oil scows.

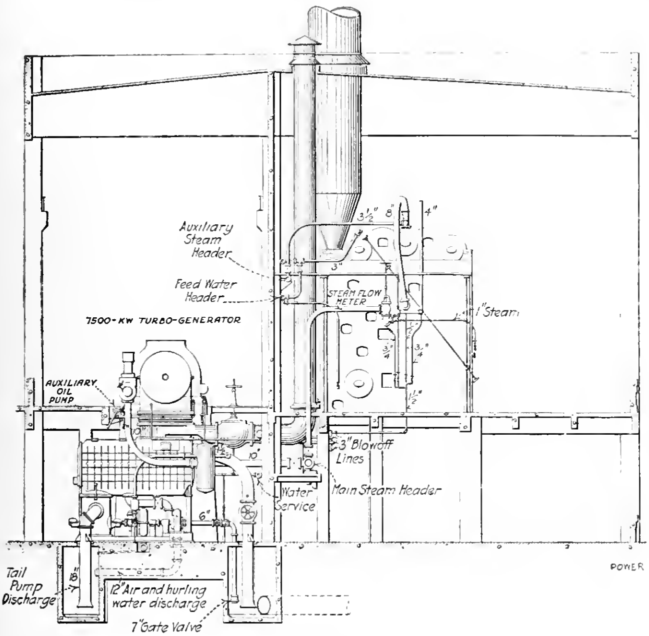

FIG. 4. ELEVATION OF THE BOILER ROOM AND BASEMENT

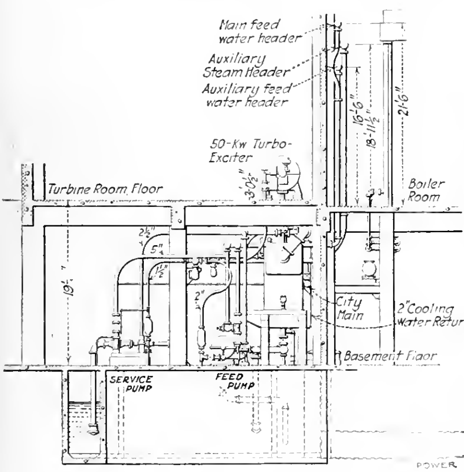

FIG. 5. END ELEVATION OF AUXILIARY PIPING

One 7200-gal. service tank, 7 ft. in diameter by 24 ft. long, is placed above the storage tanks, and the suction pipes from the two burner pumps run through the dome and down to the bottom of the tank, terminating in a foot valve. The tank is separated into halves by a partition, thus forming two tanks, both of which have a 30-in. dome with a screw cover. A steel ladder runs to the bottom of the tank. The 6-in. connections in the domes are used for filling the tanks and the 4½-in. suction pipes for emptying them. A 2½-in. overflow pipe runs from each oil heater back to the service tank. A 6-in. pipe from the filling pipes to the street makes it possible to fill any of the three tanks from oil trucks. Pumps to supply the oil burners are on the boiler-room floor, as are the oil heaters.

The boilers connect to a 12-in. header (Fig. 4), from which steam is taken to the turbine (Fig. 7). The generating unit is a horizontal turbine connected by a flexible coupling to a 2500-volt, two-phase alternator, at 1800 r.p.m., and rated at 7500 kw. at 80 per cent. power factor with 50-deg. Centigrade rise above the room temperature, and at 9375 kw. at 80 per cent. power factor with 65-deg.

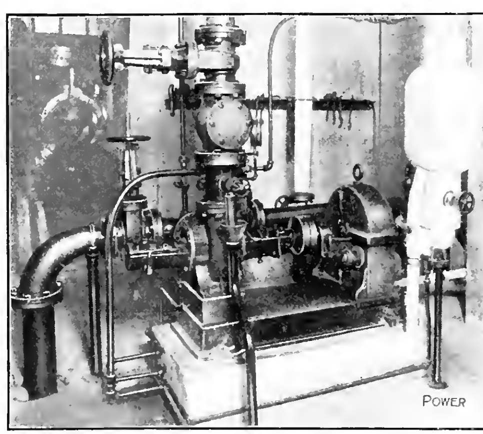

FIG. 6. TURBINE-DRIVEN HOUSE PUMP

rise. The temperature in the generator coils is measured by a resistance thermometer inserted between them, and is registered on the switchboard. The unit is guaranteed to produce one kilowatt-hour from 12.95 lb. of steam at 190 lb. pressure and 125 deg. superheat when operating at full load.

The condenser, of the rectangular-jet type, and placed under the turbine (Figs. 4 and 5), will maintain 28½ in. of vacuum when condensing 97,500 lb. of steam per hour.

The centrifugal circulating pump is mounted on the shaft with the rotary air pump and both are driven by a small impulse turbine. The boiler-feed pumps and the service pump (Figs. 6 and 9) are also of the centrifugal type with four stages, and are turbine driven. Steam for these auxiliaries is taken from a 6-in. saturated-steam header, and the exhaust is used in the 2500-hp. metering feed-water heater. The exciter, rated at 50 kw., 125

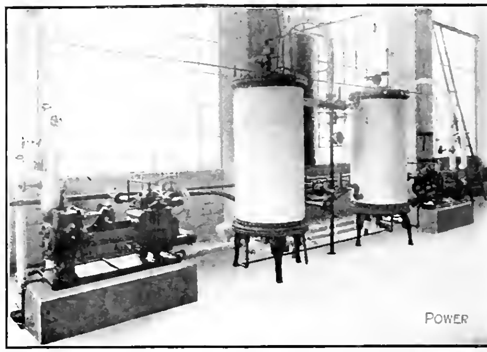

FIG. 7. OIL HEATERS AND PUMPS

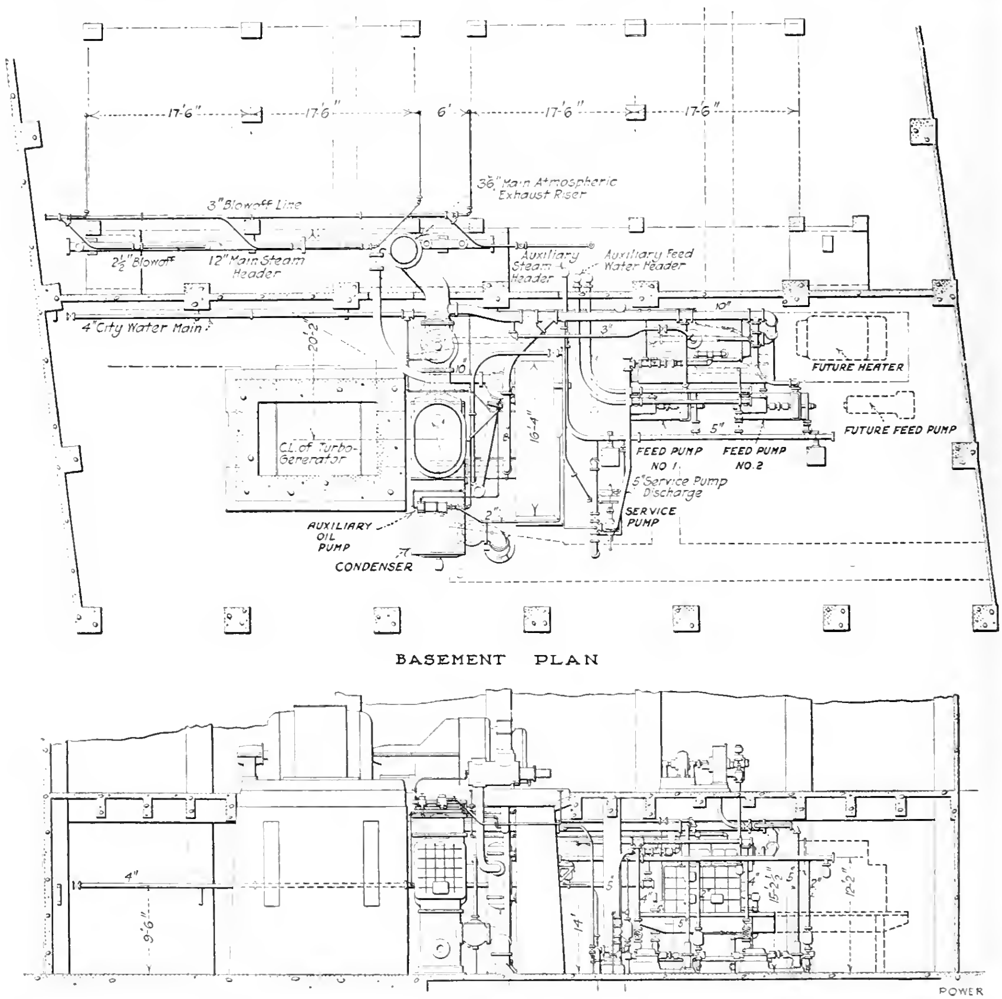

FIG. 8. PLAN AND ELEVATION OF TURBINE-ROOM BASEMENT

volts, is also turbine driven. Fig. 8 shows the piping arrangement.

As the steam-plant site is on the shore of Lake Union, a fresh-water lake, there is an abundant supply of cooling water for the condenser. The water supply is brought to the plant from an intake 120 ft. out in the lake, through a 30-in. cast-iron pipe to a concrete screen box at the west side of the building, and from there through a second run of pipe to a cold well at the end of the condenser. An 18-in. pipe supplies the condenser with cooling water, which is drawn into the condenser by vacuum. In starting, a jet of water from the city mains is used to condense

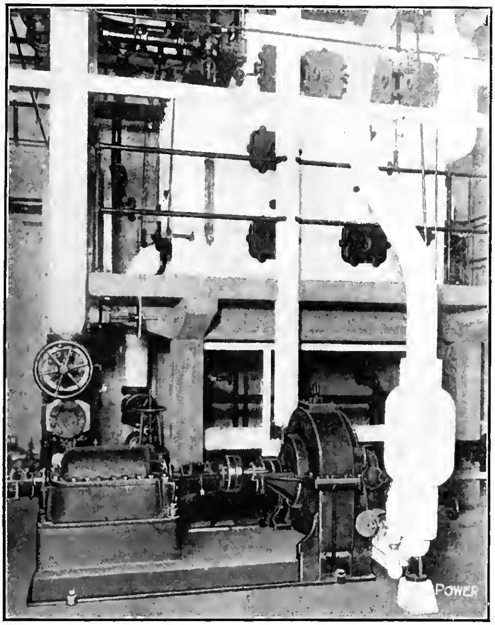

Fig. 9. One of the Two Turbine-Driven Centrifugal Boiler-Feed Pumps

the steam and create a vacuum in the condenser shell. The 18-in. discharge pipe from the condenser connects with the hotwell, which is a concrete tunnel 4 ft. wide by 10 ft. deep. In case of a future installation, this tunnel will connect the two units. A 30-in. cast-iron pipe serves as an outlet for the hotwell and discharges the hot water into the lake at the back wall of the building.

The turbine set is on the street floor, on the east side, next to East Lake Ave., and the switchboard is in the same room. Current is stepped up to 15,000 volts, two-phase, for distribution over the city, and the steam station will be connected to the main distributing station at Seventh Ave. and Yesler Way by a direct 15,000-volt tie line. The step-up transformers, of the same capacity as the turbine, are in the basement under the turbine room, where the oil switches and 2500-volt and 15,000-volt wiring are placed. Provision is also made to use the steam station for distributing, for which purpose the oil switches, feeder regulators and street-lighting transformers will go in the basement.

The steam plant is on the same lot with a 1500-kw. water-power auxiliary, which uses the overflow from the Volunteer Park reservoir of the city water system, situated on the hill 415 ft. higher than the lake. Both plants will be operated from the same switchboard and will work together to safeguard the service of the system.

The main generating station at Cedar Falls is being extended and improved by the erection of a $1,100,000 dam, which will permit of a development of 40,000 kw. J. D. Ross, superintendent of lighting, is in charge of the Seattle municipal plant.

First-Aid Jar for Power Plants

Accidents frequently happen in and about a power plant, and in many cases the injured could be attended by the laymen if first-aid materials were at hand. A first-aid jar has been prepared to meet such requirements by the Conference Board of Safety and Sanitation, of which Magnus W. Alexander, General Electric Co., West Lynn, Mass., is secretary.

The jar is structurally strong and a special annealing treatment makes the glass still stronger. It is made with smooth surfaces and with straight walls on the inside to promote cleanliness and facilitate the removal of first-aid materials. A convenient carrying handle is molded to the glass cover, held by suitable spring clips which are a part of a metal cage holding the jar; this cage affords added protection against breakage. A rubber gasket between the jar and the cover makes the outfit dustproof.

The jar is made only high enough to accommodate the bottles of medicaments stored in it so that the stoppers

First-Aid Jar

cannot come out when the cover rests on the jar. Medicine bottles, bandages, absorbent cotton, burn ointment in collapsible tubes and a wire-gauze splint are arranged along the wall of the jar, so that they are plainly visible from the outside and can be quickly located. A specially constructed metal dish placed inside of the jar keeps the materials in their proper places; it is also used as a receptacle for tourniquet, medicine glass, gauze bandages, medicine droppers, spoon, scissors, etc.

The jar is about 9½ in. in diameter, 6 in. high, and complete with contents weighs only slightly more than 12 lb. It, however, includes every material which a conference of physicians with extensive experience in the treatment of injuries agreed upon as necessary for effective first-aid treatment by laymen.

Suitable first-aid instructions are printed on the inside of the cover, while on the outside appears the standard list of materials which should always be kept in the jar and brief directions for the use and care of the outfit.

This jar has been approved by the board, which is composed of representatives of the National Founders' Association, 29 South La Salle St., Chicago; the National Association of Manufacturers, 30 Church St., New York City; the National Metal Trades Association, Peoples Gas Bldg., Chicago, and the National Electric Light Association, 29 West 39th St., New York City. The outfit is sold at practically cost price, as there is no intention to make a profit on any of the articles standardized by these associations, and can be secured by writing the secretary of any of the associations mentioned.

Oil-Engine Tendencies

By A. E. Ward

SYNOPSIS—The writer reviews the oil-fuel situation and points out the legitimate fields for the different types of engines. He warns against the defects in the low-compression, pump-injection type when attempting to use heavy oils, which should be used only in the high-compression engine, and champions the vaporizing type.

The manufacture of internal-combustion engines is being influenced to a certain extent by the fuel situation, and the consequent demand of the public for an engine which will handle heavy grades of liquid fuels. Whether this demand is to continue will be influenced by the availability of the heavy liquid fuels, their prices as compared with lighter fuels, and the success of the engines which claim to use them. Therefore, it would be well for the buying public to consider carefully and without prejudice all phases of this subject before it continues to bring about what may prove an undesirable tendency in the application of the internal-combustion engine for general power purposes.

Oil-Fuel Situation

During the past few years there have been marked changes in the oil-fuel situation, and it is practically impossible to prophesy what the future will develop. The heavy drain on the gasoline supply for the automobile trade has been the apparent cause for its rise in price. However, this has now been reduced to practically the figures which prevailed several years ago, but it is still too high to be considered for use in the larger or intermediate sizes of internal-combustion engines.

An important feature is the percentage of fuel of different grades available from crude oil. Refiners have been able to secure in recent years a larger percentage of gasoline from crude oil than heretofore, but the quality of the gasoline has also been reduced. Crude oil from different localities varies greatly in quality, but a fair average would indicate that about 15 per cent. can be turned into gasoline or naphtha. About 45 per cent. is kerosene, and about 10 per cent. of a high-grade distillate above 39 deg.; another 10 per cent. is a low-grade distillate below 39 deg; while about 15 per cent. is turned into lubricating oil, and the remaining 5 per cent. is slop. It is evident, therefore, that a small percentage of the refined product, about 10 per cent., is of such a nature as to require a crude-oil engine. Furthermore, about 50 per cent. of the refined product can be handled in the conventional four-stroke-cycle vaporizing type.

There is a large market for the heavier grades of refined oil to be used for burning under boilers, oiling streets, etc., which often makes it difficult for the small purchaser to secure, or to continue to secure, this fuel for power purposes. Sometimes the small purchaser finds that it is necessary to buy his fuel in tank-car lots in order to gain the point of economy desired. It is evident, therefore, that the purchaser of an engine designed for handling crude oil or an equivalent fuel is necessarily subjected to the caprices of the market.

It is true that there are a number of localities, especially in the West and Southwest, where the heavy liquid fuels are being purchased at comparatively low prices. However, it is questionable whether this condition will continue, inasmuch as the supply of fuel oil to burn under boilers has frequently been taken away from manufacturers who have gone to the expense of installing boiler appliances for burning this fuel. Moreover, there is wide variation in the quality and constituents of heavy oils, depending upon the quality of the crude, the method of refining, tendency of the refineries in accordance with the demands, etc.

While gasoline is also uncertain in its price, kerosene has remained at practically the same price, has always been available in most localities, and does not vary in quality.

There are, undoubtedly, many cases where the Diesel engine is the proper type to use, considering especially its high thermal efficiency and the ease with which its fuel can be stored, transported and handled. The following objections can be raised against it, however. It is complicated in design, necessitating strict attention to the minutest details and requires a very high grade of workmanship. Moreover, correct adjustment must be maintained at all times, and skilled attendance with corresponding high cost is essential. Fuels of low quality and low price have frequently been used when the plant was first installed, and later a high-grade fuel has been substituted. Depreciation and maintenance have in many cases been excessive in addition to the first cost being high. Finally, this type of engine is extremely sensitive to irregular or improper conditions.

In spite of these objections there are many successful Diesel installations. If a purchaser takes these points into consideration, arranges to keep the engine in prime condition at all times, is assured that the proper fuel will be available at a low price, if natural gas is not available, and his conditions do not favor producer gas, and if his power requirements are not less than 100 hp., he may be justified in purchasing a Diesel engine.

Semi-Diesel Engines

Coming now to a class of engines for powers of 15 to 100 hp., the purchasers of these sizes ordinarily do not give the engineering features due consideration. Being without the necessary experience and knowledge themselves, they are largely at the mercy of the ambitious salesman who has a tendency to exaggerate the qualifications of the article he is handling. There has been a clamor for engines of those sizes which will burn heavy fuels, such as have been successfully handled in the Diesel engine. Owing to this demand, there has been a natural response on the part of some manufacturers to produce

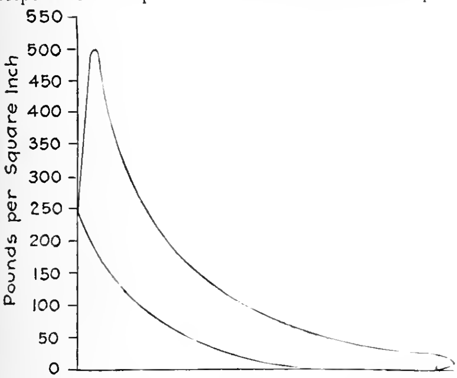

Fig. 1. Diagram from Hot-Plate, Air-Injection Engine at Rated Load

an engine which would fulfill these requirements. It is evident that the high first cost of the Diesel engine would prohibit its sale among the majority of purchasers who desire engines of this size.

There is said to be from 400,000 to 500,000 hp. in engines of the Diesel type used in Europe. There are also a number of these engines in this country, but the fuel situation in Europe is such as to necessitate the use of an engine of this type to a far greater extent than has been the case in this country. It has been repeatedly reported in this country that in engine installations of the Diesel type it has been found desirable to use a lighter grade of fuel than was originally intended. This is brought about by the fact that less trouble and less close attention are required with the lighter and higher-grade fuels. This being the case with an engine which employs extreme methods in order to burn the fuels economically and satisfactorily, how can it be at all satisfactory to handle such fuels in an engine where these methods are not employed?

In an attempt to reduce the cost of manufacture, and still satisfy the demands for an engine which will run on heavy liquid fuels, attempts have been made to depart from the Diesel principle. The first attempt was to change the compression from 500 to 300 lb. This reduction in compression means that the fuel does not burn immediately upon entering the combustion space, as the heat of compression is not sufficient, and in order to obtain the desired temperature a hot plate is projected into the cylinder.

This type retains the air system of fuel injection. A two-stage air compressor is used, which discharges at approximately 600 lb. directly through the fuel valve and against the hot plate in the cylinder. The quantity of fuel is measured in a manner similar to that of the Diesel engine. This system avoids the necessity of carrying such high injection air pressure, but there is only a partial burning of the fuel, and an explosion takes place, the initial pressure depending on various conditions, such as the timing of the fuel injection, the nature of the fuel, the temperature of the engine, the temperature of the hot plate and the compression temperature. An indicator diagram from such an engine is shown in Fig. 1.

If an engine of this type is built as heavy as it should be to withstand the high pressures, and if all other parts are properly designed and constructed, the first cost is almost as high as the Diesel.

An extreme departure from the Diesel principle is the two-stroke-cycle engine using the hot bulb, pump fuel injection, water injection, in the majority of cases crank-case compression, and light construction with a compression ranging from 70 to 150 lb., and in some cases 300 lb. In order to start this engine it is necessary first to heat the hot bulb externally, which requires ordinarily from 15 to 20 min. Sometimes difficulty with the burners necessitates a much longer time.

Two-Stroke-Cycle Principle

The main reason for the four-stroke cycle having been so universally adopted is that the scavenging of the burnt gases can be accomplished by one stroke of the main piston. This leaves the entire volume swept by the piston free for a fresh charge.

The two-stroke-cycle engine which draws the fuel into the crank case and depends upon scavenging the burnt gases by means of air is necessarily uneconomical, because it is difficult to cut off the exhaust gases at exactly the proper point and avoid all passage of the fuel through the exhaust port. However, when the fuel is injected on the compression stroke, and pure air only is drawn into the crank case, this objection is not so serious. Nevertheless, it is difficult to determine just what air currents take place inside the cylinder when it is expected that the incoming air on the one side will drive out the exhaust gases on the other, especially when both of the ports are at one end of the cylinder. Fig. 2 illustrates what probably happens in such a case.

Fuel Injection

Now, consider the fuel injection and the method of forming an explosive mixture. The conventional vaporizing type of four-stroke-cycle engine draws in a charge of air past a fuel spray nozzle at a high velocity, frequently as high as 12,000 to 15,000 ft. per min. This high velocity, together with the extremely fine spraying of the fuel, causes each particle of air to become laden with a certain amount of fuel vapor, and thus promises a very complete mixture.

On the other hand, in the engine with pump injection the combustion space is filled with a mixed charge of air and exhaust gases, with probably some irregular stratification of the exhaust gases. The fuel pump measures out a given quantity of fuel, which is sprayed into the compressed air by a hammer blow from a cam or eccentric which operates the pump. A certain mixture of fuel with the air and burnt gases takes place, but a thorough mixture of the fuel with the air does not exist (see Fig. 3). Furthermore, this mixture will vary greatly from one impulse to the next, depending upon conditions such as stratification of the charge, temperature of the hot bulb, temperature of the engine itself, nature of the fuel used, amount of fuel measured out and injected by the pump, size of the opening in the spray nozzle, condition of the spray nozzle, time in the cycle at which the fuel is injected, etc. All conditions being uniform, the results are fairly satisfactory, but there is necessarily susceptibility to these varying conditions.

These engines are ordinarily rated at a mean effective pressure of 35 to 40 lb., or about half that of a four-stroke-cycle engine of the vaporizing type at rated load. Indicator diagrams from properly designed four-stroke-cycle engines of the vaporizing type show that the mean effective pressures are practically uniform, although in some cases a pressure of 118 to 120 lb. may be indicated. Fig. 4 is a diagram from a two-stroke-cycle vaporizing engine at rated load. Mean effective pressures as high as this are extremely rare, however, and could not be depended upon. This point is brought out to show that the mean effective pressures from the two-stroke-cycle hot-bulb engines are necessarily variable. Furthermore, it is possible to obtain extremely high initial pressure if water injection is not used properly, if the fuel is injected a little too early, or if the temperature of the hot bulb is not correct. Considering that it is possible for these high pressures to exist, the engine should be built heavy to withstand them: irregular impulses mean uncertain service. Fig 5 shows these varying mean effective pressures.

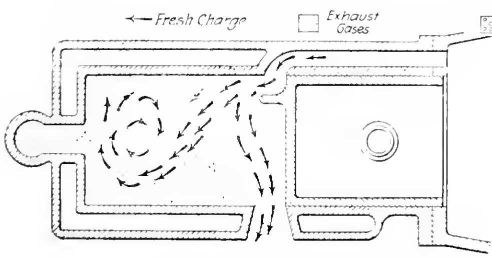

Fig. 2. Results in Two-Stroke-Cycle Exhaust-Scavenging Type of Engine

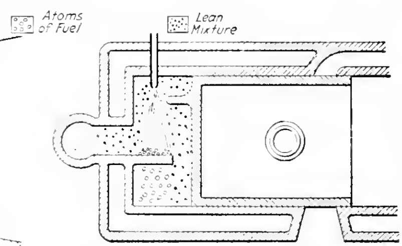

Fig. 3. Showing Small Volume of Air with Which Fuel Comes in Contact in Pump-Injection Type

Measuring the Fuel

Next consider the method of measuring the fuel. Some engines govern by changing the stroke of the pump; others through bypassing a certain amount of the fuel back to the tank. If six drops per stroke is a full load supply for a 10-hp. engine, it will readily be seen how delicate the adjustment must be to govern the speed by reducing the proportion of the six drops in accordance with the load conditions.

If the vaporizing type of engine is properly designed, the correct amount of fuel will be automatically picked up as the throttled air passes over the injection nozzle. This is so automatic that the results are dependable even under adverse conditions.

Timing of Fuel Injection

Different manufacturers commence injecting the fuel at different points in the stroke varying from the beginning of the compression stroke to about 10 deg. before the end of the compression stroke. The proper timing depends upon numerous conditions, such as compression pressure, temperature of the hot bulb, shape of the hot bulb and combustion space, location of the spray nozzle, grade of fuel, diameter of pump plunger, stroke of pump, etc.

Electric ignition is practically instantaneous, and if there is a variation of say 10 deg. in timing, the results obtained are apt to be poor. With an engine running at 300 r.p.m., 10 deg. is equivalent to 0.002 sec. This is an extremely short time for a mechanical fuel pump to act and deliver a quantity of fuel against 150 lb.

It is difficult for anyone who has not worked with them to appreciate the delicacy of these mechanical devices. If the injection of fuel takes place slightly early, in comparison with the temperature of the hot bulb, the amount of water injection, the temperature of the engine and the load, etc., excessive pressure will result.

The Hot Bulb

The mission of the hot bulb is to furnish the high temperature to assist in vaporizing heavy fuels. If its temperature becomes too high, the engine will pound heavily, due to excessive initial pressure. The hot bulb will sometimes have a tendency to crack, due to distortion, because of the unequal temperatures, and also the fuel may decompose and form deposits on the hot spoon, so as to cause cracking of the bulb. Because of this the hot bulb is occasionally the source of annoyance and irregular operation.

Water Injection

If the injection of the fuel could be accurately timed, so as to bring about the proper flame propagation, and if this fuel could be introduced into the cylinder in sufficiently large quantities in the very short time existing at the end of the compression stroke to prevent too early ignition, water injection would not be necessary. Engines that use air injection with the fuel do not use water. Water injection is the handiest means of avoiding excessive pounding and high initial pressure, provided the timing of the fuel injection and the temperature of the hot bulb, etc., are not correct. It is frequently used in large quantities, and when the quantity is too great excessive wear of the cylinder and piston will take place, due largely to interference with proper lubrication. In proper quantities it probably has some tendency to loosen the carbon, and, in accordance with a theory which has frequently been advanced, it may result in bringing about a uniting of the nascent oxygen with the carbon,

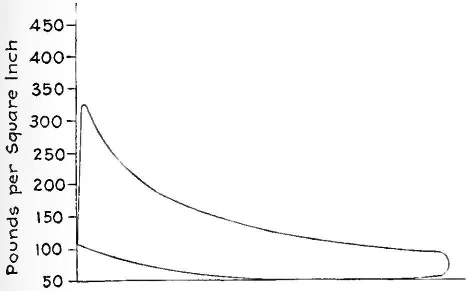

FIG. 4. DIAGRAM FROM TWO-STROKE-CYCLE VAPORIZING ENGINE AT RATED LOAD

thus keeping the cylinder slightly cleaner than would otherwise be the case.

Lubrication

Some years ago the auxiliary exhaust port in the four-stroke-cycle engine was considered good practice, and was extensively used. However, this port was later abandoned because it interfered with proper lubrication, and a dry streak through the cylinder was invariably found where these ports existed. The conditions in this respect are no different than in the two-stroke-cycle engines of today, although probably this port does not bring about so much excessive wear of the cylinder and piston as do the unburnt fuel and the water. Where crank-case compression is used, trouble with the lubrication of the main bearings is sometimes experienced.

Even with very short connecting-rods and with every available space in the crank case filled up so as to obtain as high a compression as possible, it is seldom possible to obtain a pressure in the crank case greater than 2¼ to 2½ lb. With the wear on the bearings, this pressure has a tendency to leak out and to interfere with their lubrication.

Leakage of crank-case compression also has a tendency to seriously affect the operation of the engine, as the transfer air is thereby lost and scavenging is not obtained.

This condition in conjunction with the filling up of the exhaust port with carbon, thus causing back pressure, has a tendency to equalize the pressures on both sides and interfere with proper scavenging. Incomplete scavenging means loss of power, wasted fuel, over-heated engine and premature ignition.

Compression

The compression employed by different manufacturers varies from 70 to 150 lb., some running as high as 300 lb. One manufacturer provides means of varying the compression in accordance with the fuel used and the conditions of operation. High compression should mean greater economy, but at the same time greater danger of excessive pressures. The amount of compression permissible will depend upon the temperature of the hot bulb, the temperature of the engine itself, the grade of fuel used, the method of injecting the fuel, and the time at which the fuel was injected. In consideration of these varying conditions, it is practically impossible to settle upon a satisfactory all-around compression.

Compression undoubtedly has greater influence upon economy than any other one point in connection with the design of internal-combustion engines. When the explosion engine was first attempted, no compression was used, and the engine was practically a failure on this account. Some fuels will ignite more readily than others, and, consequently, are more susceptible to heat of compression. Producer gas will stand a compression of from 150 to 160 lb., and natural gas 120 to 130 lb. without premature ignition. When liquid fuels are introduced into the cylinder of a four-stroke-cycle engine on the suction stroke, a compression of from 60 to 70 lb. is approximately all that can be obtained. Because of this low compression, an economy of less than 12,000 B.t.u. per b.hp.-hr. cannot be expected.

When high compression can be used, such as 120 lb. on natural gas, an economy of 8500 B.t.u. can be expected. This is the economy, therefore, which an engine of the pump-injection type should be able to obtain when using a compression of 150 lb. This economy is not attained, however, because the pump-injection principle is so far from perfect. In fact, it is seldom that an economy of 12,000 B.t.u. is had; the more common figure being 14,000 to 16,000 B.t.u.

Fuels

It is common for manufacturers of the hot-bulb type to state that any fuel can be handled in these engines. Most assuredly, any oil which contains heat units will vaporize when it comes in contact with a red-hot surface, and will consequently develop pressure and deliver power.

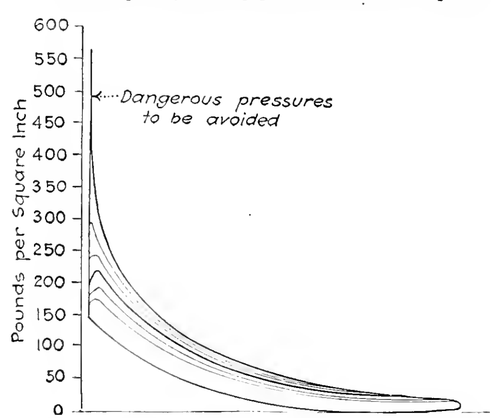

FIG. 5. DIAGRAMS FROM PUMP-INJECTION ENGINE; HEAVY LINE SHOWING EXPANSION CURVE AT RATED LOAD

This being the case, demonstrations can be made on very heavy fuels. Their continued success and satisfaction are, however, highly improbable, and in many cases lighter grades of fuel have been resorted to because less difficulty is experienced.

Can these engines operate successfully on kerosene? is a question which has been frequently asked. The majority of them do not, if they are built for operation on the heavier fuel. The flame propagation of kerosene is more rapid than with fuel oil or a heavier grade of distillate. This fact interferes with operation on either grade of fuel, as the flame propagation is dependent upon the temperature of the hot bulb, the timing of the injection of the fuel, the temperature of the cylinder walls, the amount of water injection used, and the load which the engine is called upon to handle. If these conditions are all correct for heavy fuels, they are not correct for lighter fuels, and except for a small range in variation, they are not adjustable.

It is true that all of the troubles mentioned do not exist in all installations of such engines. In fact, some of these engines operate without any of these difficulties, but they have all taken place in numerous instances, and any and all may take place in any installation.

Present State of This Type

The success achieved by heavy fuels in this type of engine is due to a peculiar combination of some of the following conditions: The high price of gasoline with the consequent desire to handle a heavier fuel; a consequent response on the part of some manufacturers to build an engine which they can claim will burn the heaviest liquid fuels; the fact that a certain vaporization of these heavier fuels takes place when brought in contact with extremely high temperatures; that there is available in some localities certain grades of heavy liquid fuels at a low price; that these engines are simple in construction and simple in appearance; that they do operate on these fuels and deliver power, and in some instances to the expressed satisfaction of the owner; and that this engine is passing through a stage at the present time when its shortcomings are being excused, and the owners are loath to admit that any difficulties are being experienced.

This attitude is due to lack of information regarding the actual causes of difficulties; consequently, there is a tendency to consider the troubles as due to improper operation or some outside influence. Excessive cylinder wear, for instance, can be laid to soft metal or to improper attention on the part of the operator; cracked bulbs and choked exhaust ports may be blamed on the operator or the fuel used; and blown-off cylinder heads or cracked beds may be attributed to insufficient water injection or possibly defective material.

Proper Fuels

Specific gravity indicates little as to the vaporizing qualities of a fuel, although the majority of fuels above 38 to 39 deg. gravity vaporize readily and the majority below 35 or 36 deg. gravity do not vaporize readily. The flash point also tells little, as fuels with a heavy body may contain sufficient lighter constituents to show a flash at a low temperature. A definite indication of the quality, however, is the boiling point, or the temperature at which different percentages of the fuel will distill.

Vaporizing Type of Engine

Another reason why the heavy-oil engine has been brought into favor is the numerous published statements that the so-called gasoline engine is not adapted to handling kerosene and the lighter distillates successfully. While this has unfortunately been proven in some cases, yet in others the application of lighter distillates to the four-stroke-cycle vaporizing type has been successful.

There are many features in connection with the proper design of the vaporizing type for handling the lighter grades of distillate and kerosene. There seems to be a mistaken impression that the carburetor is the essential feature. While the carburetor should be properly designed there are other governing features equally important, such as piston speed, ratio of the stroke to bore, method of water circulation, location of the valves, shape of combustion space, location of igniter in combustion space, valve timing, voltage of ignition current, velocities through valves and intake passages, location of carburetor in relation to the inlet valve, contour of passages, governor valve and governor, method of automatically handling the mixture with varying loads, complete mechanical vaporization without resorting to preheating the charge, etc.

Engines Below 15 Horsepower

A large number of these small engines are used for farm work. They are usually of the four-stroke-cycle vaporizing type, using either gasoline or kerosene. The farmer should not attempt to use anything heavier than kerosene for this purpose. He should have an engine which is easily started, easily handled, and sure to run on a fuel which is readily obtained in small quantities.

It is doubtful if there is any other manufactured article which will vary to such a degree after it is assembled as will the gasoline engine. Pistons, piston rings and cylinders which are subjected to high temperatures and irregular distortion must be worn in together. Springs must be adjusted to the proper tension. Governors must be put in proper operating condition. Valve timing should be properly adjusted. Bearings should be worn in to avoid the possibility of their running hot. Brake tests should be made showing the engine developing its full rated horsepower. Water tests should be made of jacketed castings, as frequently leaks will develop after the engine has been in operation for some time. Moreover, the ignition system should be timed properly and checked up carefully. Considerable cost to the manufacturer can be saved by neglecting these matters, but the farmer should insist that the manufacturer produce an inspection sheet covering the detailed inspection and testing of the engine.

Conclusions

For many years after the internal-combustion engine came into general use, there was a current opinion that the engines were unreliable and tricky. This was brought about to a considerable extent by placing on the market a large number of engines which were not scientifically designed nor fully developed. It has taken many years of consistent effort to live down this prejudice.

We are now facing to a considerable extent a similar condition, because of the attempts to use heavy liquid fuels with a type of engine of cheap construction, such as has been heretofore described. Quite a large number of comparatively small manufacturers are experimenting with this proposition, with the result that undeveloped engines have been and are being placed on the market.

This type may in time achieve the results which it now claims, but in the meantime its failures should not be permitted to influence the industry as a whole. This can be accomplished best by a greater education of the public regarding the merits and demerits of the different types of engines, the different grades of fuel, and the purposes for which they can be used to the best advantage.

Small Marine Power Plant

By D. L. Roger

A small power plant, of interest because of its unique design and its economy in steam consumption, is shown in Figs. 1 and 2. This plant was installed in a 22-ft. launch and consists of a vertical boiler, vertical fore-and-aft compound engine and all necessary auxiliaries.

The engine has 3&6x4-in. cylinders and runs at a speed of 400 to 600 r.p.m. The boiler feed pump, air pump and fuel pump are driven by a drag crank and 2-to-1 gears from the forward end of the main shaft. The link on the low-pressure valve-gear is provided with an adjustment by which the receiver pressure is regulated. A reheater of U-shaped tubes connects the two cylinders.

The boiler is mounted aft of the engine. It is 12 in. high by 18 in. diameter and contains 426 half-inch tubes. The safety valve is set to blow at 200 lb. pressure. Kerosene is used as fuel in a special burner connected to a tank on which 70 lb. pressure is carried. The breeching carries the products of combustion through a superheater mounted on top of the boiler, around the high-pressure cylinder, through the reheater, around the low-pressure cylinder and to the atmosphere through a small stack mounted on the low-pressure cylinder.

Several tests have been made on the plant under working conditions on Lake Mendota, Wis. Numerous indicator diagrams have been taken of both cylinders and these show a steam distribution which is almost perfect. The engine consumes slightly less than 13 lb. of steam per brake horsepower-hour. The boiler, cylinders and

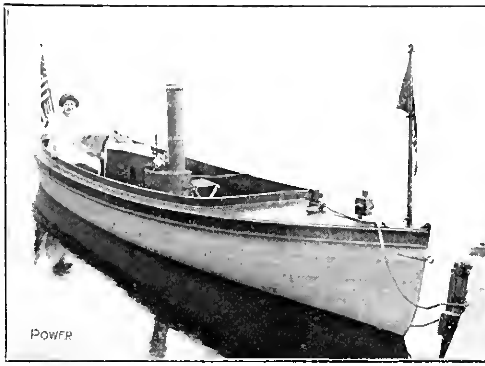

Fig. 2. Power Plant in Launch

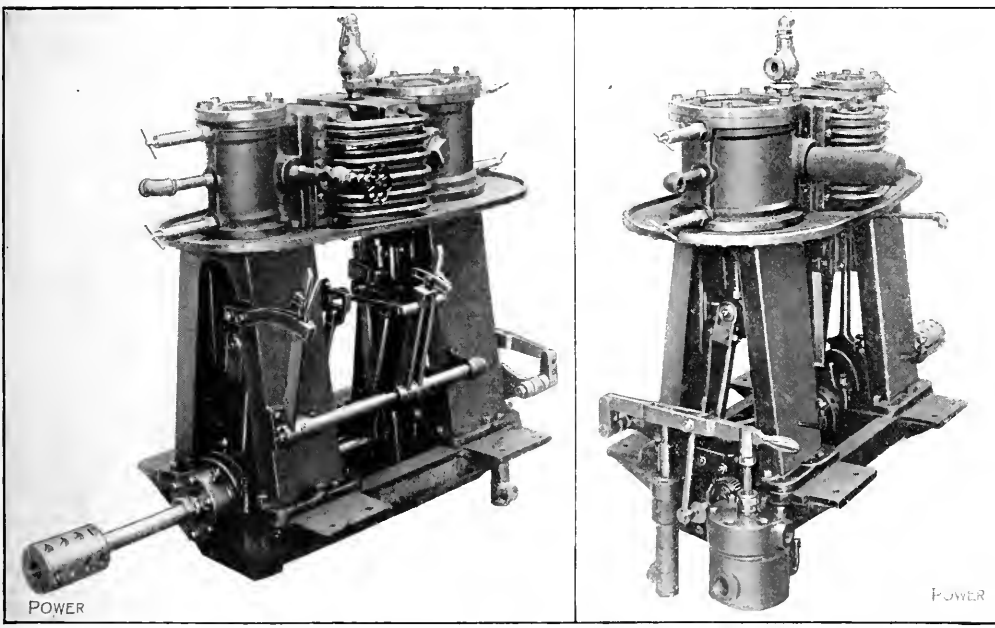

Fig. 1. Front and Rear of Compound Marine Engine

The steam from the boiler passes through a superheater, is expanded in the high-pressure cylinder, and is exhausted through the reheater to the low-pressure cylinder. After expanding in the low-pressure cylinder it exhausts into a keel condenser. The condensed water feeds the boiler. A filter is used through which the water is passed from the condenser overflow to the boiler-feed pump. The makeup water is also filtered.

breeching are so well insulated that it is possible to place the bare hand on any of these parts without discomfort. The gases escaping from the stack are exceptionally low in temperature.

J. C. White, chief engineer of the Capitol Power & Heat Co., Madison, Wis., designed and built this plant for his own pleasure. He started the work in 1909; the completed boat was put into the water in 1911.

Steam-Turbine Installation in Mexico

By John Klemm

For many years the Compañia Minera "Las Dos Estrellas" S. A., El Oro, Estado de Mexico, Mexico, has been purchasing its power from a public-service corporation. The slipping of one side of its greatest dam a few years ago seriously affected the power company for a time and caused heavy losses to innumerable customers. This company, being one of the several large consumers, in consequence installed a Westinghouse-Parsons multiple-expansion parallel-flow 1500-kw. steam turbine to generate three-phase current at 50 cycles and 3000 volts as a stand-by.

This turbine has a somewhat peculiar history. About two miles from the plant, in the center of a large masonry bridge, the trucks on one end of the car carrying the turbine broke down, precipitating the turbine to the river bed below, some 30 ft. Evidently, it did not wish to be installed at an 8000-ft. elevation. The machine was picked up uninjured except for a few paint scratches, and was installed and operated according to its specifications.

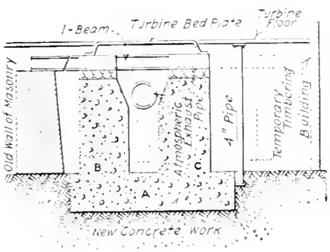

Fig. 1. Replacing a Turbine Foundation

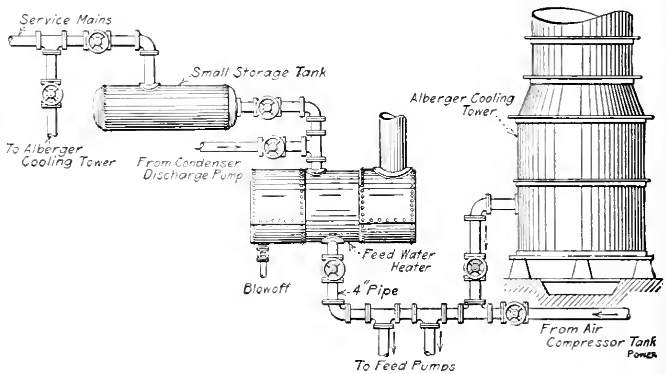

Fig. 2. Old Boiler Used as a Feed-Water Heater

Shortly after, the turbine wrecked itself so completely that an entire new spindle had to be purchased. Failure to start the auxiliary oil pump, unintelligent operation and weak masonry foundations, causing severe vibrations, were the causes, and conditions were made worse because of a 200-hp. compressor, operating on practically the same floor and foundation, whose vibrations caused a harmonic with the turbine vibrations. Another fault was that the I-beams were set directly on the masonry wall instead of being placed on some sort of material to distribute the weight; the I-beams thus sank into the masonry, and the machine, instead of resting on the entire length of the foundation wall, was practically where the I-beams had sunk.

At the time of the wreck, when the top half of the cylinder was raised someone remarked: "*Que buena ensalada*" ("What a fine salad"), adding the opinion that the most inefficient Corliss engine is far better than the most efficient steam turbine ever designed. This is a narrow-minded and prejudiced view, obviously untrue. The steam turbine has already proved its value, otherwise 30,000-kw. units would not be designed and operated, as they are today. Where intelligent and attentive labor is employed, there should be no chance for a steam turbine to wreck itself so completely as to require a new spindle. The turbine is not a very complicated piece of machinery; nevertheless, like any high-class apparatus it is not intended to stand abuse.

In this instance, to avoid further trouble it was decided to build a new foundation of concrete of the proportion 1 to 3 to 5, directly under the turbine, and do away with the masonry foundations, so designing the new work that the turbine would have absolutely no connection with the building or other apparatus, except the condenser, etc. The change was made with some difficulty, inasmuch as the machine had to be kept ready for immediate use in case of emergency.

From Fig. 1 an idea can be had of the conditions. The dotted lines show the temporary timbering. The space directly beneath the turbine, between the old masonry walls, was dug up and the concrete footing *A* laid. Wall *B* was built up to 5 in. below the 15-in. I-beam shown, and 12x12-in. and 8x8-in. timbering was placed between the new wall *B* and the old wall at *C*. This green timber was kept wet to prevent it from shrinking, so that the weight of the turbine could not come on the condenser. The old wall at *C* was then removed, a new concrete footing laid and the wall *C* built up and steamed to crystallize the cement, which was done in about 60 hr., thus avoiding the slow 28-day process.

For the steaming ½-in. pipe, previously drilled with ⅛-in. holes about 6 in. apart, was laid all around the bottom of the wall; the entire wall was then well covered with a heavy canvas and the steam turned on. At the beginning the temperature was held below 35 deg. C., then gradually increased to 70 deg. C., at which it was maintained for the last 12 hr. Great care must be taken not to overheat the concrete and thus ruin the entire work, especially if it is reinforced, as the coefficients of expansion for iron and concrete are different. The steam pressure never exceeded 1.5 atmospheres, and with this it was found that the best work was done on the top of the wall. After the steaming the electrical end was dried out before being placed in service, to avoid danger of a burnout.

Full-length 40-lb. steel rails were then placed on the new walls *B* and *C*, Fig. 1, and 1-in. plates and steel wedges set tight against the 15-in. I-beams on which rested the turbine bedplate. These rails served to distribute the weight of the machine over the entire length of the walls. All spaces between and around the rails and I-beams were then filled in with concrete to the level of the bedplate, making of the whole almost a solid box-like construction with the opening in the center. It may be criticized as inconsistent with uptodate construction not to allow more space below the unit, but this could not well be avoided, under the existing conditions; moreover, the space was sufficient, as all high-speed machines, especially turbo-generators, have artificial ventilation, cold air being blown into the windings. Without this precaution the air in the machine while it is running would be churned and would seriously affect the temperature rise.

The timbering was finally removed and the I-beams, one end of each of which was still in the old wall, were cut in a diagonal direction, as shown by Fig. 1, so that in settling, the I-beams could not again make contact with the old work, the tendency being to settle away.

An additional installation of three 400-hp. Babcock & Wilcox water-tube boilers brought the total boiler capacity up to 2400 hp. This addition may seem unnecessary, and, hence, a useless expenditure, but steam is always required for purposes other than power generation, and it is desirable to have ample margin for cleaning, etc. Further, it does away with the need for induced or forced draft and attendant loss of heat up the chimney, the extra cost of the apparatus and the disadvantages of boilers.

There are no peaks to consider; the load is steady throughout the 24 hr. The lighting load at night is hardly perceptible. The boiler feed water is taken almost directly from the condenser, a 4-in. pipe being tapped into the 12-in. discharge pipe of the circulating condenser pump (see Fig. 2). This 4-in. pipe discharges into an old fire-tube boiler used as a heater, and the water is then brought up to 90 deg. C. from the heater. It flows by gravity to the feed pumps, of which there are two Worthington 10x6x10-in. The pumps are also connected to the Alberger cooling tower and a tank, which is used to cool a 200-hp. Ingersoll-Rand compressor, so when the turbine is not in operation the boilers still get warm water. Steam is required for other purposes for 24 hr. daily, and is held for emergency. The heater is also connected to the company's service mains through a small storage tank above the heater, as Fig. 2 shows.

There are two wrought-iron expansion joints in the 8-in. steam header line, one U between what are known as No. 4 and No. 5 boilers, and a 90-deg. elbow between No. 1 boiler and the turbine. These suffice to take up any expansion in the header.

American fuel shipped to these regions comes high, costing on an average about $24.50, Mexican currency, per ton of 1000 kg. (2205 lb.) on the plant grounds.

The generator room is 39 ft. 8 in. by 89 ft., and is constructed of masonry. The doors and windows have a brick facing, presenting a neat and attractive appearance. The boiler room is 39 ft. 8 in. by 92 ft., and is constructed of the same class of material.

Coal Storage Tests—In his annual report as Chief of the Bureau of Steam Engineering, Admiral R. S. Griffin says: "The coal stored at New London under the three different conditions, in the open, under cover, and under water, was given the third annual evaporative test. No marked difference in evaporative efficiency was shown between the coal stored under different conditions, and no conclusive evidence developed as to the best method of storing coal."

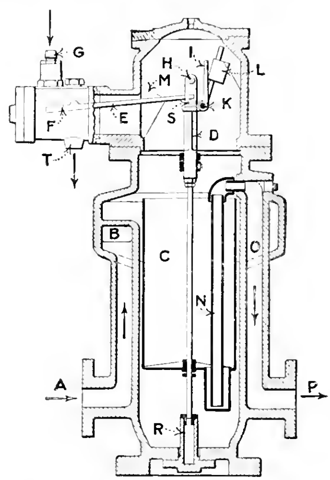
New Return Steam Trap

This trap is of the closed type, with the moving parts arranged inside the apparatus. It operates automatically when sufficient condensate has accumulated to move the float. It has few moving parts; therefore friction and wear are reduced to a minimum, and there are no stuffing-boxes.

The trap is made with a cast-iron body, brass inside parts and an open copper float. It is built for working pressures up to 180 lb. For higher pressures the body is made of steel.

In operation the condensate enters the trap at *A* and flows through opening *B* into the body. The water level inside of the apparatus rises until it reaches the top of the open float *C*, which is shown in its highest position. The float fills, loses its buoyancy and starts to sink, carrying with it the stem *D*, which pulls down on lever *E*. This lever, turning on the center *F*, opens the steam valve *G*.

As the float continues to sink, the roller *H* comes in contact with the short arm of the lever *I*, which, turning



Section through Return Steam Trap

about the center *K*, throws the attached counterweight *L* over to the left until the long arm of the lever presses on the roller *H*. The weight, falling over to *M*, will cause the roller, which is already in contact with the steam-valve lever *E*, to drop quickly. This gives a sudden increase in the opening of the steam valve, and the full pressure of the steam acts on the water in the trap, discharging it through the pipe *N*, the chamber *O* and the outlet *P*. A dashpot *R* takes up the shock caused by the counterweight falling on *M*.

A check valve on the inlet *A* prevents water from entering the intake pipes, and another in the discharge line prevents the return of the discharged water.

The empty float rising, throws the counterweight back to its original position and releases the lever *E*, allowing the steam valve to close. As the float continues to rise, the roller *S* lifts the lever *E* and opens the valve *T*, thus relieving the pressure in the trap. The steam which flows through this valve is received in a tank and condensed.

This trap is manufactured by the General Condenser Co., 1240 North 12th St., Philadelphia, Penn.

Why Direct-Current Motors Fail to Start—I

By F. A. Annett

SYNOPSIS—Directions for systematically locating the trouble, should a motor fail to start when the starting-box handle is thrown over.

When locating trouble in a motor, it is essential that certain features be given first consideration. Assume a case where the motor fails to start because of a blown fuse (f', Fig. 1). The first thing to ascertain in all such cases would be if the line is alive. This can be determined by connecting a lamp or voltmeter as at L. f', which may be removed and again tested, to make sure that a mistake has not been made in the test. This can be done as indicated in Fig. 3. If the fuse is blown, the lamp will not light.

If link fuses are used, the fact that they look good should not be taken as final, for a fuse may be broken off close to one of the terminals, and although it may look good on inspection, it is nevertheless open. Another point that should not be overlooked is the switch. One of the clips may be worn or sprung just enough to prevent it from touching the blade. Therefore, if the fuses

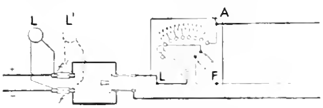


FIG. 1

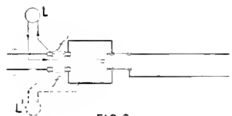

FIG 2

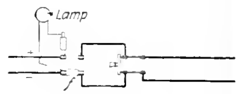

FIG. 3

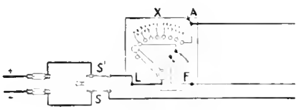

FIG 4

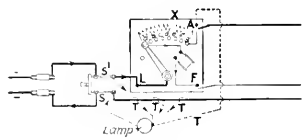

FIG. 5.

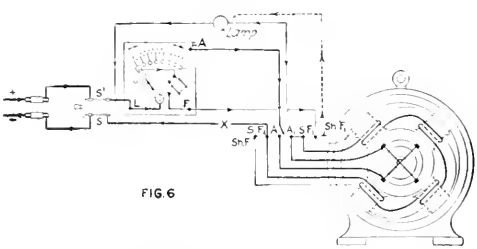

FIG. 6

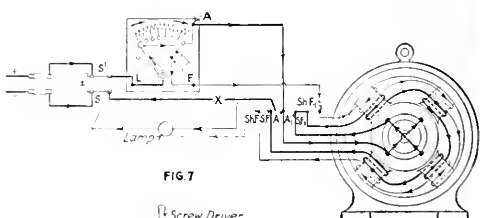

FIG. 7

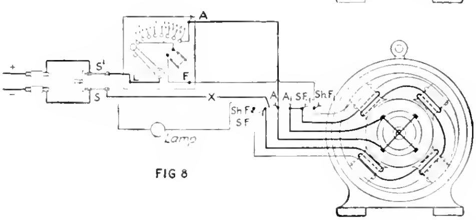

FIG 8

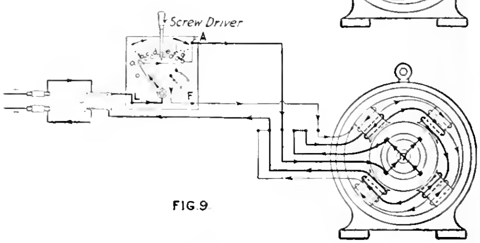

FIG. 9

How to Locate the Fault When the Motor Will Not Start

If the lamp lights, next test below the fuses as at L'. In this case it will not light, for the fuse f' is blown.

Most inclosed fuses indicate when they are blown, but this cannot always be relied upon, and when locating trouble the best policy is to depend upon nothing but what has been determined by test. To test the fuses without removing them, connect the lamp as illustrated in Fig. 2. If the lamp is connected as at L, it will light, indicating that fuse f is not defective. When connected as at L', it will not light, for the circuit is open in fuse test good, do not neglect to test the switch and see that the clips are making good contact and that none of the connecting wires are broken at the switch terminals.

If the break is in some part of the circuit other than the fuse, such as at X in the starting resistance, Fig. 4, an indication that the circuit is alive will be given when the starting arm is brought up to the first or second contact and allowed to drop back to the off position; that is, a spark will occur when the field circuit is opened.

If the motor does not start on the first or second contact point, bring the arm back to the off position and look for the cause. If it is loaded, first determine whether the load is free so that it can be started; also, that the motor bearings are not set on the armature shaft or worn so as to allow the armature to rub against the polepieces. The writer recalls an instance in which he was called in to repair a pump motor that another electrician had been working on all day, trying to get it to run. Upon attempting to turn the pump over by hand, it would not move, and the cause was traced to freezing of the pipe line running to the roof tank. There was nothing wrong with the motor or controller except what was caused by the ordeal they had been put through during the day.

After it has been determined that everything is favorable for the motor to run, the next thing is to make an inspection of all the electrical connections to see that they are tight and making good contact and that none of the wires are broken off at the connections; for sometimes a wire breaks off and will open only enough to interrupt the circuit, and unless it is moved it cannot be detected. If lugs are used on the wires, see that they are properly soldered, for if this has not been thoroughly done the wire will corrode in the connection and may cause an open circuit. All this is a hard and fast rule which may be applied to any motor whether direct- or alternating-current. Furthermore, it is well to make sure that the brushes are making good contact on the commutator and are free in the brush-holder pockets.

If the foregoing has failed to disclose the reason for the motor not starting, next test for purely electrical troubles. In this connection, first test the starting device. Fig. 5 shows a convenient way of doing this. Disconnect the armature and field connections on the starting-box and place the arm on the first contact, as shown. Then connect one lead of the test lamp to the switch terminal S (the one connecting directly to the motor), and to make sure that everything is in condition to make the test, connect the other lead T of the lamp to the other switch terminal S'. If the proper indication is had, next connect lead T to the "L" (line) connection on the starting-box. If the lamp continues to light, connect lead T to terminals A and F, as indicated, which in the present case will show a complete circuit through the starting-box to the terminal F, as indicated by the arrowheads, but not to terminal A, for the resistance is open at X. That is, when connected to F the lamp will light, but not when connected to A.

The exact location of the fault can be easily determined by testing to the contacts on the resistance. If lead T of the lamp is connected to contacts e, f or g, which are to the right of the break in the resistance, the lamp will not light, but when connected to d it will light. Since the lamp lights at d and not at e, it indicates that the circuit is open between these contacts.

A quick way to repair this fault is to drive a piece of fuse wire in between the contacts on the front of the slate between which the fault is located. A better and more permanent way is to remove the cover from the starting-box and repair the break in the resistance coil. If this cannot be located, as in some cases the coils are molded into a compound, the two contacts can be connected together on the back of the slate with a piece of wire.

In Fig. 6, X shows a break in the wire which connects the series and shunt fields direct to the switch. If the tests previously described are made and the circuit through the starting-box has been found complete, the next step will be to disconnect the two connecting wires between the motor and the starting-box, at the machine, and test through them as indicated. This will show a closed circuit, as represented by the arrowheads. Next connect the armature and field wires to their respective terminals and test through the armature and field coils, as in Fig. 7, and if they are not defective the lamps should light.

There is but one thing left to test and that is the connecting wire from the switch to the series and shunt field connections. To do this, connect one lead of the lamp to the switch terminal S' and the other to the end of the wire at the motor, as indicated in Fig. 8. In this case it will not light, which indicates that the circuit is open between the switch and the other end of the wire. The defect may then be definitely located and repaired, or the wire replaced by a new conductor. If the wires are in conduit or molding, the defective one should be replaced by a new wire, for a spliced wire in molding or conduit is a violation of the Board of Fire Underwriters' rules.

A practical way of testing for an open circuit in the starting resistance is illustrated in Fig. 9. Close the switch and bring the starting-box arm upon the first contact, and then bridge between the contact buttons with a piece of metal; a screwdriver being convenient for this purpose. If the break is in the starting resistance, such as between d and e, the motor will start when the defect is remedied; then the switch may be opened and the fault repaired, as previously explained.

An open circuit in the series field may be located as described in "Testing for Open Circuits in Field Coils," (POWER, Aug. 4, 1914).

Portable Boiler Exploded

This old boiler which the owner had recently purchased was being given a "tryout" on a wood saw. The engineer said the engine ran "snappy" with the throttle valve two

ENGINE'S POSITION AFTER EXPLOSION

turns open, which is taken as indicating that there was an excessively high pressure in the boiler, although the steam gage showed only 80 lb. and the safety valve was set, by the same gage, to blow at 100 lb.

The failure occurred at the bottom of the firebox, of the water-bottom type, where there was a section approximately 26 by 30 in. without stay-bolts. This section was forced upward, throwing the grate bars out through the fire-door. One section in its flight struck a dinner pail carried by a schoolboy, who was passing at a distance of about 200 ft., tearing it from the bail. The force of the explosion impelled the engine forward, nearly overturning it on the woodpile, as shown in the illustration. Two men were slightly injured.

Waste-Heat Boilers*

By Osborn Monnett†

SYNOPSIS—Smoke prevention in typical metallurgical furnaces operated in connection with waste-heat boilers. The latter are provided with independent furnaces.

Quite frequently the hot gases from metallurgical furnaces are available for steam making. When boilers are combined with such furnaces it is sometimes desirable to so arrange them that they may be fired by hand when the furnace is down. In this case provision for smokeless operation can be made by installing one of the hand-fired furnaces shown in previous articles. Care must be exercised in selecting a furnace adaptable to the particular type of boiler being used.

A typical installation is shown in Fig. 1. This boiler receives the waste gases from a billet-heating furnace, the gases coming through the perforated side walls of the setting. When this furnace is not in use the boiler can be fired by hand in the usual manner. As shown, the setting consists of a standard tile-roof furnace, with deflection arch, siphon steam jets and panel doors. Many metallurgical furnaces have underground breechings and it is generally simple to lead the gases to the boiler.

The underfeed type of stoker is especially adapted for the smokeless operation of metallurgical furnaces because it does not depend on natural draft for its air supply.

†Smoke inspector, City of Chicago.

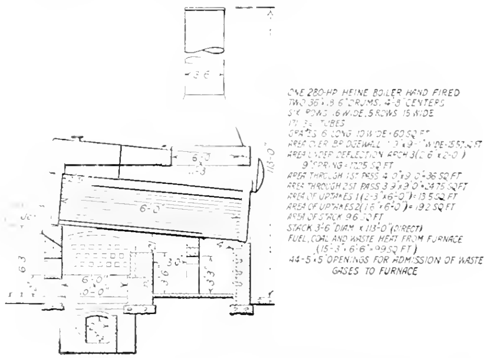

Fig. 1. Typical Waste-Heat Boiler Setting with Auxiliary Hand-Fired Furnace

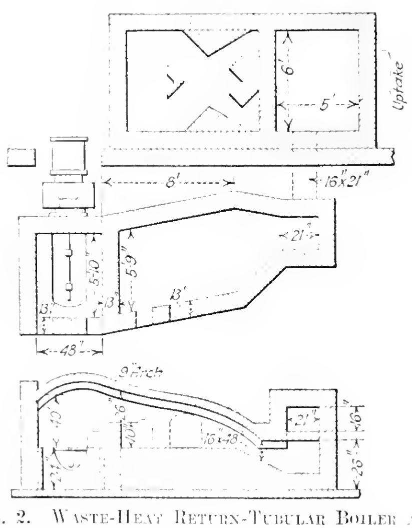

Fig. 2. Waste-Heat Return-Tubular Boiler and Forging Furnace with Underfeed Stoker

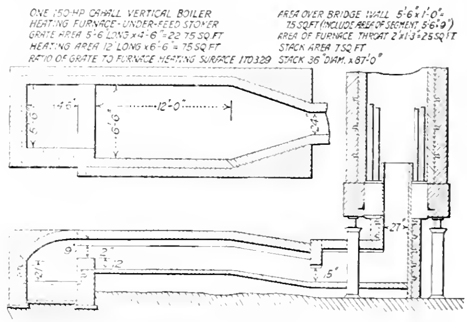

Fig. 3. American Underfeed Stoker and Heating Furnace Connected to 150-Hp. Cahall Vertical Waste-Heat Boiler

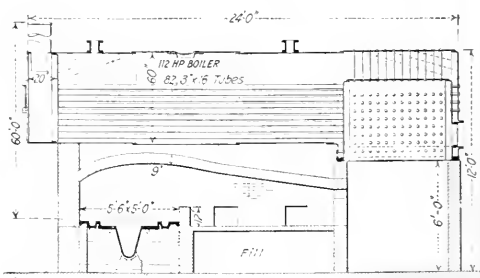

Fig. 4. American Underfeed Stoker and Forging Furnace with 112-Hp. Firebox Boiler

Owing to the length of the gas passes and number of turns, etc., there is generally but little suction over the fire from natural draft. Any stoker depending on natural draft and an ignition arch is at a big disadvantage from the standpoint of maintenance and capacity. An underfeed stoker will operate satisfactorily under conditions where a natural-draft stoker would burn up from the heat bottled in the furnace.

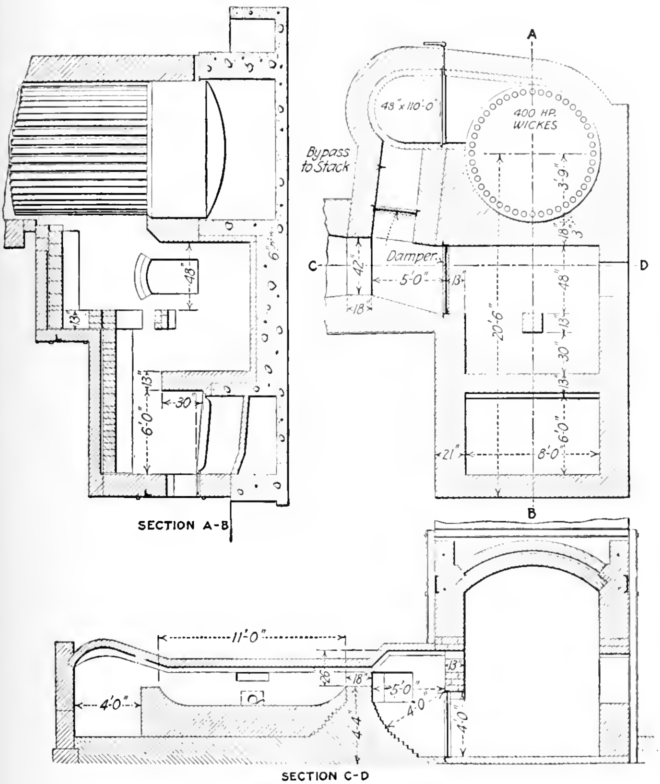

Fig. 5. Jones Underfeed Stoker and Malleable-Iron Melting Furnace with 400-Hp. Wickes Waste-Heat Boiler

Fig. 2 shows a waste-heat boiler of the horizontal return-tubular type installed in connection with a reheating furnace having an underfeed stoker. The boiler itself is equipped for hand firing, an ordinary No. 8 furnace containing a pier and wing walls being installed behind the bridge-wall. The usual rules for furnace areas based on the grate surface are allowed. If the boiler is to be used much, independently of the waste-heat furnace, the same stack height required by an independent boiler should be provided.

Another combination of metallurgical furnace and waste-heat boiler is shown in Fig. 3. In this case the ratio of grate to metallurgical heating surface is given as 1 to 3.29. The gases pass up through the lower drum of a specially constructed Cahall vertical boiler. Obviously, the proportions of the furnace depend on the product to be heated, so that the design must be varied to suit the conditions. The accompanying illustrations merely indicate how the different combinations can be operated without smoke.

Forging furnaces are often connected to waste-heat boilers, as the steam raised by the boilers can be used to advantage in the steam hammers, the same fuel sufficing for all operations in the shop. Fig. 4 shows an interesting and compact installation of this kind, consisting of a 112-hp. firebox boiler over a forging furnace fitted with an underfeed stoker.

When hand fired, the malleable-iron melting furnace produces a great deal of smoke. The underfeed stoker can be applied to this furnace with advantage and the waste heat used for steam making, as shown in Fig. 5. The latter consists of a 100-hp. Wickes waste-heat water-tube boiler attached to a melting furnace using an underfeed stoker and having an auxiliary hand-fired furnace for emergency purposes. With a bypass to the stack the melting furnace can be operated when the boiler is down for cleaning or repairs. Also, the furnace can be cut off from the boiler and the latter operated independently by closing the firebrick curtain-wall or damper, as indicated in the drawing. This makes a flexible combination. Another forging furnace with a Jones self-cleaning underfeed stoker is shown in Fig. 6, attached to a Wickes waste-heat boiler.

⁂

Belt-Driven Coal Crushers—The Edison Electric Illuminating Co., Brooklyn, N. Y., has found it advantageous to sacrifice plant efficiency obtained by using steam engines and to use motor drive with belt transmission for driving its coal crushers, as an obstruction in the crusher will either throw the belt or open the motor circuit-breaker instead of breaking parts of the crusher. Car couplings and pieces of steel frequently passed into the crusher with the coal, which stopped the rolls and the engine with a shock, thus subjecting the parts to excessive stresses. With belt drive the crusher and motor are protected against injury.

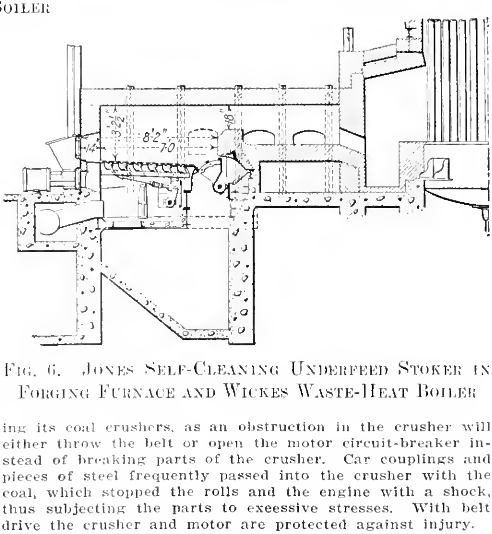

Fig. 6. Jones Self-Cleaning Underfeed Stoker in Forging Furnace and Wickes Waste-Heat Boiler

Selecting a Pump for General Service

By Charles L. Hubbard

SYNOPSIS—The article takes up briefly some of the more important points to be considered in the selection of a pump for general service in connection with power and industrial plants.

When the water is taken from the public mains or flows to the plant by gravity, the problem is simple and usually involves only the proportioning of pipes to the pressure and volume required. When the power house is at a higher elevation than the source of supply, the water must be pumped. If the conditions are such that the friction head in the suction pipe, plus the elevation, does not exceed fifteen to eighteen feet, the pumping equipment may be placed in the power house; otherwise, it must be located at some intermediate point where this limit will not be exceeded. Direct-acting steam pumps, engine- and turbine-driven plunger pumps and centrifugal pumps are adapted to the first of these conditions, and also to the last when the distance is not so great as to make the carrying of steam from the power house both expensive and wasteful. When the distance exceeds a certain limit it is usually better to drive the pump by an electric motor or gasoline engine than to install and care for a special boiler.

When the water is taken from a river, and the grades are suitable, a hydraulic ram may be employed where there is an abundance of water. This device is made in a large number of sizes and requires practically no attention, as the only parts subject to wear are the rubber valve-disks. With artesian wells there are two methods in common use for pumping the water. In the first, each well is equipped with a lift-pump driven by steam, electricity or gasoline, and connected with a common main leading to the power house. The second method makes use of the "air lift" and is especially adapted to cases where it is desirable to increase the flow and to plants using a series of wells, as one compressing outfit in the power house may be made to do the entire work.

Direct-Acting Steam Pump

This type is made in a variety of forms and sizes and is widely used for power-plant work. Piston pumps are adapted to locations where the water is free from grit or other substances likely to destroy the packing. When these are present, the plunger pump is preferable on account of the ease with which the worn parts may be repacked or renewed. One of the chief disadvantages of the direct-acting pump is its excessive steam consumption as compared with an engine or turbine, but this is offset in many cases by the low cost of installation, convenience and ease with which the speed may be regulated to meet varying requirements. Pumps of this type are made single, duplex, simple and compound, according to requirements.

Direct-acting pumps have an average mechanical efficiency of 65 to 75 per cent. and a "slippage" of 15 to 20 per cent. under ordinary conditions of adjustment. The steam consumption of small and medium duplex pumps will run from 80 to 160 lb. per developed horsepower, per hour, according to the size. By compounding, this may be reduced from 40 to 50 per cent. Pumps of this type are operated at a comparatively low speed, although the steam consumption per unit of work decreases as the speed increases. For large sizes the piston speed is usually limited to 100 ft. per minute, but for strokes of less than twelve or fourteen inches, the piston speed should be reduced proportionately. Pumps which are to run continuously should be designed to operate at about one-half the maximum allowable speed noted above.

Power Pumps

Power or geared pumps are used for practically the same purposes as the steam pumps just mentioned, but they are more economical to operate as they may be driven by an engine, turbine or motor. When belted to line shafting or driven by prime movers requiring a constant speed, they are not so desirable as the steam pump, owing to the difficulty of regulation. When used for supplying tanks and reservoirs or other purposes where they may be

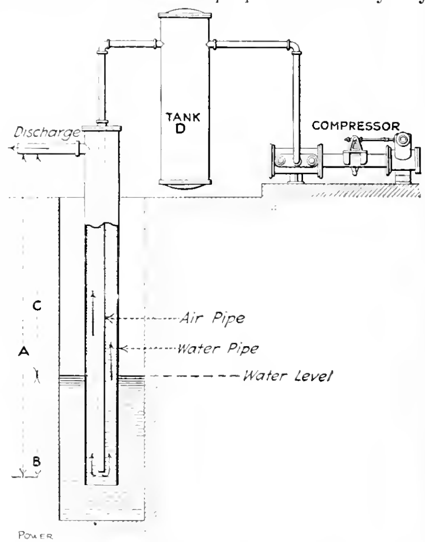

Fig. 1. Showing Principle of Air Lift

run at constant speed for long periods, they give satisfactory results and are supplanting the steam pump in many lines of service.

The efficiency of the triplex pump may be taken as about 60 per cent. for total heads of 100 ft., 70 per cent. for 200 ft., and 80 per cent. for 300 ft. The slippage is usually from 15 to 20 per cent.

Centrifugal Pumps

Pumps of this type have come into general use with the advent of the electric motor and the steam turbine. These are of two general forms, the "volute" and the "turbine," varying chiefly with the interior construction of the casing.

The volute pump is usually single-stage, and limited to heads of 100 to 120 ft., although two-stage machines are constructed for much higher pressures. Turbine pumps are designed for high lifts and are usually compounded in order to reduce the peripheral velocity and thus reduce the friction. It is important when using a centrifugal pump of any type to select one designed for the conditions under which it is to operate.

The efficiency of centrifugal pumps commonly runs from 60 to 80 per cent. for the better types, working under the conditions for which they were designed. The slippage varies from about 20 to 60 per cent., according to size and construction.

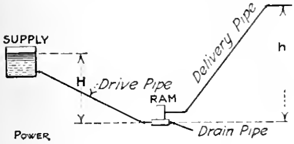

FIG. 2.

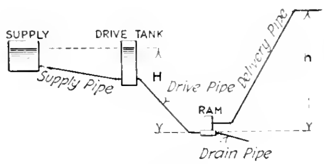

FIG. 3.

METHODS OF CONNECTING HYDRAULIC RAMS

Among the advantages of this pump are simplicity and compactness, absence of valves, low cost, uniform delivery and high rotative speed, adapting it to direct connection with motors and turbines. On the other hand, it is not possible to obtain as high an efficiency as with the best designs of piston pumps when the latter are kept in first-class condition. Furthermore, the speed cannot be varied, except within narrow limits, without loss of efficiency.

DEEP-WELL PUMPS

Deep wells are of two kinds—open wells having a large diameter, and driven or artesian wells. The type of equipment required in the first case consists of one or more pump cylinders placed within eighteen or twenty feet of the surface of the water and connected with some form of pump head at the top of the well by means of a long rod. The water is raised to the cylinder by suction and is then lifted or forced from this point to the surface of the ground.

With an artesian well an outer tube is driven to the required depth, extending to the surface of the ground. Inside of this, submerged in the water near the bottom, is the "barrel" containing the pump bucket and foot valve. The bucket or plunger is connected with a pump head at the top of the well by means of a wooden sucker rod, this material being used in order to reduce the weight. Pumps of this kind may be operated by a direct-acting steam cylinder or by a geared electric motor or a gasoline engine.

Deep-well pumps have an efficiency of 40 to 50 per cent. and a slippage of 10 to 15 per cent.

AIR LIFT

The principle of the air lift is shown in Fig. 1. A water pipe is carried down to the required depth, together with an air pipe either on the outside or the inside, as convenient. Compressed air is forced into the water pipe near the bottom, thus decreasing the density of the water within it, due to the air bubbles, and an upward flow is produced by the difference in weight between the column of solid water and the mixture of air and water. Air under sufficient pressure for raising the water is furnished by a compressor in the power house, the air pipe following the line of the water pipe.

The tank D is for equalizing the pressure and reducing the pulsation between the strokes. The distance B is called the "submergence," C the lift, and A the total head. In practical work the submergence is expressed as a percentage of the total head. For example, if A and B are 250 and 150 ft., respectively, the submergence is

$$\frac{150}{250} = 0.60$$

or 60 per cent. The efficiency of an air lift increases with the percentage of submergence and commonly runs from about 30 per cent. for

$$\frac{B}{A} = 0.5$$

up to 50 per cent. for

$$\frac{B}{A} = 0.8$$

A ratio of about 1 to 6 between the areas of the air and water pipes gives the best results for average conditions. If the air pipe is too large, power will be wasted in a high water velocity, and if too small, the air bubbles will not expand sufficiently to fill the discharge pipe, but will rise through the water without lifting it.

HYDRAULIC RAM

This offers the cheapest means of pumping where there is a sufficient supply of water and suitable grades.

Two general methods of connecting a hydraulic ram are shown in Figs. 2 and 3. If the drive pipe is too long, the excessive friction will interfere with the proper action of the ram, and if too short, water will be forced back into the drive tank. In practice it is customary to make the length of drive pipe equal approximately to the lift (h) to the tank or reservoir. When it is necessary, for any reason, to locate the ram at a greater distance from the source of supply, the required length of drive pipe can be secured by introducing a standpipe or intermediate drive tank nearer the ram, as shown in Fig. 3. For large quantities of water the fall from the source to the ram should not be less than two feet and, unless special provisions are made, should not in general exceed twelve or fifteen feet, owing to the shock when the flow is suddenly checked in the drive pipe.

Standard rams are made in large sizes, using from 400 to 15,000 gal. of water per minute (G), operating under a fall of 1½ to 50 ft., and raising water 35 ft. per foot of fall, up to a maximum of about 800 ft.

The working formulas for the hydraulic ram are as follows:

$$g = \frac{2 \times G \times H}{3 \times h}, \qquad G = \frac{3 \times h \times g}{2 \times H}$$

$$H = \frac{3 \times h \times G}{2 \times G}, \qquad h = \frac{2 \times G \times H}{3 \times g}$$

in which

g = Gallons discharged by ram;
G = Gallons required for operating the ram;
H = Fall, in feet, from source of supply to ram;
h = Height, in feet, to which water is lifted above the ram.

Chart for Coal Purchasers

By W. V. Bowles

Although coal is bought for evaporating water, few buy it on an evaporative basis. The reason usually given is that the human element or "error" cannot be accounted or compensated for. Most engineers agree that the evaporative basis is the correct one on which to buy coal.

Assume a plant which requires, say, 3000 or more tons of coal a year, and it is desired to purchase coal on an evaporative basis. The first thing to do is to run a test on the boilers with various coals and make a chart from the records obtained. The accompanying chart is plotted from a stoker plant and illustrates the idea and plan of procedure.

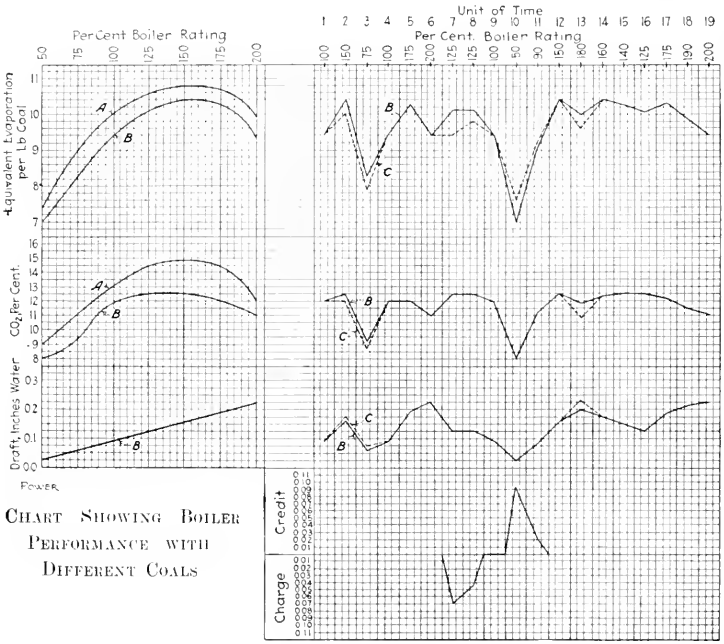

Chart Showing Boiler Performance with Different Coals

It is understood that the coal company should have a competent representative present during the test and at the calibration of all instruments and to have access to all records. First, the attainable evaporation and CO_2 curves are plotted at all boiler loads, together with a curve showing the best draft to use. Below is plotted a curve showing what is in the plant, termed "the adopted standard." This is based on a longer test when uncontrollable conditions may be taken into account.

The chart is also divided into a number of time periods, hours or days, as may be found most suitable. As each period is ended the average boiler rating is marked at the top, and below is plotted the adopted standard.

Referring to the charts under period 2, it is found that the average rating was 150 per cent. The equivalent evaporation should be 10.1 lb. per pound of coal, but the actual evaporation fell off to 10 lb. Following down the column, may be found the reason. The CO_2 dropped from 12½ to 12 per cent. Following still further down the column, the draft has increased from 0.16 to 0.175 in., showing the operating force to be at fault. A similar condition is indicated in the next column.

Under period 7 the evaporation dropped 0.069 per cent., but the operating conditions were according to adopted standards, when the coal company is penalized an equivalent of 0.069 on the coal burned during that period. If a better evaporation is gained than is shown by the standard line, as in period 10, the coal company is given a bonus equal to the increase; in this case, 0.092 per cent. If a shipment of bad coal comes in and the operating conditions are allowed to deviate from the standard, both will be shown in their correct proportion.

It may be found desirable to add draft lines to show conditions in other passes of the boiler, also temperature curves from the various passes. With proper checks on drafts, temperatures and CO_2, the human element can be accurately checked and accounted for; so there appears no good reason why the human element should control or influence the purchase of coal on an evaporative basis.

Such a chart should be an excellent thing to carry along from day to day for the benefit of the plant, even though it is not intended to buy fuel on this basis, for it will show the value of the firemen in dollars and cents.

Like all other kinds of record keeping these charts require much time to be made out. But in plants large enough to warrant checking of performances of apparatus a clerk is available who can plot curves from the tabular matter given him. Cross-section paper may be purchased that will fit nicely into large loose-leaf book covers.

Conditions Are Reversed in Making Gas—The steam engineer aims at minimum CO and maximum CO_2, while the gas producer engineer strives for maximum CO and minimum CO_2. A boiler works with a fuel bed usually varying in thickness from 3 to 12 in., whereas the depth of fuel bed in the producer varies from 2 to 10 ft. Maximum temperature in the furnace is the ambition of the fireman; on the other hand, a combustion zone of approximately 2000 deg. F., but varying with the nature of the fuel, gives the best results in the gas producer.

Philadelphia Municipal Lighting Plant—It is said that definite plans are being drawn up by the city of Philadelphia for the establishment of a municipal electric-lighting plant, which is to be ready to take over the lighting of the streets by 1916. It is understood that the plans of the Mayor, and Director of Public Works Cooke, contemplate the installation of a municipal electric plant at the old Spring Garden pumping station of the water-works, and the Keystone Telephone Co. has been asked for an option on the use of its underground conduits for the distribution system. The action was brought about by a recent decision of the State Public Service Commission, that a municipality has the right to establish a lighting system of its own without authority from the Commission, so long as it does not attempt commercial lighting.

Editorials

Engineers' Wages

Quite a few letters commenting on Mr. Pagett's article on this subject in the January fifth issue have been received, for the subject, broadly, is of interest. Nothing new or valuable is contained in these letters and for this reason we do not publish them. The writers, with few exceptions, recognize the fact that local conditions vary so widely that one should not expect to find a uniform wage over several sections of the country. These letters reflect the good judgment of power-plant men by claiming that it is right that there is no wage standard among engineers. The very nature of the service precludes such a thing if equity to all is to be had.

If an engineer's duties consisted chiefly of a few movements, physical or mental, if there were even a remote possibility of "Taylorizing" him, if there were a semblance of standardization about his routine, then well enough to talk about a standard wage. But these things cannot be. The individual's service is the only true measure of his worth.

Coal-Saving (?) Dope

There seems to be an epidemic of coal-savers on the market—not methods and apparatus for saving coal in a legitimate way, but nostrums which, sprinkled upon the coal, are claimed to greatly intensify its calorific value or at least the efficiency with which it can be burned.

As the rustic visitor to the circus said of the giraffe, "There ain't no such animal." And even as the rustic said it in the actual presence of the beast, we reiterate it in the face of claims of results produced and testimonials to savings supposed to have been accomplished.

There is no substance known to man which, sprinkled upon coal, will make it evaporate more additional water than the extra coal which the price of the dope would have bought could generate. Let us make a slight reservation. There are some coals which, thrown upon the fire, will immediately disengage a lot of volatiles like a bunch of kerosene-soaked waste. A little water sprinkled upon such coal will retard this action and perhaps save enough in volatiles which would otherwise escape, to more than offset the loss of the heat required to evaporate the water. But the action is as described and not due, as is often claimed, to the combustion of the decomposed water; for it takes just as much heat to decompose the water as it generates in getting together again.

We got caught once with one of these concoctions. We told the promoter that if he would have a test made of it by a competent and reputable engineer, and if it showed a material saving, we would publish the test and proclaim the results. He let us choose the authority, and to our astonishment the test showed from seven to sixteen per cent. better evaporation with the dope than without it.

The files of POWER will show that we carried out our promise; but even with the treated coal the evaporation was only six and a half to seven pounds, and a very little difference in manipulation would account for the bringing of a wretched performance up to this not much better one. That our skepticism was warranted is shown by the fact that the stuff was never able to hold its place upon the market.

This was many years ago. Before and since, many compounds for the same purpose have been hawked about, found a few victims and passed away. We have analyzed and exposed several of them. If they were any good, they would be in universal use now. Do not spend good money for them and be made ridiculous without something better than a salesman's claims or a lot of questionable testimonials to fall back upon when the inevitable failure comes.

Uniflow or Una-flow

The German term *Gleichstrom* (*gleich* = even, same; *Strom* = stream, current) used by German electricians for "continuous current" applies naturally to the continuous or unidirectional flow of the steam in the central-exhaust engine, reinvented and made a success by Professor Stumpf; and in German this is known as the *gleichstrom* engine. The English equivalent, unidirectional-flow, is cumbersome and soon became contracted to "uniflow." When the English translation of Professor Stumpf's book upon the engine appeared it bore the title "The Una-flow Engine." Curious as to the reason for this variation, we wrote to Professor Stumpf and to the translator.

Professor Stumpf says: "After considerable correspondence between Mr. Alexander and myself we decided upon the name 'Una-flow.' This is a little in line with, for instance, contra-flow condenser, and should be better than 'Uni-flow.' I prefer to use the hyphen, but this is a matter of taste. Uni-directional-flow engine was our first name, but we found it to be too long. Nobody would say contra-directional-flow condenser. Therefore we dropped this name and replaced it by 'Una-flow.'"

Mr. Peter S. H. Alexander, the translator of the book, says in reply: "The full term which was used by Professor Stumpf and myself was originally uni-directional-flow. When the book was fully prepared for the press in England, the English licensees, Messrs. Musgrave, had already issued a circular in which they had described it as the 'Una-flow.' In view of this, after some little discussion, it was decided, in deference to the new christening of Messrs. Musgrave, that the title of the book should be 'The Una-flow Engine.' If a short title is to be preferred to the full title of uni-directional-flow, I should say that 'Uniflow' in one word would be the best, from the point of view of everyday language. I am exceedingly sorry that there is not a more subtle or logical reason for calling the engine by the name 'Una-flow.'"

We quite agree with the translator. The English prefix for one is uni, not una. The prefix for counter or against is contra, but it is just as logical to signify the unidirectional flow of the steam in the central-ported engine by "Una-flow," in an attempted analogy with contra-flow, as it would be to speak of the contri-flow condenser, in a forced attempt to be consistent with the other prefix.

We apprehend that Professor Stumpf knows more about inventing and designing the engine than he does about coining an English name for it, and are afraid that we cannot follow his lead in this respect, although we were inclined to adopt the spelling proposed by the man who is responsible for the success of the engine itself.

Formulas for Bumped Heads

At a recent hearing of the Massachusetts Board of Boiler Rules, it was shown that a number of the changes proposed by the board and which were considered at this hearing, were not intended as they were written. An engineer of national prominence who was present suggested that it would be well for the board to employ an engineering editor to draft such changes or additions to the rules as might be desired, so that the intent of the board would be expressed by the rules as written. The Air Tank regulations, just issued by the Board of Boiler Rules, is another evidence that the advice of this engineer was good. It is difficult to express just what is intended unless one is a master of the English language, and especially is this so when technical subjects are treated.

In the Air Tank regulations that were adopted under date of December 16, 1913, the rules were intended to be very specific as regards the calculation of the strength of bumped heads, and were drawn up as follows:

BUMPED HEADS

11. The minimum thickness of a convex head, convex to pressure, shall be determined by the following formula:

$$\frac{R \times F.S. \times P}{T.S.} = t$$

The minimum thickness of a concave head, concave to pressure, shall be determined by the following formula:

$$\frac{R \times F.S \times P}{0.6\ (T.S.)} = t$$

R = One-half the radius to which the head is bumped;
F.S. = 5 = factor of safety;
P = Working pressure, in pounds per square inch, for which the tank is designed;
T.S. = Tensile strength, in pounds per square inch, stamped on the head by the manufacturer;
t = Thickness of head in inches.

It was unfortunate that a convexed head was referred to as one convexed to pressure, because this was contrary to the generally accepted idea on the subject; but this would not have been an insurmountable difficulty if it had not happened that the formulas were somehow reversed as applied to the two forms of heads, resulting in a higher pressure being allowed on a head which was convexed to pressure than on one concaved to pressure, as will be seen by noting the formulas given.

Soon after the publication of this set of rules, it was found that they contained a number of errors and the rules were never rigidly enforced; but the present issue was prepared after a new act of the legislature, and it was anticipated that the previous errors would be corrected. The present Air Tank rules were approved by the Board on August 12, 1914, and the subject of bumped heads was treated as follows:

BUMPED HEADS

Convex Head, Curved Outward from the Shell

12. The minimum thickness of a convex head for riveted or forged welded shells shall be

$$t = \frac{8\tfrac{1}{3}\ R\ P}{S}$$

except that the least thickness shall be 3/8 in. on tanks 20 in. in diameter or larger, and 5/16 in. on tanks of less than 20 in. diameter.

The minimum thickness of a convex head for seamless cylinders shall be

$$t = \frac{5\ R\ P}{S}$$

except that the least thickness shall be 1/4 in.

Concave Head, Curved Inward to the Shell

The minimum thickness of a concave head shall be

$$t_1 = 1.67\ t$$

where

t = Thickness, in inches, of a convex head;
P = Working pressure, in pounds per square inch, for which the tank is designed;
R = Radius, in inches = 1/2 the inside diameter of the outside course of the shell;
S = Tensile strength of the shell plates, in pounds per square inch;
t_1 = Thickness of a concave head, in inches.

Convex and concave heads shall be dished to a radius equal to or less than the diameter of the shell, and shall be true portions of spheres.

The description of a convex head defines what is intended and the formula given is correct as far as the evident intent to increase the safety factor on such heads is concerned; but in calculating the strength of a convex head there is no occasion to involve the tensile strength of the material of the *shell* plates of the vessel to which it is attached. That the Board of Boiler Rules believed that there was some connection between these two or that it has made the mistake of improperly expressing itself, is evident from the definition of *S*.

It will be seen, too, that an error has been made in the definition of *R*. If *R* had been stated as equal to one-half the radius in inches or, more correctly, as equal to one-half the radius to which the head was bumped, in inches, without any further additions, the formula would have been correct as far as the calculation of the strength of a bumped head was concerned. However, allowing that this error is a possible mistake of the printer, the matter is still not cleared up with the added information as given in the rule, for it will be noted that the sentence immediately below the definitions of the letters used in the formulas does not coincide with the definition of *R*. The sentence referred to provides for any radius for a bumped head which does not exceed the diameter of the shell to which the head is attached, while the definition of *R* would preclude the use of any radius which would not equal the radius of the shell to which the head was attached. It will be seen that if the rule must be literally followed as written, only a hemispherical head will be acceptable, and the value of *t* as found by the formula, will be twice as great as was really intended.

As stated in the beginning, it is difficult to write rules so that they will express just what is intended, but the employment of an experienced editor to review the rules before their publication would have avoided the errors here pointed out and would have been a real economy to the State of Massachusetts.

In every plant and factory some sort of an emergency first-aid-to-the-injured kit should be provided. A modest and yet complete one is that described on page 185, adopted as standard by the Conference Board of Safety and Sanitation. As this outfit is sold without profit, we are free to recommend it most heartily.

Correspondence

A Correction

In the issue of Jan. 5 I note in the article by Norman G. Meade, "Electromagnets for Alternating-Current Circuits," in the calculation of the magnet to work on 25 cycles, that the line voltage is taken at 440 volts. In figuring the formula for turns (T) the value 1468 turns is the number required for the entire core, or the 440 volts, and not for one coil, as stated. The computations then should be as follows:

$$Turns\ per\ spool = \frac{1468}{2} = 734$$

The ampere-turns as stated in the article are 3150 per spool. Therefore, the amperes would be $\frac{3150}{734} = 4.3$. At 2000 circ.mils per ampere this figures 8600 circ.mils. The nearest wire to this size is No. 11 B. & S., which has an area of 8234 circ.mils.

From the table given in the article, No. 11 wire has 9.7 turns per inch and, allowing 8½ in. for the length of the spool, gives 82.5 turns per layer: $\frac{734}{82.5}$ is approximately 9 layers. Assuming that the layers and the insulation between them measure 1.5 in., the length of a mean turn will be 18 in. and

$$\frac{734 \times 18}{12} = 1100\ ft.\ per\ spool$$

or 2200 ft. as the total length.

No. 11 wire has a resistance of 1.25 ohms per 1000 ft., or for the coil of 2200 ft. the resistance would be $2.2 \times 1.25 = 2.75$ ohms. Then the I^2R loss equals $4.3 \times 4.3 \times 2.75 = 50.9$ watts. The hysteresis and eddy current losses will not change and the total loss in watts will be $50.9 + 41.4 + 10 = 102.3$ watts.

W. O. Jacobi.

Omaha, Neb.

Peculiar Gas-Engine Accident

After studying over the account of the gas-engine accident as reported in the Dec. 29 issue, page 935, I cannot see how the engine could have been wrecked in any other way than by preignition or a continued too early ignition, which can readily develop from the use of a hot tube. The jacket water becoming very hot and heat radiating up around the tube guard, the flame around the tube, being better guarded, would increase in temperature. This would heat the tube to a whiter heat, which would ignite the gas at a lower compression; also, the cylinder being hot, the gas would reach a higher temperature in an earlier stage of the compression. Continued early ignition would put an unusual strain upon the housing or bedplate, and it may have been gradually fractured until one very early preignition caused it to give away.

The conditions do not indicate that the break was caused by water. In the first place, the clearance of a gas engine is nearly 20 per cent., or one-fifth the volume of the cylinder. Using illuminating gas, it is probable that the mixture was about one to eight and not lower than one to six; therefore, the gas volume of any charge would be less than the volume of the clearance. Consequently, the gas opening to the cylinder would probably not pass at any one stroke a larger volume of water than that of the gas, so that it would be impossible for enough water to pass into the cylinder in one stroke to more than fill the clearance. Moreover, if there had been enough water in the gas line to fill the opening at any one time, the gas flow previously would have been so reduced that the engine would have stopped or operated irregularly. Again, if small quantities of water had been coming over, before enough water had accumulated to interfere with the piston the cooling effect and moisture would have "killed" the hot tube, so that the engine would have continued to miss fire and stop.

The resulting condition of the engine would indicate an explosive break rather than a water break. In the latter event the strain would not have reached the breaking point until the piston was nearly in the center, in which case the breaking strain would have been in almost a straight line and the engine would not have buckled upward very much. With preignition, the break might have resulted while the piston was two-thirds or three-quarters of the way to the head center, which would leave the crank at a low angle and the strain upward. This would have the tendency to throw the shaft end forward and the cylinder upward, and the still expanding gas of the explosion would blow the piston clear out of the cylinder and upward, where it afterward fell back on top of the cylinder. If the force of the explosion had been a little greater, no doubt the piston would have been found lying on the floor in front of the engine.

L. M. Johnson.

Emsworth, Penn.

A personal inspection of this engine might disclose some peculiar reason for this accident, but if I understand the nature of the accident, one does not have to look far for the cause. It is stated that the bedplate cracked square across, and if that means a crack extending roughly in a vertical direction from a point on the frame just back of the main bearings to the bottom of the frame, the cause would seem to have been faulty design. The forces acting are exerted in a line coincident with or parallel to the engine axis, and yet, in this type of engine the metal through which the total force of each explosion reacts (the frame) is placed some distance below this axial line. The resulting action may be compared to the process of breaking a chicken's wishbone by pulling on the ends. The frame must stand a much greater stress than if the metal were placed symmetrically about the center line, and many builders do not seem to appreciate this fact sufficiently to induce them to put enough metal in the frame.

A better method is to design the frame so that the reaction is taken up by metal distributed about the line of action (the forces transmitted through the piston rod and connecting-rod); builders of large gas engines would not dare build them with any other type of frame.

Every explosion, in the type of engine illustrated, is a force tending to open up the frame in exactly the place and manner in which it evidently let go, and the intermittent application of such a force is very apt to have the observed effect in time.

The writer has seen a number of accidents of this very kind in this type. The peculiar circumstance was the position of the piston after the accident and the fact that the frame settled back into place. The rear end of the frame, together with the cylinder, usually makes a rapid rearward journey until stopped by something solid.

L. B. Lent.

Brewster, N. Y.

The break would seem to have been caused by a premature ignition. This is a common occurrence with hot-tube ignition, causing beds to break unless made extra heavy. It was only a short time ago that the writer saw a new 50-hp. engine bed break from this very cause.

G. Strom.

Titusville, Penn.

The accident was probably caused by water in the cylinder or preignition, as stated. Personally, I favor the preignition theory, as the hot tube is quite liable to vary the time of ignition—more so than the mechanically timed electrical system; or the charge may have preignited because of incandescent carbon in the cylinders, overheating, etc. It doesn't seem that enough water could have been drawn into the cylinders from the gas line to have caused any damage, as only a small part of the charge is gas.

Salmon Falls, N. H.

Comment on Ammonia Diagrams

I note in your Dec. 29 issue, page 930, two articles on ammonia-compressor diagrams. The first, by Charles Mugler, does not give the clearance of the compressor either in per cent. of displacement or in per cent. of the crank-end and head-end volumes. This information should be given, as otherwise it is impossible to judge whether or not the compression obtained is that for a machine in good condition. The compression curves just after the suction valves have closed seem to show an unusual increase in pressure, which may be due to piston leakage, but without knowing the clearance of the compressor it is impossible to draw correct adiabatic curves on these diagrams. If the diagrams are drawn to scale, the pressure at the end of suction for both ends of the compressor is about 19 lb., whereas for a compressor with properly designed suction valves the pressure at this point should be higher than the pressure recorded on the suction gage. This is due to the inertia of the vapor in the suction pipe which keeps the valves open even after the piston has reached the end of the stroke. The excessively high discharge pressure, even after the discharge valves are open, indicates that either the ammonia condenser to which this machine is connected is too small, or the discharge pipe too small in diameter for its length.

The fact that there is a hook at the end of the expansion line of the right-hand diagram, and not one on the left-hand one, shows that the suction valve on the right-hand end of the machine either sticks or is provided with a stronger spring than the one on the left-hand end.

In regard to D. H. Crawford's discussion of the ammonia-compressor diagram, I do not agree with his explanation of the broken-line discharge curve *BCDE* (Dec. 29). Whenever an ammonia-compressor diagram is taken with a rather weak indicator spring, these zigzag lines are frequently noticed and are generally caused by the momentum acquired by the indicator piston from the rapid rise of pressure in the compressor near the end of the compression stroke, and seldom by the chattering of the discharge valve.

Feed-Water Heaters

In the issue of Oct. 13, page 540, L. B. Carl commented on the relative merits of open and closed feed-water heaters.

The writer, having had considerable experience with feed-water heaters, begs to call attention to one statement made therein as follows: "A closed heater is not suitable, where the exhaust steam is intermittent, because the sudden changes in temperature will loosen the tubes." This is true of the straight-tube type only, and where proper provision is not made to allow for the unequal expansion of the shell and tubes.

I believe the best heater for resisting the effect of sudden temperature changes is the coil type when properly designed and built, as it will operate for any number of years without any of the joints becoming loosened, due to expansion and contraction. All the joints should be brazed, as these are best able to stand the boiler pressure and sudden temperature changes.

Hartford, Conn.

The Night Engineer Off Duty

The editorial in Power, Oct. 13, 1914, entitled "The Night Engineer Off Duty" was certainly appreciated by me, for I spent three years on the night turn.

It calls to my mind a little incident of Yankee ingenuity. Several years ago, while erecting an ice plant in the South, I visited the factory one night to see how the machine was running, for we had just started and I was on the lookout for trouble. I found the old man who had the night turn sitting in a chair, holding a 12-in. monkey-wrench in his hand. As he did not seem to be using it, I asked why he was holding it, and this was the answer: It had been too hot that day to sleep much and he was sleepy. If he went to sleep he would loosen his hold on the wrench, it would fall to the floor and awaken him. He would then get up and take a look around the engine room, sit down and pick up his monkey-wrench alarm and take another rest.

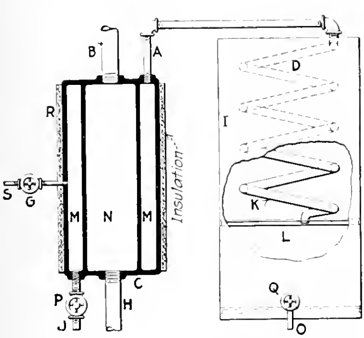
Practical Use for Gas-Engine Exhaust

The sketch shows a water-distilling apparatus operated by the waste heat in the exhaust gases from an internal-combustion engine. It is adapted to power houses, factories and boats where pure water for drinking and other purposes is desired.



Section through Distilling Apparatus

The apparatus consists of a cast-iron drum C divided into two separate compartments N and M, a heat-insulating cover R, a cooling tank D divided into two separate compartments I and L, and a condensing coil K.

The exhaust gas from the engine enters the drum C through the pipe H, fills the chamber N, and passes out the pipe B. Water enters the compartment M, through the pipe S, regulated by the valve G, is vaporized from the heat in compartment N, passes through the pipe A into the condensing coil K, surrounded by cold water in the tank I, is condensed, and flows into the reservoir L, whence it is obtained from the faucet Q. The residue from the distilled water is run off through the pipe J, controlled by the valve P.

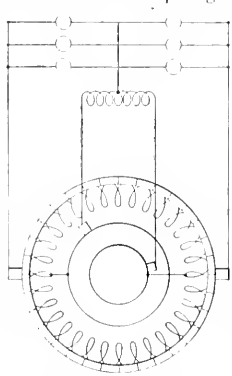
Houston, Tex.

Flickering Lights

The sketch shows the connections of a three-wire generator. For simplicity it is shown with two poles, although four or more are usual. The armature generates 220 volts, obtainable from the outside wires connected to the brushes. Two slip-rings mounted upon the armature shaft are connected at diametrically opposite points of the armature winding, and from brushes bearing upon the slip-rings conductors are carried to the ends of an iron-cored reactance coil, to the center of which is connected the middle or neutral wire of the three-wire system. A resistance might be used for this purpose, but as the device is continuously subjected to alternating e.m.f., reactance is more effective in limiting its value.



Connections of Three-Wire Generator

The net result of the arrangement is that 220-volt motors may be operated from the outside wires and 110-volt lamps from either outside wire and the neutral. The reactance carries direct current only when the two sides of the service are unbalanced. The unbalancing direct current entering the reactance at the center divides, half flowing around the core in one direction and half in the other; its magnetizing effect is, therefore, practically nothing.

An inspector was called to find out why the lamps fed by such a unit flickered. Inspection of the taps from the rings to the winding disclosed that they were not tapped to the winding at equidistant points. Changing the taps to points of symmetry stopped all flickering.

Drains above Back-Pressure Valves

A drain should be connected just above the back-pressure valve. If connected at a higher point, the vapor may condense and create a static head above the valve, which will prevent it opening under ordinary pressure.

The vent pipe may be dispensed with by drilling small holes in the seat of the back-pressure valve. The escape through these openings will be sufficient to relieve air-binding in the heater and drain back any condensation in the exhaust or vapor pipe.

Unsafe Blowoff Piping

A couple of years ago I was a fireman and assistant in a small cold-storage plant. There were three boilers, but we only fired one, which was sufficient to carry the load. The night fireman asked me to do all the blowing down on No. 2 boiler, as its blowoff valve was situated so far back in a dark corner that if anything should happen he wouldn't have as good a chance to get out in the dark as I would in daylight.

I did so until one day the boiler inspector told us to disconnect No. 2 blowoff, as he did not believe the pipe between the valve and boiler was made up very tight. You may imagine our surprise to see it drop out of the elbow near the boiler after giving it only a half turn when unscrewing it. The pipe had only two threads caught, and they were nearly eaten out. The steam fitters had cut it too short, but used it anyway to save cutting another. I learned afterward that the night fireman knew of this, hence his distaste for blowing down this boiler.

Why the Gage Hand Vibrated

The cause of the gage hand vibrating, as referred to by A. E. Aldrich in the Jan. 5 issue, was the intermittent steam flow caused by the cutoff of the reciprocating engines. During the daily periods referred to there was some change in conditions, as an additional unit in service or *vice versa*. The oiler in turning the valve simply closed it a little more than usual, which should have been done before.

Cost of Operating Vacuum Ash-Handling Systems

The discussions of vacuum ash-removal systems in the July 7, Sept. 8 and 15, and Oct. 20 issues, following the article describing the Girtanner-Daviess system in the April 7 number, have been both interesting and fair-minded and have brought out a number of instructive features. The point is to be emphasized, however, that the instances of expensive installation and heavy repairs cited do not refer to the system described in the original article, as the discussions refer to motor and blower costs instead of a steam jet. Even Mr. Sandstrom's estimate of charges in the July 7 number is based on his experience with a blower system.

The absolute cost per ton of ashes removed has no comparative value as a criterion. The most economical system, from wheelbarrow up, for an unfavorable location, may still leave costs high. Furthermore, the final receiving tank may be ignored for purely comparative costs of different systems (unless special expense is here necessitated by the peculiarities of a system) since such tank should rather be imposed equally on each system by the final disposition made of the ashes. This system will discharge directly onto a dump or into any receptacle.

The maximum repair bill for a year on steam-jet installations ranging in price, for pipe line only, from a few hundred up to $1100 has been a fraction over $32—about one-seventeenth of the 40 per cent. experience of Mr. Sandstrom. Again, one man is well able to handle the seven tons per hour for which Mr. Sandstrom wishes to hire two, and this cuts his labor cost in half. In moderate-sized plants the system may be operated by the fireman along with his other duties, and in larger plants the attendance is a minimum. The initial cost is low, so that interest on the investment does not eat up economies secured. The steam used in the jet amounts to 5.29c. per ton (see Apr. 7 POWER).

Finding the Best Coal

The letter, "Finding the Value of Coal," by William A. Dunkley, in the Jan. 5 issue, interested me. One point of importance was not stated in the article, and that is, whether the coals furnished by the roads A and B were of sensibly the same character. If the fuel tests of the two coals showed wide variations in ash, volatile, sulphur and heat, trouble in the fire-room could have been predicted in advance of the change from one coal to the other, provided no change was to be made in the method of handling the fires.

The following quotation from a paper read by me before the New Jersey Clay Workers' Association at the winter meeting at New Brunswick, N. J., Dec. 29, 1914, should serve to make clearer the fundamentals involved in the problem which confronted Mr. Dunkley:

. . . The combustion of coal in a furnace is a complex process, and the different combinations of equipment and methods of handling the equipment are almost infinite. And there are numberless kinds of coal. That statement is made advisedly. Considering alone the inherent characteristics, that is, the sulphur, volatile, ash, the fusing point of the ash, and the heating value of the coal, you can, within certain limits, find coals with all of these factors in any proportion you may desire. Here are five variables and each one has a considerable range of variation. In addition there is the variation in the physical condition of coal; that is, whether it comes in the form of dust—the slack—or screened to a certain size, or what is called the "run of mine." Then there is the question of coking or noncoking.

There are few, if any, industrial uses for coal which require definite adjustment of every one of these variables. Certain definite limits of part of the characteristics already mentioned are especially required in any particular case, without, however, limiting the remaining factors. The first point is, therefore, that you must know what factors are material in the selection of your coal before you can change to a new coal with any reasonable expectation of getting better results, or the same results at less cost.

The chief use of coal is to produce heat by its combustion. In any particular process to accomplish the best results a certain amount of heat must be released in a certain length of time. Let us assume for the present that this is the whole problem, disregarding all other questions, such as the avoidance of smoke, fumes injurious to the product, etc. That limits us to three variables—the heating value of the fuel per pound, the amount of fuel burning at one time, and the amount of fuel burned per hour. The first is determined by the selection of the fuel, the second by the area of the grates, and the third by the thickness of the fire and the amount of air supplied to it. It is obvious that if we change any one of the three, we will directly affect the result, which is a given amount of heat liberated in a given time. This may seem rather elemental, but the point I wish to bring out is that frequently the user tries to change one of these factors (usually the coal) without making corresponding readjustments in one or both the remaining conditions, with the result that he concludes there is only one kind of coal he can burn satisfactorily. Frequently, a minor change in equipment or methods of firing will make possible the use of another coal at considerably less expense.

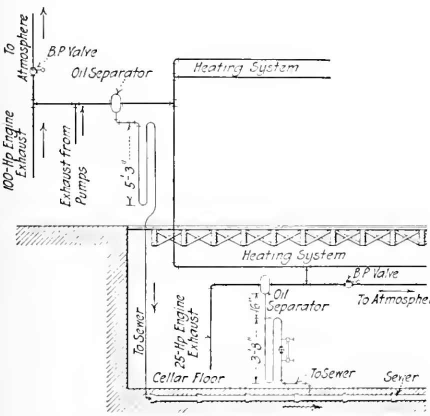
Trouble with Oil Separator

Can any POWER reader suggest a remedy for trouble with an oil separator? Since taking over my present plant I have had considerable annoyance from grease passing over with the steam into the heating system from the separator of a small engine located in the cellar, where the connections are arranged as in the accompanying sketch.

A new separator and various kinds and sizes of seals



ARRANGEMENT OF OIL SEPARATOR WHICH GIVES TROUBLE

have been tried without effecting a remedy. We carry 8 in. of vacuum and the grease is drawn through the separator. Several so called experts have seen the conditions and each has advised different sizes, loops, etc., but upon trial none of them has proved satisfactory.

Industrial Education Again

My article on industrial education for operating engineers, which was published in POWER, July 28, 1914, was intended to draw out discussion. I was glad, therefore, to hear from William E. Dixon, in the Nov. 10 issue, even though he does not agree with me and thinks the sort of trade school I was connected with so long is a "pure and arrant fake."

This problem of industrial education is far from being solved; those who have worked the hardest and the longest realize that better than those who are on the outside looking in. Many mistakes have been made, and many more will be made. The fact remains, however, that the industries are today so organized that learning any trade under the old conditions is practically impossible. The few large shops which realize this fact are providing schools within their own walls. These have all the problems to meet which are met by the public trade school, if politics can be kept out of the latter, and that is possible.

There is no need to forget the cultural, civic or business side of a boy's education because he is in a trade school. I do not know what schools Mr. Dixon has seen, but his name is not on the visitors' book at the Worcester Trade School, so I am sure he has not been shown that school by anyone in authority able to explain what is really done there. While some things are far from perfect, they are not those to which he alludes. These schools should, and most of the state-aided schools do, give at least one-third of the pupils' time to regular high-school studies. Their hours are much longer, and consequently this time is almost equal to the total time which the regular high schools give.

Some interested in industrial education do believe a trade school should teach trades solely. We have never felt that we could conscientiously send out a graduate unequipped, so far as his mentality allows, for the battle of life.

It is not easy to find the right teachers. We had one for a short time who had a first-class license. He had handled some big plants and came well recommended He knew nothing except by rule of thumb, could not tell that to anyone else, and would not be helped by those who did know how to teach.

A man who knows what he is trying to teach, who has not forgotten that he was a boy, and who has a cheerful disposition has a fair chance of learning to teach by experience alone. Certain tricks of the trade of teaching he may learn from more experienced men. These relate almost entirely to discipine. The largest job is how to impart what one knows to students so that it makes an impression and is within their comprehension. When an engineer has done a certain thing for years he easily loses sight of why he does it. It is enough to tell a helper to do a thing, and he does it until it becomes a habit. That is not education. A man has not learned how to do a thing until he understands the reasons for doing it.

Mr. Dixon should prove his statement that "the schools cannot even hope to get an equipment that would serve for much more than a toy." There is no reason why a school's money should not go as far as that of any corporation. In fact, experience shows that it can be made to go farther than any other city money. Builders of the best machinery have made concessions that, taken alone, would fit out a school in far from toy fashion. The cost per pupil for adequate equipment is less than that for equally good machine-shop equipment.

Mr. Dixon hints that desirable boys will not go to school to learn to be engineers. That depends on what you will take. If you start a school with riffraff it will be hard to get decent boys into it. A school cannot afford to be snobbish, but it can make a manly attitude toward the work a condition of membership. There are plenty such boys, but they will not go where the other kind are tolerated in any considerable numbers.

"It is bad practice to try to teach a person an idea until that person has a desire to know it," says Mr. Dixon. If my father had humored me when I was a small boy, I would not have begun to get ideas yet. A boy should be taught while he is young and receptive. The instructor is of little use who cannot make steam engineering attractive to a boy. A boy must be brought to the point where he knows that it is up to him to learn before he will learn many things.

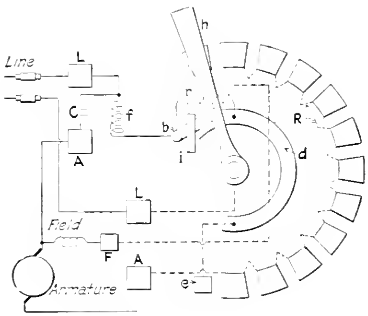
The crying ill of all our educational systems is that the pupils do not wake up to their needs until it is too late. They are so delicately handled now that they think they know much better what is good for them than their parents. The adequate substitute for the stiff stick in the hands of a raw-boned Yankee teacher as an idea awakener has never been found. If this notion that a boy should not be taught anything until he has discovered for himself that he needs to know it were ever followed except on paper, our schools would be picnics and education would be below zero.

E. H. Fish.

Worcester, Mass.

Contactor Closed and Opened

The diagram shows the connections of a starting-box used in conjunction with a contactor which ruptures the arc, thereby saving the rheostat contacts when the starter is thrown to the off position. It also acts as a no-voltage release to open the motor circuit should the line become dead, with no one in attendance. Upon simultaneously twisting handle *h* and moving it in a clockwise direction, an auxiliary contact arm mounted on *h*, and brought down by the twisting motion, touches the button *b*, to which is connected one end of the operating coil *f* of contactor *c*. This closes the local break through the contactor and the motor takes current. If the handle is kept twisted and in contact with *d*, as it is advanced, coil *f* will remain energized throughout the travel of the handle. At the end of its travel the handle engages a spring clip on post *e* and the twisting stress may be released, because coil *f* is then energized independently of the auxiliary contact.



Starting Device

It will be noted that at the start, when the auxiliary contact rests upon button *b*, the full line voltage is applied to the coil *f*, but after the contact reaches segment *d*, resistance *r* is cut into series with coil *f*. This is a feature of safety as well as of economy, because less current is required to hold the contactor closed than is required to close it; and if the voltage should leave the line, thereby causing the contactor to open, it would remain open until someone returned the starter to the "off" position and repeated the starting cycle, because with *r* in series with *f*, the current would be insufficient to close the contactor.

One of these outfits in a lumber camp, where it was exposed to the weather, was complained of because in going from the "off" to the "on" position the contactor would open immediately after closing. Insulation strip *i* is used simply to preserve a smooth surface for the auxiliary contact in its travel from button *b* to the segment *d*. Investigation showed the trouble to be due to this insulating strip having absorbed rain and so swelled as to raise the auxiliary contact finger out of contact with *b* before it had made contact with *d*. This, of course, demagnetized coil *f* and permitted the contactor to open. The trouble was remedied by sandpapering the surface of *i* below the surfaces of button *b* and of segment *d*. It is interesting to note that an open-circuit in resistance *r* may cause the same failure.

Schenectady, N. Y.

Loss by the Use of Slack Coal

Here is an account of two boiler tests that may interest some engineer operating the Hawley down-draft furnace. Plants with these furnaces have their troubles when using slack coal. When we have mixed coal we can show good results, but with slack we cannot keep it on the top grate. The result is that we cannot carry the load with the same number of boilers on the line. With mixed coal I ran a test on Dec. 2, 1914, on a 150-hp. Coatsville fire-tube boiler with a Hawley down-draft furnace. The first test was very good, the evaporation from and at 212 deg. F. per pound of dry combustible being 11.66 lb., the horsepower-output 287, an over-rate of 91 per cent., and the efficiency of the boiler and furnace was 69 per cent. It cost 10.21 cents to evaporate 1000 lb. of water.

The following day I ran a test on the same boiler, with the same fireman, and tried to get as near to the first test as was possible, but using coal containing very few lumps. This second test showed a decided falling off. We evaporated 10.63 lb. of water per pound of combustible and developed 249 hp., an over-rate of 66 per cent. in place of 91 per cent. It cost 11.25 cents per thousand pounds of water in place of 10.21 cents and the efficiency was only 64 per cent. The loss in twenty-four hours on nine boilers amounted to $21.33 with slack coal.

Harry Biehl.

Philadelphia, Penn.

Commutator Short-Circuited

An inspector was called to find out why the armature of a motor was heating and "shooting like a gun." He ascertained that the commutator had just been slotted in a lathe. The side mica was very thin and the lathe tool used was too thick; the result being that the tool curled shavings from the bars and at the end of the stroke the stub of the shaving was jammed into the mica and across an adjacent bar. The burrs had been picked out where they could be seen, but some were too deeply embedded.

As soon as the motor was started, all the coils that were short-circuited by bridged bars were heated by the local short-circuit currents which, as the speed became greater, became sufficiently heavy to burn out the short-circuits that had not been picked out. The noise like the report of a gun was due to the extinction of the arc by the magnetic field. The motor was then run up to full speed and without any further demonstration. The arc-extinguishing properties of the magnetic field explain why armatures that burn out in service are not as badly damaged as might be expected.

Schenectady, N. Y.

Inquiries of General Interest

Salt in Fireclay—What is the purpose of adding salt to fireclay used in setting the firebrick of boiler furnaces?

M. G. W.

The addition of about a pint of salt to a bucketful of ordinary fireclay causes partial vitrification of the fireclay when it becomes heated, and increases its adhesiveness to the firebrick.

Removing Stains from Gage-Glasses—How can stains be removed from boiler water gage-glasses?

S. M. E.

Most stains formed on boiler gage-glasses can be removed with a swab of clean waste moistened with a weak solution of muriatic acid. In the cleaning process care should be taken, however, not to employ wire or other material likely to scratch the glass and thereby weaken it.

Coefficients of Expansion—What are the relative rates of expansion of aluminum, brass and cast iron for the same increase in their temperature?

C. R. H.

The coefficients of expansion or proportionate increase of length for each degree increase of temperature of the metals named are: Aluminum, 0.00001234; brass, 0.00001; and cast iron, 0.00000556.

Bedding Underground Pipes in Sand or Gravel—What benefit is to be derived from bedding underground steam or water pipes in sand or gravel?

J. N. R.

The principal advantages obtained are more perfect grading and better subdrainage. In case of steam pipes, whether or not they are laid in conduits or coverings of any kind, subdrainage is important in reducing the convection of heat from the pipes to the surrounding earth, and in case of water pipes complete bedding in sand or gravel affords better protection against frost.

Drainage of Boiler Steam Main and Arrangement of Stop Valve—How should a main steam pipe slope and boiler stop valve be placed between a boiler and engine?

D. J.

The slope of the piping and arrangement of the stop valve should be such that all condensation between the valve and the boiler will drain back into the boiler, and the slope of the piping beyond the valve should be such that the water will drain from the boiler toward the engine. Stop valves should be so arranged that pressure from the boiler will tend to raise the valve from its seat, and they should be given such a position that there will be no accumulation of condensate above the valve when it is closed.

Care of Standing Boiler—When a boiler of a battery is not required for some time, is it injured by standing with water at the usual level carried for steaming?

W. B.

There will usually be more rapid corrosion of the interior above the regular water line, and especially near the water surface, when so standing than when steaming. When not required for some time, the boiler is better preserved by emptying it of water and drying thoroughly. If that is impracticable, interior corrosion can be reduced by completely filling the boiler with water, although for most situations this results in more rapid exterior corrosion than when the boiler stands empty, due to condensation of the moisture of the atmosphere.

Pressure in Discharge Pipe with Drop Leg—Neglecting pipe friction and inertia, what pressure would a pump have to work against if the discharge pipe rose to a height of 150 ft. and returned with an open end at the level of the pump?

G. K.

For starting flow in the descending leg, the pressure pumped against would increase to

$$150 \times 0.434 = 65.1 \text{ lb. per sq.in.}$$

As a column of water 34 ft. high would balance the pressure of the atmosphere, then if a solid column 34 ft. or more in height were maintained in the descending leg of the discharge pipe, a vacuum would be formed in the upper end of the ascending pipe, thus relieving it of pressure equal to that of the atmosphere. The net head pumped against would then be 150 — 34 or 116 ft., which would be equivalent to

$$116 \times 0.434 = 50.34 \text{ lb. per sq.in.}$$

Coal Required under Stated Conditions—With the temperature of feed water at 200 deg. F. and a combined boiler and furnace efficiency of 60 per cent., how many pounds of coal of a calorific value of 1",500 B.t.u. per lb. would be required to evaporate 13,600 lb. of water into dry saturated steam at 130 lb. gage pressure?

T. B.

The total heat required to convert a pound of feed water from 32 deg. F. into dry saturated steam at 130 lb. gage or 145 lb. absolute pressure would be 1192.8 B.t.u., and as each pound of feed water at 200 deg. F. would contain 200 — 32 or 168 B.t.u. above 32 deg. F., then to raise 13,600 lb. of water from 200 deg. F. to dry saturated steam at 130 lb. gage pressure would require

$$13,600 \times (1192.8 - 168) = 13,937,280 \text{ B.t.u.}$$

With a combined boiler and furnace efficiency of 60 per cent., from each pound of coal containing 13,500 B.t.u. there would be realized

$$13,500 \times 0.60 = 8100 \text{ B.t.u.}$$

and, consequently, the evaporation of 13,600 lb. of water under the conditions stated would require

$$13,937,280 \text{ B.t.u.} \div 8100 \text{ B.t.u.} = 1720 \text{ lb. of coal.}$$

Pipe Surface Required for Heating Water—How many lineal feet of 2-in. iron pipe, or of brass or copper pipe of the same size, would be required as heating surface in a closed tank to heat 800 gal. of water per hour from 50 to 180 deg. F. with exhaust steam at 1 lb. gage pressure?

A. M. D.

In raising the water from 50 to 180 deg. F., each pound would receive 180 — 50 or 130 B.t.u., and as 800 gal. of water would weigh $800 \times 8\frac{1}{3} = 6666$ lb., and, neglecting losses by radiation, the total heat to be transferred would be

$$6666 \times 130 = 866,580 \text{ B.t.u. per hr.}$$

As the temperature of the steam would be about 213 deg. F. and the average temperature of the water would be

$$\frac{50 + 180}{2} = 115 \text{ deg. F.}$$

then the mean temperature difference between the steam and the water would be

$$213 - 115 = 98 \text{ deg. F.}$$

For this mean temperature difference, iron pipe would condense about 18.5 lb. of steam per square foot per hour, and the latent heat of steam at 1 lb. gage pressure being 969.7 B.t.u. per lb., then for each square foot of pipe surface there would be a liberation of

$$18.5 \times 969.7 = 17,939.45 \text{ B.t.u. per sq.ft.}$$

so that

$$\frac{866,580}{17,939.45} = 48.3 \text{ sq.ft.}$$

of iron-pipe surface would be required. As 1.608 lin.ft. of 2-in. pipe would be required per square foot of external surface, the total heating surface would require

$$1.608 \times 48.3 = 77.7 \text{ lin.ft.}$$

of 2-in. iron pipe. Under the same conditions brass pipe would condense about twice as much and copper pipe about $2\frac{1}{3}$ times as much steam per square foot of surface, and therefore

$$\frac{77.7}{2} = \text{about } 38.8 \text{ lin. ft.}$$

of brass pipe, or

$$\frac{77.7}{2.33} = \text{about } 33.3 \text{ lin.ft.}$$

of copper pipe, of the same external diameter as standard 2-in. iron pipe, would be required.

Engineers' Study Course

Steam-Engine Cycles

The diagram representing the ideal performance of the steam plant is given in Fig. 1, repeated from Fig. 3 of the article on "Heat-Engine Cycles." A brief review of this Rankine cycle is as follows:

Line *AB* shows complete evaporation and the transfer of the steam to the engine or turbine, without loss of heat by radiation, loss of pressure by pipe friction or throttling, or loss of volume by initial condensation. Its right-hand end may also cover superheating, which, of course, takes place at boiler pressure.

Curve *BC* shows adiabatic expansion, possible only in a cylinder of some imaginary, thermally neutral substance. This expansion is carried clear down to the exhaust pressure at *C*.

Line *CD* represents complete expulsion of the steam from the engine and its contraction to the liquid state in the condenser (or atmosphere).

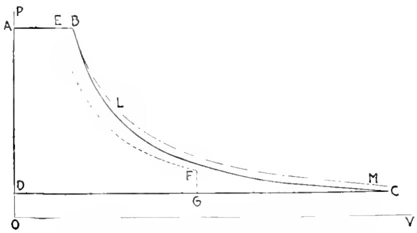

Fig. 1. Diagram Representing Ideal Performance of Steam Plant

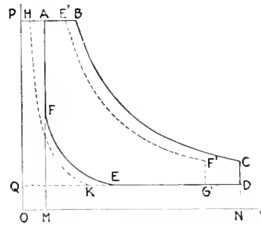

Fig. 2. Illustrating Clearance and Compression

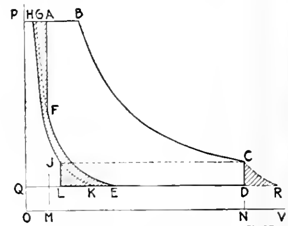

Fig. 3. Loss Due to Clearance

This diagram implies that the engine has no clearance at all. It is the form of ideal action in either piston engine or turbine, but the interpretation is somewhat different for the two types of machines. The engine will now be considered.

Area *ABCDA*, Fig. 1, shows the maximum output of work per pound of steam, within the particular limits of pressure and temperature, and the best possible efficiency. In the actual plant there are four ways or directions in which this ideal performance fails of realization. These sources of loss are:

(1) Pipe and valve losses, of heat and pressure, incurred in the transfer of steam to and from the cylinder.

(2) Thermal action of the cylinder walls.

(3) Incomplete expansion.

(4) Clearance and compression.

Of these, Nos. 2 and 3 will first be taken up, then No. 4, and finally No. 1; and in the consideration of them the evolution of the actual indicator diagram from the ideal outline *ABCDA* will be shown.

The effect of initial condensation, by the cooler metal surfaces with which the steam entering the cylinder comes into contact, is evidenced in the shrinkage of steam volume from *AB* to *AE*. And then, because the heat thus taken from the steam at high pressure begins to come back as pressure and steam temperature are lowered, curve *EF* falls less rapidly than would an adiabatic from *E*. In shape, curve *EF* is here drawn as an equilateral hyperbola, following the law

Pressure × *volume* = *a constant*, or $pv = c$.

Sometimes the hyperbola is called the theoretical curve of steam expansion. The title is undeserved, for thermal conditions within the cylinder are so complex that the formulation of any theory of expansion is impossible. The very prevalent use of this curve in laying out preliminary or illustrative diagrams is based on two wholly practical facts or considerations. The first is that the hyperbola is a fairly good working average of the expansion curves of actual indicator diagrams; the second, that it is an easy curve to plot.

The best collection and discussion of data as to the form of real steam curves that have been made will be found in the paper on "Cylinder Performance," presented to the American Society of Mechanical Engineers by J. Paul Clayton, in May, 1912, and reviewed in Power for June 18, 1912. The subject is too extensive for more than a reference here. It is enough to say that when there are conditions favoring excessive cylinder-wall action, such as small size and low speed, with early cutoff, the expansion curve will run much above the hyperbola. On the other hand, with high superheat and small thermal action, it will fall much more rapidly. But in the general run of ordinary conditions, departures from the form $pv = c$ are comparatively small.

Returning to Fig. 1, it will be noticed that the assumed curve *EF* rises steadily toward the adiabatic *BC* as the steam expands. In further illustration of the same point, curve *LM* is a hyperbola drawn from *B*. The vertical distance between *LM* and *BC* at first grows larger, then diminishes; but when it is remembered that this difference is a relative quantity, to be compared with the whole pressure from base line *OV* up to the curves, it is seen to increase progressively.

Now in ideal operation, or in the process reasoned out for getting the maximum work from a pound of steam, expansion is carried clear down to exhaust pressure. There is very good reason why this ought not to be done in the real engine, and why it is more economical to stop at some such point as F. To get the small amount of work represented by the triangular area to the right of line FG would require a cylinder more than twice as large as is needed to contain volume DG. First of all, this would make the engine cost more, but worse than that, it would involve continual losses in operation. If the cylinder is too big and cutoff too early, the waste due to thermal action by the cylinder walls becomes relatively greater. And in driving the piston by a small mean effective pressure such as will prevail beyond FG, the loss of work through machine friction will exceed the effective work done by the steam upon the piston, and the result will be a net loss rather than a gain.

The matter of clearance and compression is taken up in Fig. 2. As the first step, the combined expansion and release lines $E'F'G'$ are transferred directly from Fig. 1. These lines represent the performance, in an engine without clearance, of one pound of steam which enters the cylinder, does work, and goes to the exhaust. But now there is to be associated with this working steam a certain proportionate amount of clearance steam. In Fig. 2, the volume PE' of the working steam in its condition at cutoff is moved out to HB, leaving back of it a space PH

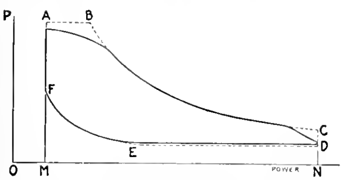

Fig. 4. The Diagram Obtained in Practice

filled with clearance steam. Of course, this division is imaginary, for there is no separation into distinct volumes. The point is that, of the steam present at cutoff, a portion HB is going to be discharged, while the remainder PH will be caught and compressed.

As the whole body of steam expands along curve BC, the clearance quantity has its increasing volume measured out to the similar curve HK. Since these curves are taken to be of the same form as $E'F'$, horizontal distances between curves HK and BC are the same as between line OP and curve $E'F'$. In effect, then, the original no-clearance diagram $PE'F'G'Q$ is shifted over to the right of curve HK. This distorts its shape, but does not change its area above a horizontal line through F' or C; below that pressure, however, there is a loss, the cause of which can be stated in two ways. The first is, that $F'G'$ would be changed to a curve CR, as shown in Fig. 3, at a constant distance from curve HK; and the vertical release line CD cuts off the extended area CRD. The other form of statement is, that since effective volumes of the working steam are measured over from curve HK, and these grow shorter below the terminal pressure at C, the lower end of HK cuts under the effective diagram and diminishes its area.

The loss due to clearance is more fully illustrated in Fig. 3. At the beginning of expansion the steam in the cylinder is partly condensed, because of wall action. At the beginning of compression the steam left in the cylinder is likely to be nearly or quite dry, perhaps even a little superheated. Consequently, the quality of the clearance steam is higher at E than at K, and its volume is greater; then the compression curve runs to the right of HK, or the clearance steam requires more work for its compression than it gives back in expansion.

The lost area $CRDC$ is, in effect, an addition which compression makes to the work not utilized because of incomplete expansion. This triangular figure may be carried over to the position $JKLJ$; and then we say that while the clearance steam really follows curve HK all the way down to exhaust pressure, its effective delivery of work ends at the pressure of release. Any work of expansion to the right of JL simply helps the outrush of steam during release. A condensed statement regarding clearance losses may be made as follows:

If the whole weight of steam represented by volume PB came from the boiler into an engine without clearance, it would do the work represented by area $PBCDQP$, Fig. 3.

Actually, because of clearance and compression, the useful work really performed is only that represented by area $ABCDEFA$.

But the area $PAFEQP$ is not all loss, for a part of it is covered by the work $PHJLQP$ of steam which did not come from the boiler, but was saved over from the preceding cycle. The net loss is then the shaded area $AFELJHA$.

This lost area is made up of three parts. In order to separate them, the compression curve is extended as FG, here made similar to HK. This continues up to admission pressure, the prevailing difference in quality between compression and expansion, and shows a complete working cycle $EGHKE$ for the clearance steam. Then the three partial losses are:

Area $AFGA$ due to throttling of the live steam as it enters and fills the clearance space.

Area $EGHKE$ due to cylinder-wall action, working out through the cycle of operations of the clearance steam.

Area $JKLJ$, in effect, as has been explained, an addition to the incompleteness of expansion.

In regard to the proportions of this diagram, it is to be noticed that the difference between curves EG and HK is exaggerated, being too great relative to the quality at cutoff shown by the ratio of AE to AB in Fig. 1.

The ideas developed in Fig. 3 open the way to a more or less definite rational determination of the best degree of compression corresponding to a certain set of conditions on the expansion side of the indicator diagram. The indefiniteness is due in part to uncertainty as to the exact form of the expansion and compression curves in the actual engine, and for the rest to modification of the sharp-cornered diagram by the pipe and valve effects shown in Fig. 1. But this general idea of the several sources of loss makes it easier to understand the results of experiments made to determine the effect of compression upon economy.

In Fig. 4, the outline $ABCDEFA$ is the same as in Figs. 2 and 3, but its proportions are changed to something nearer those of common indicator diagrams. It only remains, then, to sketch in curves of admission and release and a line of increased back pressure, and thus come to the end of the evolution of the actual indicator diagram. Knowledge of the magnitude of these pipe and valve effects comes wholly from experience, or from familiarity with the performance of the various classes of engine.

Performance of Refrigeration Plant at Lubeck, Germany*

SYNOPSIS—Description and data of test results of the municipal refrigeration plant at Lubeck, Germany. The poppet-valve compressor engines use highly superheated steam and some exhaust steam is used for ice making. Unusually good results are obtained.

In contracts for ice-making and refrigerating machinery it is customary for the manufacturer to guarantee the capacity, to enumerate the temperatures to be maintained in cold-storage rooms, and, if the purchaser is exacting, to insert the guarantees for coal, steam, power and cooling-water consumption. A test is usually made to see if the machinery supplied fulfills the various requirements. Such tests are instructive, but for commercial reasons, probably, they seldom get into print.

In the following only the acceptance tests of the equipment of the refrigeration plant for the city of Lubeck, Germany, are given.

The mechanical equipment of the "Kuhlhaus Lubeck" consists essentially of one 17$\frac{3}{4}$ and 29$\frac{1}{2}$ by 29$\frac{1}{2}$-in. tandem-compound Swiderski steam engine of 320 hp., using superheated steam, connected to a Balcke surface condenser. In the connection between the low-pressure cylinder and the surface condenser is inserted an oil separator. From the condenser the condensate is taken to a reboiler for the purpose of expelling air and foreign gases, a portion of this water being required for making distilled water ice, and the remainder is returned to the boiler. The distilled water is forecooled in a countercurrent cooler.

This main engine is coupled to a pair of 13x23$\frac{5}{8}$-in. double-acting horizontal Borsig ammonia compressors of the opposed type. A duplicate engine, intended for reserve, is connected to a single ammonia compressor 13x23$\frac{5}{8}$ in.

To take advantage of the increased capacity obtained when operating with a higher evaporating or suction pressure, one of the four ends of the double compressor unit is used only for ice making, keeping the brine in the freezing tank at about 19 deg. F. The guaranteed capacity of this compressor cylinder half is 36.4 tons or

$$110{,}000 \text{ calories} \times 3.9683 = 436{,}513 \text{ B.t.u. per hour.}$$

The ice-tank room and brine tank are designed on the Linde system, the brine-cooling coils being placed underneath instead of between the cans. The rated daily capacity is 22 tons of 2000 lb. each.

With the 300- or 400-lb. American blocks the freezing time is 42 to 60 hours, while the small European 55-lb. blocks (average size 7x7x35 in.) with 19-deg. brine freeze in 18.4 hours; there are 612 of these small cans in the freezing tanks.

When cooling brine to 14 deg. F. for the cold-storage warehouse the guaranteed capacity of any one of the compressor cylinders is 61.15 tons of refrigeration. (One ton of refrigeration = 2000 × 144 B.t.u. = 288,000 B.t.u. per 24 hours.) The brine is cooled by direct-expansion coils. The brine tank has circulation partitions and agitators. Another tank, supplied with cold water, is used for cooling the liquid ammonia. The ammonia condensers of the atmospheric type are on the roof.

From the flywheel of each engine a belt leads to a lineshaft under the engine-room floor, and from this lineshaft are driven two 70-kw. Siemens-Schuckert generators, one being a spare. The boiler house has two Borsig water-tube boilers, one a spare, built for 170-lb. pressure and superheating to 625 deg. F. Each boiler has 969 sq.ft. of heating surface.

The cooling water supply, guaranteed capacity 268 gal. per minute, is obtained from two wells. The water in one is lifted 131 ft. to the surface, in the other 98 ft., by a Borsig air compressor, also in duplicate. The water is discharged into a receiving basin near the boiler house, and forced to the ammonia condensers by a belt-driven volute pump. A duplicate pump, driven electrically, is provided for this service. As a further safeguard for insuring uninterrupted operation, provisions are made for using city water if necessary.

For producing the necessary hot water for scalding purposes in the abattoir a steam-heated hot-water apparatus is erected in the boiler house; capacity 26.5 gal. of water per minute heated from 86 deg. to 176 deg. F. Preheated water is taken from the surface condenser, the latter in turn receiving its cooling water from the ammonia condensers. In this manner the water is utilized to the fullest extent. Steam meters measure the quantity of live steam fed to the hot-water apparatus. The plant is well equipped with all kinds of indicating and recording instruments.

The following is abstracted from the report of acceptance tests made after all the machinery had been installed and operated during the summer of 1913.

BOILER TEST

Of the two boilers, which are alike, only the one which happened to be clean at the time was tested, it being assumed that the other boiler would have shown equal efficiency.

Date of test	Oct. 18,1913
Type of boiler (Borsig Steilrohr Kessel)	Water-tube
Number of boiler and year built	20,994—1913
Evaporating surface, sq.ft	969
Superheating surface, sq.ft	269
Grate surface (flat) total, sq.ft	36.2
Economizer, sq.ft	377
Guaranteed performance:	
Evaporation normally, 5070 lb. water per hour; 3968 lb. steam to be superheated.	
Overall efficiency, per cent.	76
Temperature of superheated steam, deg. F.	625
Gage pressure, lb	170
Conditions:	
Heating value per pound of coal as fired, minimum B.t.u.	11,500
Permissible residue, per cent	6
Draft after passing economizer, at least 0.6 to 0.8 in. of water column.	
Feed-water temperature, not less than 95 deg. F.; from economizer, 158 deg. F.	
Coal analysis:	
Average calorific value of coal sampled, 12,145 B.t.u. per pound as fired.	
Results of test:	
Date	Oct. 18, 1913
Load	Normal
Duration of test	4 hr. 2 min.
Temperature of fireroom	57.2 deg. F.
Draft at rear of boiler, in. water column	0.3
Draft after passing economizer, in. water column	0.68
Flue-gas temperature after economizer, deg. F.	405
Flue-gas temperature at rear of boiler, deg. F.	653
Per cent. of CO_2	13.38
Per cent. of O	5.72
Steam pressure, gage, lb	167
Steam pressure, absolute, lb	181.7
Temperature of superheated steam, deg. F.	628
Temperature of saturated steam, deg. F.	374
Amount of superheat, deg. F	253
Total heat of saturated steam (above 32 deg. F.) B.t.u. per lb	1,197
Heat of superheat, 254 × 0.646 (spec. heat) B.t.u. per lb	164
Total heat of superheated steam, B.t.u	1,361
Feed-water temperature to economizer, deg. F.	97.1
Feed-water temperature from economizer, deg. F.	181.3
Heat supplied in boiler, per lb. of superheated steam, B.t.u., 1361 — (97.1 — 32) =	1,295.9
Water evaporated during test, lb	21,076
Water evaporated per hour, lb	5,225
Water evaporated per hour per sq.ft. heating surface, lb.	5.39
Coal consumed during test, lb	2,595
Coal consumed per hour, lb	643
Coal consumed per hour, per sq.ft. grate surface, lb.	17.8
Water evaporated during test, per pound of coal fired, lb. 5225 ÷ 643	8.14
Heat contained in 1 lb. of saturated steam = 1197 — (97.1 — 32), B.t.u	1,132.9
Ash and refuse, percentage	9
Heat imparted to saturated steam per lb. of coal as fired, B.t.u., 8.14 × 1131.9 =	9,214
Efficiency of boiler and economizer, referred to saturated steam, per cent., $100 \times \frac{9214 \text{ B.t.u. in steam}}{12{,}145 \text{ B.t.u. per lb. coal}}$ =	76

At the time of this test it was impossible to ascertain the steam consumption of the main engine, which would have shown the capacity of the superheater. Therefore, the over-all efficiency of steam generation could not then be had. However, a month later the steam consumption of the engine was found to be 2888 lb. of superheated steam per hour. The work done by the superheater may, therefore, be taken at

$$2888 \times 164 \text{ B.t.u.} = 473.632 \text{ B.t.u.}$$

This divided by 643 results in 736.6 additional heat units obtained per pound of coal fired, making the total

$$9214 + 736.6 = 9950.6 \text{ B.t.u.}$$

*Excerpts from an article by Richard Stetefeld, "Eis Und Kalte Industrie."

The heat utilized by the boiler, economizer and superheater, based on coal as fired, is

$$100 \times \frac{9950.6}{12,145} = 82 \text{ per cent.}$$

Based on combustible it is

$$100 \times \frac{9950.6}{12,145 \times 0.91} = 90 \text{ per cent.}$$

The number of pounds of superheated steam obtained per pound of coal as fired is

$$\frac{9950.6}{1295.9} = 7.68 \text{ per cent.}$$

A repetition of this test was deemed unnecessary because substantially the same results had been secured at a preliminary test.

TEST OF ENGINE COUPLED TO AMMONIA COMPRESSORS

An official trial of the tandem-compound main engine with 17¾ and 29½ by 29½-in. cylinders, of the poppet-valve type, coupled to two 13x23⅝-in. opposed ammonia compressors, was conducted. The reserve engine, a duplicate, was not tested for steam consumption, because the indicator diagrams taken from it under like conditions agreed with the diagrams obtained from the main engine, proving that the power and economy of the two engines in the plant are the same.

Dimensions and Conditions Imposed:	
Diameter of high-pressure cylinder, in.	17.718
Diameter of high-pressure piston rod, in.	3.736
Diameter of high-pressure tail rod, in.	2.749
Diameter of low-pressure cylinder, cold, in.	29.525
Diameter of piston rod, crank end, in.	4.128
Diameter of piston rod, head end, in.	3.736
Stroke, in.	29.527
Revolutions per minute	95
Gage pressure of steam at throttle, lb.	164
Temperature of steam at throttle, deg. F.	572
Cooling surface of surface condenser, sq.ft.	592
Amount of cooling water supplied per hour, cu.ft.	2120
Temperature of cooling water, deg. F.	68
Guarantees:	
Indicated English horsepower of engine, normally	320
Indicated English horsepower of engine, maximum	394
Steam consumption per English i.hp.-hr., lb., at normal load	10.5
Steam consumption per English i.hp.-hr., lb., at maximum load	11.2
Mechanical efficiency of engine, per cent., at normal load	89
at maximum load	90

As for guaranteed efficiency of the exhaust-steam oil separator, the amount of oil remaining per thousand pounds of condensate was not to exceed 0.003 lb.

Results:	
Horsepower indicated	275.9
Revolutions per minute	95
Gage pressure of steam at throttle, lb.	160
Temperature of steam at throttle, deg. F.	576.3
Receiver pressure, inches mercury	5.7
Vacuum, inches mercury	27.6
Duration of test, hr.	4.8

The steam consumption of the engine was found to be 2888 lb. per hour. In calculating the indicated horsepower from the diagrams due allowance was made for the expansion of the cylinders under working temperature. The result was 275.9 i.hp. Accordingly, the steam consumption per indicated horsepower-hour during the test was

$$\frac{2888 \text{ lb.}}{275.9} = 10.47 \text{ lb.}$$

The coal consumption per i.hp. per hour was

$$\frac{10.47}{7.68} = 1.363 \text{ lb.}$$

This consumption, it will be noted, was obtained while the pressure of admission and the load were slightly below the figures stipulated in the contract. The normal indicated horsepower of 320 was not developed because the attached ammonia compressors and auxiliary machines required less than 320 i.hp. Diagrams show that the engine is easily capable of developing 320 i.hp., and will not at this load exceed the consumption guaranteed. By lengthening the cutoff the maximum power of 394 i.hp. may be obtained.

TESTS OF COLD STORAGE AND ICE PLANT

Of the two double-acting opposed Borsig ammonia compressors coupled to the engine one and one-half compressor cylinders operate on the cold-storage plant, cooling brine to 14 deg. F., while the fourth compressor cylinder half operates on the ice-making tank, cooling brine to about 19 deg. F. The refrigerating capacity of the one and one-half compressor cylinders was ascertained by measuring with Poncelet nozzles the column of circulating brine cooled per hour through an observed range of temperature. The fourth compressor-cylinder half as well as the single compressor of the reserve engine were indicated to ascertain their working conditions and refrigerating capacity.

Dimensions and Conditions Imposed:	
Diameter of ammonia compressors, in.	12.992
Piston-rod diameter (no tail rod)	3.643
Stroke, in.	23.622
Revolutions per minute	95
Exterior pipe-cooling surface, sq.ft. in brine-cooling tank	3,229
in ice-making tank	1,292
in ammonia liquid cooler	291
in atmospheric ammonia condenser	4,338
Temperature of circulating brine in tank, deg. F.	14
Temperature of brine in ice tank, normal, deg.	19.4
Temperature, initial, of condenser water, deg.	50.0
Temperature of liquefaction of ammonia, deg.	71.6
Temperature of under-cooled ammonia, deg.	52.7

Guaranteed tons refrigerating capacity of one compressor when cooling brine to 14 deg. F. equals

$$\frac{185{,}000 \text{ calories per hour}}{3023.95} = 61.2 \text{ tons.}$$

Same for one and one-half compressor cylinders, tons	91.8
Guaranteed daily ice-making capacity of one compressor-cylinder half from distilled water cooled to 53.6 deg. F., lb.	44,000
Indicated horsepower of one compressor when cooling brine to 14 deg. F.	57.2
Indicated horsepower of one compressor-cylinder half, cooling brine to 19.4 deg. F.	33
Consumption of 50-deg. F. condenser water, gal. per min.	265

The power consumption expressed in horsepower was as follows:

One and one-half compressor cylinders, cooling brine	85.8
One-half compressor cylinder making ice	33
Steam-condenser pump	4.4
Water-supply pump	20.5
Brine-circulating pump	9.7
Brine-circulating pump	8.8
Generator, $\frac{70 \text{ kw.} \times 1.34}{0.925}$ =	101.5
Losses in transmission	29
Total	292.7

Dividing by 0.89, the mechanical efficiency, the indicated engine horsepower necessary according to the guarantee is 328.4.

Capacity of brine-circulating pump for brine-wetted air-cooler, per min., gal.	396.5
for frosted air-cooler, per min. gal.	396.5
Current consumption of ice crane, kw.	2.5
Current consumption of fans, kw.	13.5

Results of tests made Oct. 18 to 21, and Nov. 21, 1913. Refrigerating capacity of one and one-half compressor cylinders:

Quantity of brine circulated per min., gal.	543
Heat capacity per gal. of salt solution per deg. F. temperature rise, B.t.u. = $\frac{62.35 \text{ lb.} \times 0.946}{7.4805}$ =	7.88
Temperature of incoming brine, deg. F.	19.9
Temperature of outgoing brine, deg. F.	13.8
Temperature reduction of brine, deg. F.	6.1
Heat abstracted from brine per min., B.t.u. 543 × 7.88 × 6.1 =	26,100
Corresponding tons of refrigeration performed by one and one-half compressor cylinders, $\frac{26{,}100}{200}$ =	130.5

Excess capacity of the one and one-half compressor cylinders over the capacity guaranteed = 130.5 — 91.8 = 38.7 tons, or 42* per cent.

In connection with this brine-cooling test the following interesting temperatures were noted:

Temperature of ammonia at suction pressure, deg. F.	5
Corresponding gage pressure, lb. per sq.in.	19.1
Temperature of ammonia in suction pipe of compressor No. 1, which operates with the same suction pressure in both ends, deg. F.	4.1
Temperature of ammonia in suction pipe of compressor No. 2, only one-half of which operates on the brine tank, deg. F.	6.3
Corresponding gage pressure, lb per sq.in.	20.2
Temperature of saturated ammonia at discharge pressure, deg. F.	74.6
Corresponding gage pressure, lb. per sq.in.	125.5
Temperature of ammonia in discharge pipe No. 1 compressor, deg. F.	187.7
Extent of superheating, deg. F., 187.7 — 74.6	113.1
Temperature of ammonia in discharge pipe of No. 2 compressor, deg. F.	182.2
Temperature of liquid ammonia leaving aftercooler, deg. F.	54.4
Temperature of ammonia entering brine-cooling coils, deg. F.	14.6
Temperature of ammonia vapor at inlet to atmospheric condensers, deg. F.	148.8
Temperature of liquid ammonia leaving condensers, deg. F.	65.4
Temperature of cooling water,	
to liquid ammonia cooler, deg. F.	48.9
from liquid ammonia cooler, deg. F.	55.8
leaving ammonia condenser, deg. F.	65.4

Under the above conditions the double compressor (with cylinders Nos. 1 and 2) was running at 94.5 r.p.m., and the

*The amount of this excess capacity suggests the possibility of error in the quantity or specific heat of the brine.

diagrams taken showed the following indicated horsepower:

Compressor No. 1, working full..	78.85
Compressor No. 2, one end only..	39.16
Total indicated horsepower..	118.01

Thus the indicated compressor horsepower per ton of refrigeration in cooling brine to 14 deg. F. was

$$\frac{118.01}{130.5} = 0.904 \text{ per ton,}$$

while the guaranteed power consumption had been equivalent to

$$\frac{57.2}{61.18} = 0.935 \text{ i.hp. per ton refrigeration.}$$

The piston displacement (area × stroke × r.p.m.) of compressor No. 1 is as follows.

$$12.992^2 \times 0.7854 = 132.6 \text{ sq.in.}$$

less one-half the area of the rod or 4.93 equals 132.6 — 4.93 = 127.67 sq.in., which, times the stroke of 23.6 in., is 3013 cu.in.; and this multiplied by 94.5 × 2 strokes = 569,500 cu.in. as the displacement of the cylinder.

The brine-cooling half of compressor No. 2 has a displacement of 273.900 cu.in., and the total for the one and one-half cylinders is 843,400 cu.in. per minute.

Thus the piston displacement per minute per ton of refrigeration when cooling brine to 14 deg. F. was 6419 cu.in.

The piston displacement of the head end of compressor No. 2, making ice, is 3132 cu.in., which times 94.5 strokes gives 296,000 cu.in. per minute, or 40 tons of refrigeration when cooling brine to 14 deg. F.

Since it requires, with the water available, at most 1.6 tons of refrigeration to produce one ton of ice, the ice-making capacity of this compressor-cylinder half is 28.7 tons in twenty-four hours, or 26.3 tons for twenty-two hours' operation daily. The guaranteed capacity of 22 tons is, therefore, exceeded.

The indicated horsepower of the fourth compressor-half when cooling brine to 14 deg. F. was 39.65, equivalent to

$$\frac{39.65}{28.7} = 1.38 \text{ i.hp. per ton of ice,}$$

which corresponds to 1.55 i.hp. in the steam cylinder of the engine.

During the brine-cooling test the cooling water was supplied by the electrically operated volute pump located in the boiler house. The quantity delivered at 1985 r.p.m. was found to be 252 gal. per min. Consequently more than the normal quantity of work was done with less water than the 268 gal. allowed under the guarantee.

The power indicated at the main engine was 283.32 i.hp., and the total power consumption of the establishment was but 9 per cent. more than was guaranteed.

The delivery capacity of the deep-well pump also was checked by noting whether the water level in the receiving basin remained constant while the cooling-water pump was discharging to the condensers at the rate of 268 gal. per min. It was found that even then some water returned to the wells, consequently the well pump was fully up to the capacity guaranteed.

The various features of special interest in the plant are the consistent use of reserve machinery, the obtaining of all power from one economical engine using superheated steam, making ice as a byproduct from exhaust steam, the efficient boiler plant, also the comparatively high rotative speed of the compressors (95 r.p.m., against 80 to 60 in this country). The low coal consumption and low power consumption lead to an unusual economy in the ice-making department. The coal consumption per indicated horsepower-hour was 1.365 lb., or 32.76 lb. per twenty-four hours. This, multiplied by 1.55 i.hp. per ton ice, equals 50.8 lb. Increasing this by 33⅓ per cent. to cover all possible auxiliaries, the total is 67.7 lb. Thus the number of tons of ice made per ton of coal fired is

$$\frac{2000}{67.7} = 29.5.$$

In American plants 10 tons of ice per ton of coal is considered quite satisfactory. It must be remembered in this connection that the initial temperature of the cooling water was 50 deg. F., the suction pressure nearly 20 lb. gage, and the condenser pressure only 126 lb. gage. The remarkable economy of this plant is directly traceable to these favorable operating conditions and to the use of a compound condensing engine using highly superheated steam for driving the compressors and for all the auxiliaries of the plant. The required distilled water for filling the ice cans was obtained only because the refrigerating effect needed to make the ice was only 26 per cent. of the total refrigerating effect produced by the two compressor cylinders. The total amount of steam passing through the engine was 34 tons per day, which, after deducting the water of condensation and other losses, would not have yielded quite enough distilled water for making the maximum of 29.5 tons of ice per day.

An Eight-Cylinder Gasoline Engine*

By Henri G. Chatain†

The object of this paper is to describe and discuss the features of design of an eight-cylinder, four-stroke cycle gasoline engine, which has been developed during a number of years for railway traction.

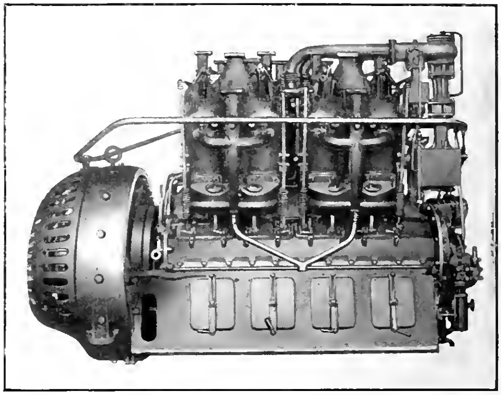

Fig. 1. Side View of Eight-Cylinder Engine

The problem was to design a complete motor car for branch railway service, of sufficient size for seating fifty passengers and a small baggage compartment, etc., and capable of attaining a maximum speed of 50 miles per hour on level track. The first design included an eight-cylinder V-type, 90-deg. engine, with cylinders 7½x8 in., and running normally at 550 r.p.m. This operated commercially in a little car on a Western road until quite recently, when it was destroyed by fire. The second attempt was a larger and heavier engine of essentially the same type. This was run experimentally in service 50,000 miles in one year on various roads, and served its purpose admirably in showing up some glaring defects, among which were the following:

Fig. 2. Timing Diagrams

1. The exhaust valves needed regrinding once a week, as they were unduly distorted and burnt.
2. The camshaft and valves were extremely inaccessible.
3. It was uncommercial to make the cylinders sufficiently strong.
4. It was difficult to mount the engine in the car so as to take care of the horizontal component of the reciprocating forces; hence, there was vibration.
5. The total width of the engine was excessive.

With these facts at hand and an ever-increasing demand for more power, the third and present engine, which fulfilled expectations and met conditions, was designed. Fig. 1 gives

*From a paper presented before the Society of Automobile Engineers.
†Engineer, Gas Engine Department, General Electric Co.

an idea of its construction. To overcome the first difficulty mentioned, auxiliary exhaust valves with port entrance to the cylinders were embodied in the design. The cams actuating these valves are so laid out that the valve is entirely free of its seat when the piston passes the port opening. The timing is shown in the diagrams of Fig. 2. This arrangement

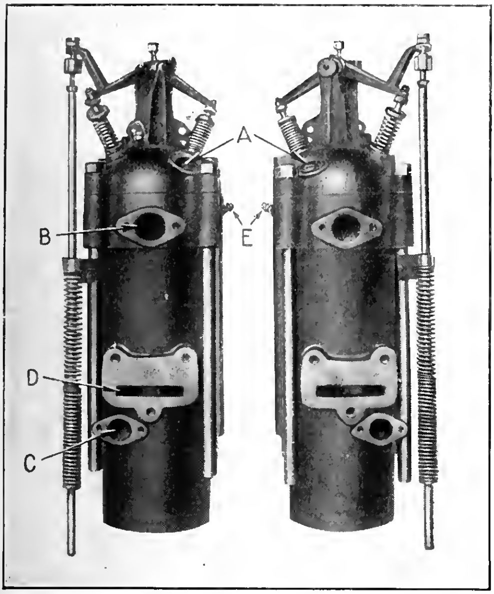

FIG. 3. SHOWING CYLINDER CONSTRUCTION

has worked well, and the auxiliary valves need practically no attention except about once a year. The exhaust valves in the head need to be ground about every 50,000 miles.

The second change was the relocation of the camshaft due to its inaccessibility, and also because the stroke of the engine was to be lengthened. Two externally located camshafts

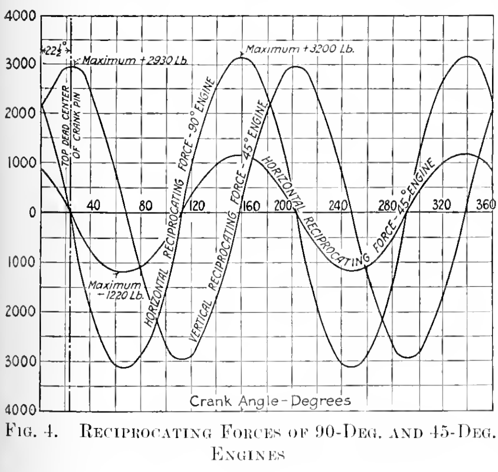

FIG. 4. RECIPROCATING FORCES OF 90-DEG. AND 45-DEG. ENGINES

were decided upon, with the cams, shafts, etc., running in a bath of oil. One actuates the auxiliary exhaust valve, and the other imparts the proper motion to the long push rod extending to the top of the cylinder and connected to the intake and exhaust valves.

In an engine of this size the L-head form of cylinder had little to recommend it. The castings had to be made very heavy, otherwise they would crack; and heavy castings interfere somewhat with the cooling. Extremely strong construction at this point was essential. Fig. 3 shows the form of cylinder construction adopted, namely, a barrel, a head and valves contained therein, held down to the base by long studs. Note that the water-circulating systems of the head and the barrel are distinct. The arrangement of two valves actuated from one cam is quite satisfactory at 500 to 600 r.p.m. With higher speeds the design would be unsatisfactory, as the mass of the moving parts would necessitate unduly high spring pressures. In Fig. 3, A indicates the make-and-break spark plugs, E the air-starter valves, C and B the water inlets, and D the exhaust ports.

A 45-deg. angle between the rows of cylinders was decided upon, to decrease the horizontal component of the reciprocating forces as well as the overall width. Thus each cylinder is set 22½ deg. from the vertical.

The crankshaft has four crankpins, of which the two outer are 180 deg. from the two inner pins and two pistons are attached to each pin. The connecting-rods are mounted side by side on each crank. It was thought advisable to adopt this construction for mechanical simplicity. The piston-pins are held fast in the rods and find their bearings in the piston proper. No bushings are used.

The reciprocating forces for one cylinder along its axis are

$$0.0000284 \times W \times r \times N^2 \left(\cos\theta + \frac{\cos 2\theta}{n}\right) \text{ lb.}$$

W = Weight of reciprocating parts = 59 lb.;
r = Crank throw in inches = 5;
N = R.p.m. = 550;
n = Length of connecting-rod divided by throw of crank = 4.5;
θ = Crank angle in the direction of rotation from top dead center of piston.

Fig. 4 shows the reciprocating forces for this engine represented graphically and compared with the 90-deg. cylinders.

The specifications of this engine are as follows:

Cycle		4
Number of cylinders		8
Revolutions per minute		550
Bore		8 in.
Stroke		10 in.
Displacement		503 cu.in.
Valve area:	Inlet	7.07 sq.in.
	Exhaust	4.91 sq.in.
Valve lift		½ in.
Mean velocity of air in intake pipe		7100 ft. per min.
Exposed radiating surface per cylinder:	Max	384 sq.in.
	Min	133 sq.in.
Projected bearing surface:	End	24 sq.in.
	Center	15 sq.in.
Section of connecting-rod:	Max	2.58 sq.in.
	Min	1.57 sq.in.
Number of bearings		5
Length of cylinder		23⅛ in.
Length of piston		11⅝ in.
Piston-pin center below piston top		5⅝ in.
Number of rings		6
Ring size		½ in.
Ring spacing		¼ in.
Length of connecting-rod, c. to c.		22½ in.
Diameter of piston-pin		2 in.
Diameter of shaft		4 in.
Length of end bearings		6 in.
Length of center bearings		3¾ in.
Number of camshaft bearings		4
Length of camshaft bearings		2½ in.
Diameter of camshaft		1½ in.
Cylinder-wall thickness		½ in.
Water space around cylinder		¾ in.
Height overall		6 ft. 3⅝ in.
Length less generator		7 ft
Length including generator		9 ft. 3 in.
Width overall		4 ft. 7¼ in.

Alaskan Coal

Last year a sample of coal from the Bering River field in Alaska was tested by the Navy Department and found to be unsatisfactory for the use of the navy. A test has since been made with coal from the Matanuska field, of which Admiral Griffin says:

Unlike the tests that were made with Bering River coal last year, it was not necessary to hand-pick the Matanuska coal for the purpose of these tests. It was used in the same condition as when delivered, and the results are so satisfactory as to justify the belief that Matanuska coal is in all respects satisfactory for navy use, provided the coal tested is a thorough indication of the general character of the coal in the field.

Secretary Daniels said at a recent hearing that it compared favorably with the best steaming coal that the navy has, and that it was put down at 97 per cent. against 100 for the best coal.

Behavior of Riveted Joints under Stress*

By James E. Howard

The efficiencies of riveted joints under rupturing tensile stresses constitute the values on which working loads are commonly based. Alleged factors of safety are employed, fortunately not less than five on important work, because a fairly good distribution of load is not always characteristic of riveted construction. The most important feature, however, is in the elastic behavior of the joints, which appears to be ignored. As a matter of fact, few riveted structures are free locally from strains which do not exceed the elastic limit of the material. The structures are not necessarily endangered by the presence of such overstrains, as this will depend upon the character of the work to be performed. Multiple-riveted, double butt-strap joints may have a degree of rigidity equal to or even in excess of the solid plate for comparatively low tensile or compressive stresses, but loads ranging from, say, 15,000 to 25,000 lb. per sq.in. commonly show a material divergence in the behavior of a joint over that of the solid plate.

When frictional resistance contributes toward the initial rigidity of the joint, it is uncertain whether the favorable showing of the joint in the laboratory test is realized and maintained under service conditions. Vibratory effects and changes in temperature seem likely to cause a creeping of the plates and disturb the initial state of the different plies, when taken in conjunction with a constant load, or, it may be more marked, in the case of alternate stresses.

Referring specifically to the strength of those parts on which reliance is placed in the design of a riveted joint, first comes the tensile strength of the plate taken as a whole; next to this the strength of the steel between the rivet holes—that is, on the net section. On the latter section the strength per unit of area is not the same with different pitches. It may be greater or less than that accredited to the gross section per square inch It is also modified according to whether the holes are drilled or punched, and may be greater in one case or the other according to the distance from rivet hole to rivet hole. It is not likely that the strength with punched holes will be greater than with drilled holes in practice, since very closely pitched work is required to bring about such a result. The reason, however, that a punched plate may display greater strength than a drilled one is found in the hardening of the steel by the punch and die at the sides of the holes.

The tensile strength on the net section of the plate is usually greater than on a strip of uniform width several inches in length. The increased area of metal on each side of the center line passing through the rivet holes has a reinforcing effect on the net section of the plate. This gain in strength is a substantial one in single-riveted work, and in multiple riveting when the same pitch is maintained in the different rows. The reinforcement is greater in close-pitched than in wide-pitched riveting, and is at the sides of the holes, but if they are very far apart there results a loss instead of a gain. The reinforcement is therefore not a fixed amount, but depends upon the proportions of the joint.

When the pitch has been considerably increased, as in butt joints with double covers, in which one strap is considerably wider than the other, joints which fail by the rupture of the plate not infrequently show a diminution in strength on the net section, and the plate tears apart at the outside row of rivet holes. The presence of a few rivets, widely spaced, in the outside row promotes tearing of the plate, the line of rupture starting at a rivet hole and reaching an advanced stage before the plate at the middle of the pitch is separated.

Tests on staggered riveting have shown a tendency for the plate to draw down along shearing planes, obliquely to the direction of pull, encountering a rivet in the adjacent row. That is, the design of the joint was such that those in adjacent rows occupied critical positions with reference to each other, and while the zigzag path from one row to the other was longer than from rivet to rivet of the same row, nevertheless the plate showed a preference to fracture along this greater length, and the interposition of rivets in the second row in critical places was a probable source of weakness.

Chain-riveted work creates a favorable impression when observing and comparing the behavior of different types of joints under test. The distance between rows in chain riveting admits of being very much reduced over current practice without impairing the ultimate strength of the joint.

It will be of interest to refer to the strength of riveted joints at higher temperatures. Under exceptional circumstances the joints of steam boilers might be exposed to temperatures considerably above that due to the steam pressure. Joints have been tested up to a temperature of 700 deg. F., and the strength was found to follow the law which governs that of plain steel bars at different temperatures. There was a drop in strength at 200 deg., followed by an increase, which reached a maximum at about 500 deg., after which the strength fell off. Among the several joints tested at 500 deg. the maximum gain over the cold joints was 27.6 per cent. The shearing strength of the rivets showed an increase at the higher temperatures. Furthermore, it was found that joints which were overstrained at these higher temperatures, even beyond the limits of duplicate cold tests, when subsequently tested to destruction at ordinary temperatures, retained substantially the strength which they had when hot. There was some loss in the ductility of the steel, but without approaching a state of brittleness.

So much for the ultimate strength of riveted joints. Attention must be given the behavior of the joints under stress and whether the working loads are constant or variable, direct or reversed stresses, and in the case of repeated stresses, how many repetitions there will be and the maximum stresses involved. The examinations of some stress-strain curves prepared from earlier tests shows that the joints in general take a wide departure from the curve representing the solid plate, this being noticeable at 15,000 lb. per sq.in., and in some joints as early as at 10,000 lb. This was true with joints having efficiencies of 70 to 80 per cent. Among the joints thus compared were double- and triple-riveted butt joints and quintuple joints in which the inner butt strap was wider than the outer one.

Under 15,000 lb. per sq.in. the joints, in general, displayed an extension one and a half times to over twice the extension of the solid plate. These joints were of the types which are used in steam boiler construction. Observations on the behavior of double-riveted lap joints on some steam boilers which had been in service showed greater extension across the longitudinal seams at the middle of the sheets than in the vicinity of the girth seams.

It is of interest whether riveted seams retain their primitive state under prolonged service stresses or whether they do not slip and eventually display increased extensions under lower loads than suggested by the laboratory tests. From the limited number of observations made it cannot be said that the rigidity of joints on actual structures is greater than would be expected. If there is a difference, they are probably less rigid in actual structures.

The frictional resistance due to the shrinkage of the rivets is apparently a factor in the early behavior of a joint. Whether this force drawing the plates together is acting to its full extent will depend upon the manner in which the riveting is done. A limited range in temperature in cooling is sufficient to apply a contractile force equal to the elastic limit of the rivet metal. But since the hot rivet metal has a very low elastic limit it is necessary to hold the plates together firmly until the rivet has cooled to nearly its final temperature. This requirement is an obstacle to rapid driving, but full efficiency in frictional resistance between the plates requires its observance.

*From a paper presented at the twenty-second general meeting of the Society of Naval Architects and Marine Engineers.

A Coal Treatment Alleged to Be Advantageous—There has recently been in Germany quite a flood of preparations put upon the market for the purpose of making a brew in which coal or coke is to be wetted before being put upon the fire. The alleged result of using these preparations is that the coal burns more readily and that there is a great saving in the amount of fuel required. Herr T. Oryng, of the laboratory of the Berlin Fermentation Institute, has analyzed a number of these preparations and found them to consist of various salts, such as sulphate of magnesia, sulphate of soda, common salt, nitrate of soda, and so on, generally with a small proportion of oxide of iron. He concludes that they cannot have the effects attributed to them.—Foreign Exchange.

Create the Opportunity

THE *man who "makes good" usually has to create his own opportunity.*

□ □ □

We often hear it said: "Wait until the opportunity offers itself." Many men are still waiting. Many men will be waiting when they are old and gray.

We might as well say to a salesman: "Wait until business offers itself! Wait until business comes to you!"

The successful salesman is he who creates his own business; his own opportunity, in other words. He is the man who uses his head, and gets all there is out of his own faculties, education and energy.

In a like manner the successful engineer or the successful man in any other job is he who creates his own opportunity—make yourself so valuable to your employer that he cannot do without you.

When this point is reached you are on the road to advancement and success.

A man may arrive at his work before the whistle blows in the morning—he may not leave until after it blows at night.

Yet—he does not earn his salary if his mind is not on his job. And even if opportunity does knock at his door he will be asleep and it will pass on to the next fellow. But, *you* are as good as the next fellow if you only realize it.

Therefore:

Wake up! Put your mind to your work! Think! Be a little bigger than your job! Create an opportunity! You can do it—and the future will be bright and rosy.

[*Written by K B Lamb, New York City.*

Kalamazoo Municipal Plant

By Thomas Wilson

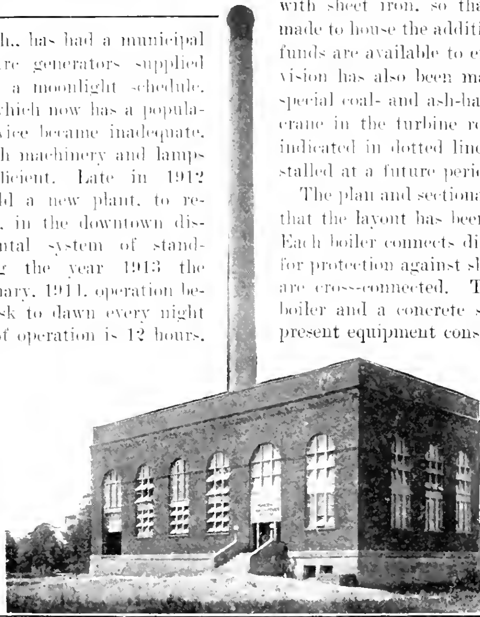
SYNOPSIS—Modern 1200-kw. plant, arranged on the unit plan, supplies current for street lighting and eventually will enter the commercial field. Cost of installation and operating expense. A feature is a provision to utilize auxiliary exhaust steam in the lower stages of the turbines.

Since 1895 Kalamazoo, Mich., has had a municipal plant for street lighting. Arc generators supplied about 100 lamps operated on a moonlight schedule. With the growth of the city, which now has a population of about 15,000, the service became inadequate, and after 17 years of use, both machinery and lamps were out of date and inefficient. Late in 1912 the city issued bonds to build a new plant, to rehabilitate the arc system and, in the downtown district, to install an ornamental system of standard five-light units. During the year 1913 the plant was erected and in February, 1914, operation began. The service is from dusk to dawn every night and the average daily period of operation is 12 hours.

The plant is near the Kalamazoo River, so that an abundant supply of cooling water is available for the condensers. As boiler feed it is used only when the city supply fails, as the river water is muddy and contains acid from the discharge of paper mills. A spur from the Michigan Central R.R. enters the property to facilitate coal delivery.

The exterior of the building (Fig. 1), which rests on concrete foundations, is built of brick supported by steel framework and is covered by a flat concrete roof. Its present dimensions are 52x100 ft. and one end is sealed with sheet iron, so that an extension may be easily made to house the additional equipment necessary when funds are available to enter the commercial field. Provision has also been made for overhead coal bunkers, special coal- and ash-handling systems and a traveling crane in the turbine room. These improvements are indicated in dotted lines in Fig. 5. They will be installed at a future period.

The plan and sectional elevation, Figs. 5 and 6, show that the layout has been arranged on the unit system. Each boiler connects directly with a turbine, although for protection against shutdown the steam-supply pipes are cross-connected. There is a feed pump for each boiler and a concrete stack serving both units. The present equipment consists of two boilers rated at 310 hp. each and two 600-kw. turbo-generators with their condensers and auxiliary equipment. For each kilowatt of turbine there is 0.52 boiler horsepower. At rating each turbine alone calls for 9720 lb. of steam per hour. The steam is supplied at 200 lb. gage pressure and an average



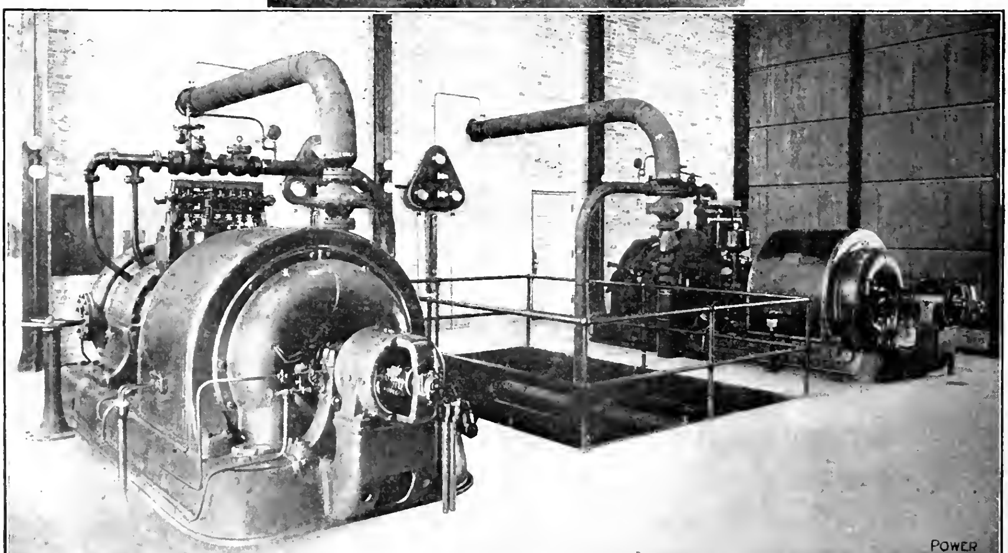


Fig. 1. Exterior of Kalamazoo Municipal Lighting Plant. Fig. 2. The Two 600-Kw. Generating Units

superheat of 150 deg. The cost of the installation is given in Table 1:

TABLE 1—COST OF STATION

Building, site and engineering fees	$40,384
Stack	2,850
Piping	5,686
Equipment	46,643
Total	$95,563

Cost per kilowatt of turbine capacity, $79.64.

The various items include all labor and installation charges, but the amount charged for equipment does not take into account the cost of rectifiers, lamps, or other apparatus belonging to the lighting system proper. Omitting the building and engineering fees, the cost per kilowatt reduces to $46. At present the building item is top-heavy, but the additional capacity soon to be installed will reduce the unit cost considerably.

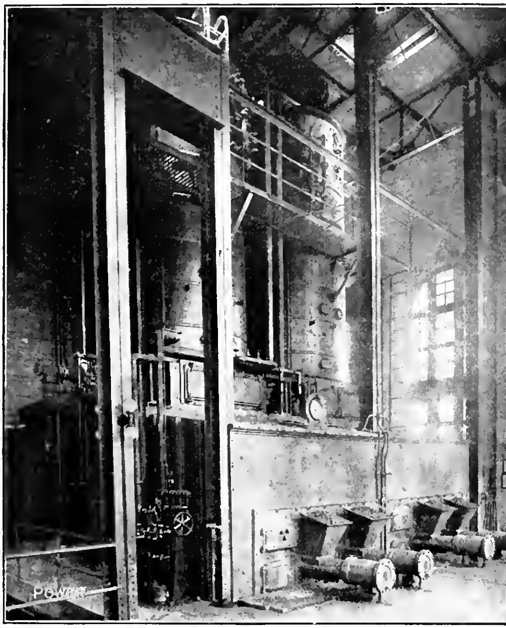

Fig. 3. Vertical Water-Tube Boilers and Underfeed Stokers

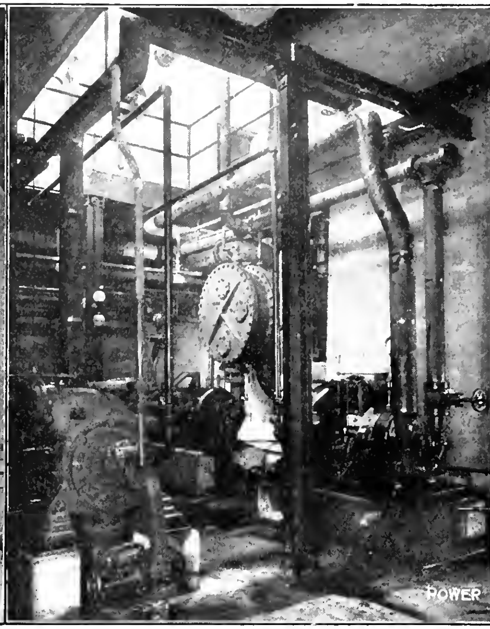

Fig. 4. Condenser Auxiliaries in the Condenser Pit

Boiler Room

Vertical water-tube boilers were selected. Each has 3089 sq.ft. of heating surface and 104 sq.ft. in the superheater. As shown in Fig. 3, underfeed stokers serve the boilers and forced draft is supplied by a 110-in., three-quarter-housed steel-plate fan driven by either one of two vertical engines, one on each side of the fan. The speed of these engines, and consequently the draft, is controlled indirectly by the steam pressure through automatic regulators. The stack rises 145 ft. above the boiler-room floor. The inside diameter at the bottom is 8 ft. and a taper of 1 in. to every 5 ft. reduces it at the top to 5 ft. 6 in.

At present the coal is stored in a temporary shed. It is loaded into a car which passes over a platform scale on its way to the stokers. The ashes are wheeled out and disposed of on the premises. Much better facilities have been provided for the ultimate construction. The plant is to have a wet coal storage into which the coal will be dumped from railroad cars. A gantry crane with a grab bucket will pick up the coal and deliver it through the roof into overhead coal bunkers, each having a capacity of 85 tons. Automatic scales and a chute to each stoker hopper will complete the equipment. Ashes will be discharged into a hopper underneath the boiler-room floor thence into an ash car. The latter will be wheeled to the end of the building, raised by a hydraulic hoist to the first floor and its contents will be delivered to a section of the coal-storage pit reserved for the purpose. The crane can then be used to load the ash into the cars which deliver the coal.

West Virginia slack averaging about 13,000 B.t.u. per lb. is the fuel burned. It is bought on the B.t.u. basis established by the Bureau of Mines and the cost is close to $2.50 per short ton.

Generating Units

Horizontal four-stage turbines of the velocity type drive three-phase, four-wire generators at a speed of 3600 r.p.m. (Fig. 2). Sixty-cycle current is supplied at a voltage of 2300 or 4000, and the rating of the turbines at 80 per cent. power factor is 600 kw.

The steam-supply pipes to the turbines are 5-in. diameter, and with a rate of 16.2 lb. per kw.-hr. at normal load, 9720 lb. of steam per hr., or 162 lb. per min., must flow to the turbine. At 200 lb. gage pressure and 150 deg. superheat, the volume of this amount of steam is 434.16 cu.ft. The velocity of the steam in the supply pipe is then

$$434.16 \div 0.1389 = 3126 \ ft.$$

or, in round numbers, 3100 ft. per min. For a turbine this velocity is low. A supply velocity of 8000 ft. per min. is not uncommon in the present-day practice. A smaller supply pipe could have been used, but in the present case the saving in first cost would have been negligible.

Each turbine is served by a three-pass surface condenser having 1600 sq.ft. of surface. This is an allowance of a 16-hp. turbine at 4000 r.p.m. and a 7-in. circulating pump capable of delivering 1200 gal. per min. The latter is driven by a 25-hp., 440-volt motor which receives its current from the generator leads through a step-down transformer. This connection was made to facilitate starting and to insure the presence of cooling water as

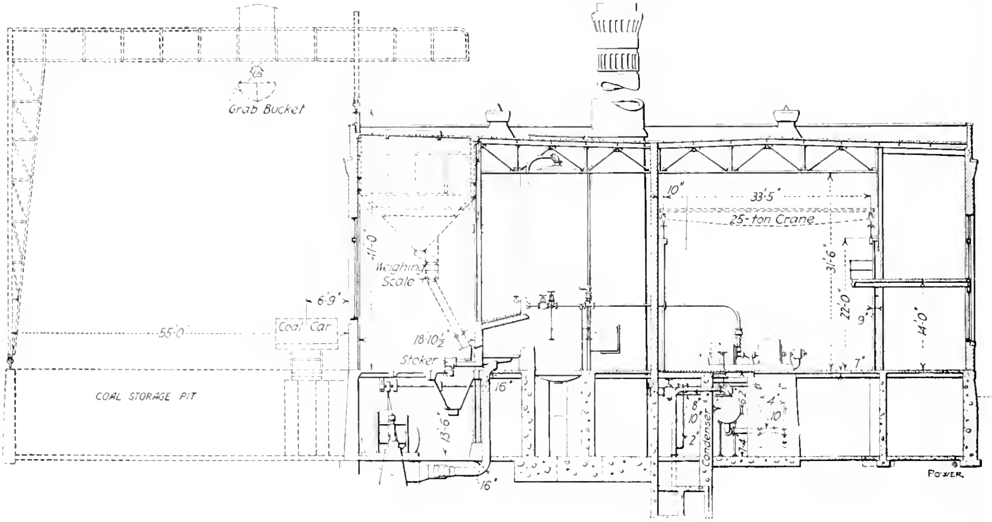

FIG. 5. SECTIONAL ELEVATION THROUGH STATION, SHOWING PROPOSED COAL- AND ASH-HANDLING FACILITIES

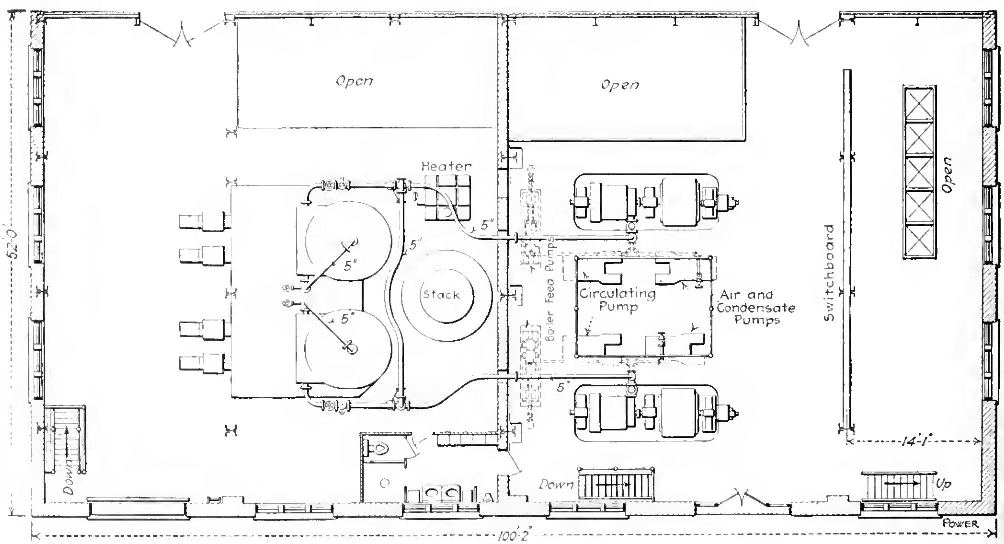

FIG. 6. PLAN OF THE STATION

$2\frac{2}{3}$ sq.ft. of surface per kilowatt of turbine rating. At 28-in. vacuum and with 75-deg. cooling water, the condenser is guaranteed to care for 8500 lb. of steam per hr. This reduces to 5.3 lb. of steam per sq.ft. of condensing surface. The auxiliaries (Fig. 4) are a combined air and condensate pump of the radial jet type driven by soon as the main unit is put into operation. It was thought that one steam and one electrically driven auxiliary would make a more flexible outfit than two similar units. From the feed pumps, stokers, fan engines and the turbines operating the air pumps there would be more than enough exhaust steam to heat the feed water, and turbine-driven circulating pumps would only increase the surplus.

Turning Exhaust Steam into Turbines

To utilize the exhaust steam from the sources just mentioned to best advantage, the ingenious plan shown in Fig. 7 has been adopted. Each of the steam-using auxiliaries discharges into a common exhaust system which enters the feed-water heater and is also tapped into the fourth stages of the main turbines. To the latter automatic regulating valves control the supply, and check valves prevent steam flowing from the turbines to the exhaust system. The heater uses as much steam as it requires. Any excess builds up the pressure in the system, and when it exceeds the pressure at the points of entrance to the turbines, the automatic valves open and admit the surplus. This usually occurs when the turbine is carrying a light load. A back-pressure valve opening to the atmosphere protects the system.

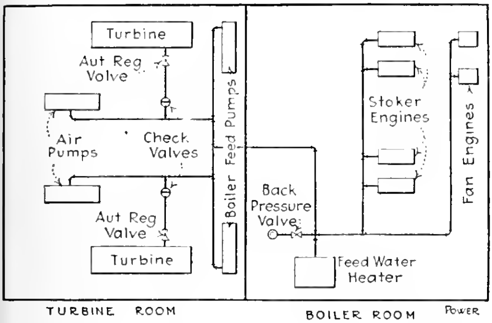

Fig. 7. Piping for Utilizing Exhaust Steam

In another plant this idea has been completed by the same engineers so that exhaust steam may enter the turbine or steam may pass from the turbine to the exhaust system, depending on the relative pressures. The connections are shown diagrammatically in Fig. 8. Two back-pressure valves are employed. The one at *A* opens toward the turbine and valve *B* toward the exhaust system. These valves are set at approximately 2 lb. pressure. If the turbine is heavily loaded and the pressure at the point of entrance is relatively high, valve *A* must remain closed and valve *B* will admit steam to the system. With conditions reversed and the pressure greater in the system, valve *A* opens and admits steam to the turbine. As usual, an atmospheric relief valve set at a higher pressure than the other valves, affords protection against a possible emergency.

Switchboard and Line

Fig. 9 shows the front of the switchboard, which has 11 black-slate panels and four double blue Vermont arc panels set out 14 ft. from the wall. The board is equipped with the latest instruments and provides for remote control. Back of the board are the oil switches, instrument transformers, etc., mounted on pipe framework, and four of the mercury arc rectifiers. There is a total of eight 75-light outfits, four being in the basement. It will be noticed in Fig. 10 that the wiring is unusually neat and accessible and that there are free passageways immediately behind the board and between the switches. Fig. 11 is a view in the basement showing rectifiers, cut-outs and the entrance of the cables into the underground ducts. About 225 ft. from the station the cables are brought up through iron-pipe risers to a terminal tower and by means of flexible jumpers are connected to the pole line leads.

The 534 luminous arc lamps, each taking 4 amp. at 80 volts, are hung on 12-ft. mast arms and are equipped with a special cutout to protect the trimmer against the high voltage of the circuits. These arcs serve the residence district, the business center being lighted by 234 ornamental five-light posts spaced 75 ft. apart on both sides of the streets. The top lamp of each cluster is rated at 100 watts and the four side lamps take 60 watts each. For the illumination of alleys there are 41 four-ampere tungsten lamps. The city hall is also lighted by the plant.

Operating Costs

As previously stated, the plant is operated from dusk to dawn every night in the year, irrespective of the phase of the moon. One boiler is banked through the day, but two shifts of employees are required. Seven men are employed in the plant—one chief engineer, two assistant engineers, two firemen and two day men. The period of daily operation averages 12 hr. and as the entire load is lighting, it remains practically constant. Up to midnight the load averages 280 kw. The lower lamps of the ornamental clusters are then cut out and the load drops to 230 kw. The total kilowatt-hours for the night, then, average 3060. In this, however, the current for the air-pump motors is not included, as the supply to these motors is tapped directly from the generator leads and is not metered.

On an average from Apr. 1 to Sept. 1, 5.85 tons of coal were burned per night; from start to midnight, 5800 lb.:

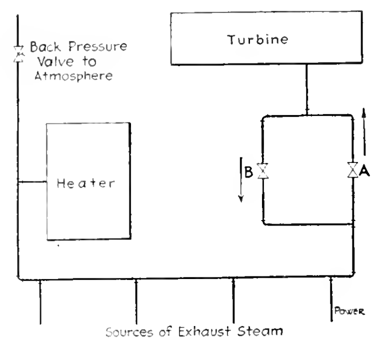

Fig. 8. Improved Arrangement Allowing Steam to Flow to or from the Turbine

from midnight to shutdown, 4800 lb., and 1100 lb. were required for banking. This is an average of 3.82 lb. per net kilowatt-hour. In the above period, containing 153 days, the total money spent on the plant for coal, labor, supplies, etc., was $7249. This figures $47.38 per day, and dividing by the output gives an operating cost of 1.55c. per kilowatt-hour. A fixed charge of 12 per cent. for interest, depreciation, taxes and insurance on an investment of $95,563, the total cost of the plant, amounts to $11,467.56 per year, or $31.42 per day, and, based on the present net load, 1.02c. per kw.-hr. Adding the operat-

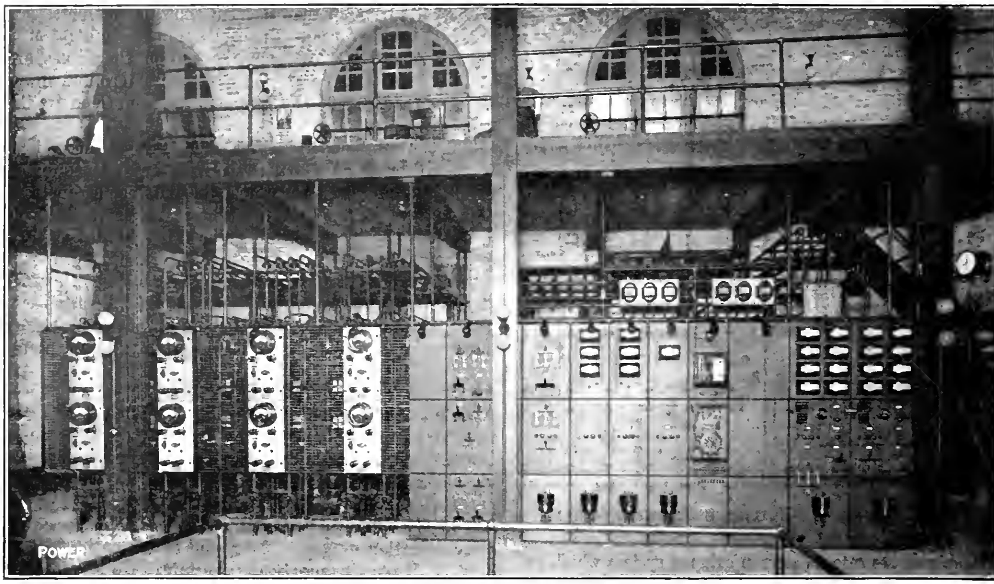

FIG. 9. FRONT VIEW OF SWITCHBOARD AND ARC PANELS

ing and fixed charges gives a total cost of 2.57c. per kw.-hr.

As might naturally be expected, the cost of putting a kilowatt-hour on the line is high, but considering the conditions, the showing is excellent. The plant was designed for a much larger load than it is now carrying, and

TABLE 2—RESULTS OF TESTS ON BOILERS

	Boiler No. 1	Boiler No. 2
Total Quantities, Lb.—		
Total water evap., corrected for losses, lb.	67,054.00	70,938.00

as soon as the city enters the commercial field, it is expected that additional generating capacity will be required. At present only one unit is maintained in operation at less than half load for 12 hr. out of the 24. The overhead expense imposes a heavy burden on small output. The double shifts make the labor cost high, and coal for banking adds to the fuel cost. With a commercial load requiring current during the day, the plant would be kept in continuous operation and the generating units would be operated at about rated capacity. There would be less loss from banking the fires and some returns for the work of the day shift. The total output would be much larger at but little additional expense, so that the cost per unit would be greatly reduced.

is not as high as might be expected, but is attributed to the fact that the boiler was started cold, so that a certain amount of the fuel was required to heat up the setting. The efficiency of 70 per cent. obtained on No. 2 boiler is good, considering the fuel burned, which is West Virginia slack of the analysis given in the table.

The results of the tests on one of the generating units are given in Table 3. The duration of the tests was 8 hr.: 5 hr. at full load, 2 hr. at three-quarter load and 1½ hr. at one-half load. At half load the electrical energy was absorbed in the lighting circuits normally supplied from the generators. For the higher loads a water rheostat was used. The coal consumption during the tests was 2.31 lb. per kw.-hr., as compared to 3.82 lb. obtained

The fuel cost per unit is one of the best indications of plant economy. In the present instance this item approximates ½c. per kw.-hr. For the conditions (coal costing $2.70 per ton, only one unit running and at less than half load, and nearly 20 per cent. of the coal used for banking) this cost is low. It compares favorably with plants of the same or greater capacity running at full load, and indicates what may be expected of the present plant when it is operated under favorable conditions.

Official Tests

That the plant is efficient is shown by the results of the official tests made on May 15 and 16 of this year by representatives of the consulting engineers and the city. Table 2 gives the results of the boiler tests, each of 8-hr. duration. An efficiency of 65.2 per cent. for boiler No. 1

under the present unfavorable operating conditions. The steam consumption at full load was found to be 15.3 lb. per kw.-hr., and when corrected to the guaranteed conditions of 200 lb. steam pressure, 150 deg. superheat and an absolute back pressure of 2 in. of mercury, was 16.2 lb.

The coal burned under the boilers had an average heat value of 12,650 B.t.u. per lb., as fired. An average of 2.31 lb. was required per kilowatt-hour, so that the total heat expended under the boiler to generate a unit of electrical energy was

$$2.31 \times 12{,}650 = 29{,}221.5 \textit{ B.t.u.}$$

One kilowatt-hour is equal to 3412 B.t.u., so that the thermal efficiency of the generating plant is

$$\frac{3412}{29{,}221.5} = 11.67 \textit{ per cent.}$$

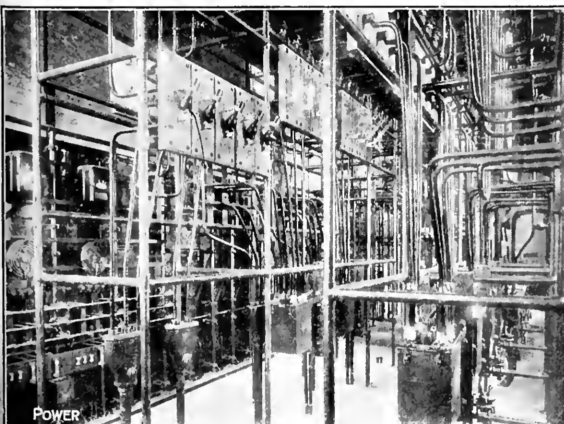

Fig. 10. Switching Chamber at Rear of Board

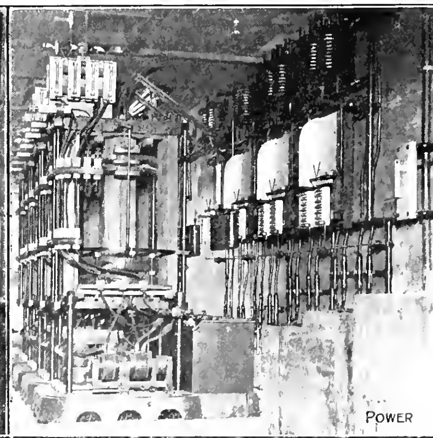

Fig. 11. Rectifiers in Basement and Equipment Protecting Line

For any steam plant of the type and capacity, this is as high a thermal efficiency as can be expected.

It is evident that the plant is uptodate in every respect and can be operated at high efficiency. To reduce the present unit cost, it is merely a question of obtaining enough commercial service to properly load the plant.

E. W. Messany is chief engineer of the plant, and Woodmansee & Davidson, of Chicago, were the consulting engineers responsible for the design and construction of the station.

Return-Pipe Compressed-Air Practice

By Frank Richards

A letter from a California correspondent asks why it is that more has not been made of the Cummings system of compressed-air power transmission. He says that from the results which have been actually attained by the system it could be advantageously employed in many places, especially as, besides the economy of it, there is no danger of fire or explosion, and it can be operated under water.

Notwithstanding that the return-air or two-pipe pumping system, for raising water by the direct pressure of air, is quite extensively and successfully employed in different parts of the country, and that this system has been fully described in various publications, the essential principles of the Cummings system in its entirety are not generally well understood even where it happens to be known at all. Patented a full generation ago, it seems to have been exploited mostly in California, and it may be worth while to call the attention of power users to it again.

It is rather curious that the new departure which this system represents—the use of higher pressures—is quite in line with the improvements in steam engines, in oil engines, especially of the Diesel type, and in electrical practice. It may be claimed, however, that the two-pipe

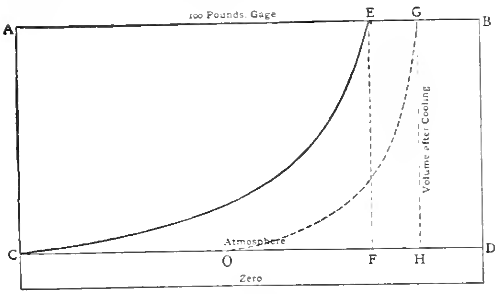

Fig. 1. Air between 0 and 100 Lb. Gage

air system "goes them one better." In the compound- or the triple-expansion steam engine it seems to be the last added portion of the pressure which secures the economy, but the entire range of the pressure from the bottom to the top has all been retained, while the compressed-air system here to be spoken of retains and uses only the higher, and presumably more profitable, range of pressure.

The essential feature of the system is the constant maintenance of a high pressure upon the air employed. Instead of continually compressing fresh atmospheric air up to, say 100 lb. gage, using it in the motor at that pressure, with or without expansion, and then exhausting the air into the atmosphere again, a constant intake pressure of, say 100 lb. is maintained at the compressor. The air is compressed to, say 200 lb., is transmitted to and is used in the motor at that pressure, and then is exhausted and carried back to the compressor at a pressure of 100 lb., to be compressed and used again, and so on.

Different Pressure Ranges Compared

The accompanying diagrams, Figs. 1, 2, 3, are all drawn to the same scale for equitable comparison, and may be studied together, although each represents an operation entirely distinct from and unrelated to the others; that is, they are not successive stages of one operation. In each case the same volume of air fills the cylinder at the beginning of the compression, but the actual weights

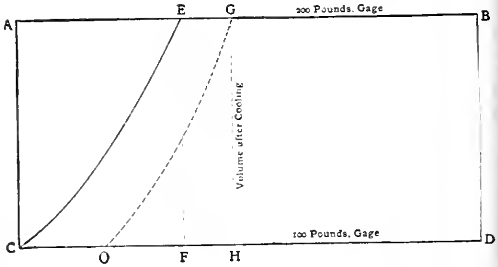

Fig. 2. Air between 100 and 200 Lb. Gage

or quantities of air are very different, only Fig. 1 beginning the compression with "free air," or air at atmospheric pressure.

Fig. 1 represents the adiabatic compression of a given volume of air from atmospheric pressure, say 15 lb. to the inch absolute, to a gage pressure of 100 lb., or 115 lb. absolute. Fig. 2 shows the compression of an equal volume (not an equal weight) of air, but under an initial pressure of 100 lb. gage, to a delivery pressure of 200 lb.; and in Fig. 3 an equal volume of air at 200 lb. is compressed to 300 lb.

In each case the initial volume of air compressed is represented by the area of the rectangle *ABDCA*. When the air has been compressed to the gage pressure specified in each case its volume is represented by the area *EBDFE*, and this will be the volume assumed to be discharged into the pipes and receiver. As we are speaking now from the purely theoretical viewpoint, nothing is said about clearance or other allowances made in practice.

It is well understood that the operation of compression invariably increases the temperature of the air very much, but this temperature it is impossible to maintain, and unless reheating is employed, the air is never used at the high temperature at which it is delivered by the compressor. As the air cools to normal temperature before it is used, its volume being reduced proportionately, the actual volume available for use is represented by the area *GBDHG*, this being in Fig. 1 only about an eighth of the initial volume, and not much more than one-half the volume *EBDFE*, as delivered by the compressor.

The air delivered under either compression represented may be said to have equal working value, volume for volume, the available pressure being 100 lb. in either case, the air in Fig. 1 at 100 lb. working against atmosphere only, the air in Fig. 2 at 200 lb. working against a back pressure in the return pipe of 100 lb., and that in Fig. 3 at 300 having a back pressure of 200 lb.

In compressing air from 100 to 200 lb., as in Fig. 2, the temperature of the air is not raised nearly as much as in Fig. 1 and, consequently, the shrinkage in cooling from volume *EBDFE* to volume *GBDHG* is proportionately much less than in Fig. 1. The volume *GBDHG* here

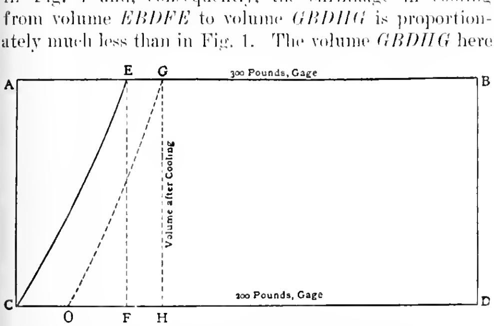

FIG. 3. AIR BETWEEN 200 AND 300 LB. GAGE

available for work is more than one-half the initial volume *ABDCA*, or four times the volume available in Fig. 1. At the same time it is to be noted that the mean effective pressure in the compressor cylinder for the stroke, which is the measure of the actual work of compression, is decidedly less than double that of Fig. 1. Getting fully four times the available volume for less than double the power employed certainly looks like doubling the efficiency by halving the relative cost of the compression.

In Fig. 3, compressing the air from 200 to 300 lb., the heating of the air is still less and the consequent shrinkage by cooling also is less. The available volume delivered, *GBDFG*, is five times the corresponding volume in Fig. 1, while the mean effective pressure required for the compression and delivery of the air is less than 2.1 times as much, which seems to be decidedly more than doubling the efficiency.

It has been assumed in each case above that the initial air temperature is 60 deg. F. With the same increase of 100 lb. in pressure the final temperatures will be 485, 163 and 121 deg., the rise of temperature being, respectively, 425, 103 and 61 deg. The enormous rise of temperature in compressing from atmospheric pressure has led to the general adoption of two-stage compression, with intercooling of the air, thereby gaining something in economy, avoiding the overheating of the surfaces, the burning of the lubricants and the danger of fires and explosions. With the heating that occurs in Figs. 2 and 3 there is no necessity for employing the two-stage compressor, and little possibility of any increased economy through its employment.

The ratio of final and initial absolute pressures is: In Fig. 1, 7.666; in Fig. 2, 1.869; in Fig. 3, 1.465. The ratio of the volume after cooling to 60 deg., or the volume available for use, to the initial volume is: In Fig. 1, 0.1304; in Fig. 2, 0.535 and in Fig. 3, 0.6825. The relative costs of compression, as measured by the power used, or the mean effective pressures for the compression divided by the volume after cooling, are: In Fig. 1, $11.6 \div 0.1304 = 319$; in Fig. 2, $78.88 \div 0.535 = 147$; and in Fig. 3, $86.83 \div 0.6825 = 127$. Here the ratio of the cost in Fig. 1 is $319 \div 147 = 2.17$, and of Fig. 1 to Fig. 3 it is $319 \div 127 = 2.51$.

It is understood that wherever this air is used—that is, the air of Fig. 2 and Fig. 3—whether for driving a rock drill, for a steam pump or an air motor of any kind, the air instead of being discharged into the atmosphere, as it would be from Fig. 1, is piped back to the compressor with only 100 lb. of its pressure used; then, volume for volume, the air used would be of the same power value in either case, if not used expansively. As the available volume delivered as shown in Fig. 2 is four times that in Fig. 1, a compressor of one-fourth the capacity, or, at equal piston speeds, with a cylinder one-half the diameter, will be sufficient for the work. The maximum unbalanced pressure against the piston would be no greater in one case than in the other, only it would be continued for a longer or a shorter portion of the stroke. There would be no additional strength required in any of the working parts of the machine, except that the air cylinder and connections would have to be strong enough for the maximum pressure.

As the same air is used over and over again in the two-pipe system, arrangements being provided for making up leakage losses, there is no appreciable accumulation of moisture and no possibility of freezing up, even if sufficiently low temperatures should occur, which they do not. At the same time more or less of the lubricant is carried back and forth in the air and comes in contact with the working surfaces. As the system is a closed one, being entirely out of touch with the surrounding atmosphere and not affected by the local pressure, it will work at one altitude just as well as at another.

WHY THE SYSTEM'S USE HAS BEEN LIMITED

Now as to why the system has not been more extensively employed; there is the fact to begin with that even yet it is not generally as well known and understood as it should be. Then, evidently, it would not be likely to be much used for intermittent work, such as the driving of rock drills which are continually changing their location, and where the maintenance of the return connection would cost in time and trouble enough to cancel the prospective advantage.

Apparently, the best employment of the system would be for the driving of ordinary steam pumps where constant pressure is usually required for practically the entire stroke. The air of Fig. 2, at 200 lb. pressure and 100 lb. back pressure, or the air at the higher pressures of Fig. 3 does not permit much profitable expansion in use. When used for rotative purposes in an engine or motor, the cutoff, as the compression diagram suggests, should never occur earlier than three-quarter stroke, so that the cutoff that may be accomplished by a good slide-valve engine would be all that would be available in any case. In this respect the air in Fig. 1 would have some advantage, as, to secure the greatest economy, it should be cut off before half-stroke, and a certain saving would be accomplished by the expansion which would not be possible where the higher pressures were employed.

There is a necessity for the compressor supplying the air and the engine or motor using the air to approximately keep pace with each other, not necessarily stroke for stroke, but so that, with the aid of suitable receiver capacity, the delivery and the return air pressures shall be maintained as constant as possible. This implies that the two working units of the system should be adapted to each other in capacity and that an automatic pressure governor should control the compressor.

A Gas-Tractor Power Plant

By C. V. Hull

SYNOPSIS—Description of the growth and development of a novel power plant in which the gas tractors under test are employed to furnish electricity for the factory.

One of the manufacturers of gas tractors has an unusual power plant. Power is furnished by the tractors under test, which are belted to 220-volt generators operated in parallel. A three-wire system with balancer set is used for current distribution. The growth of this plant has been rapid and the changes in its development are interesting.

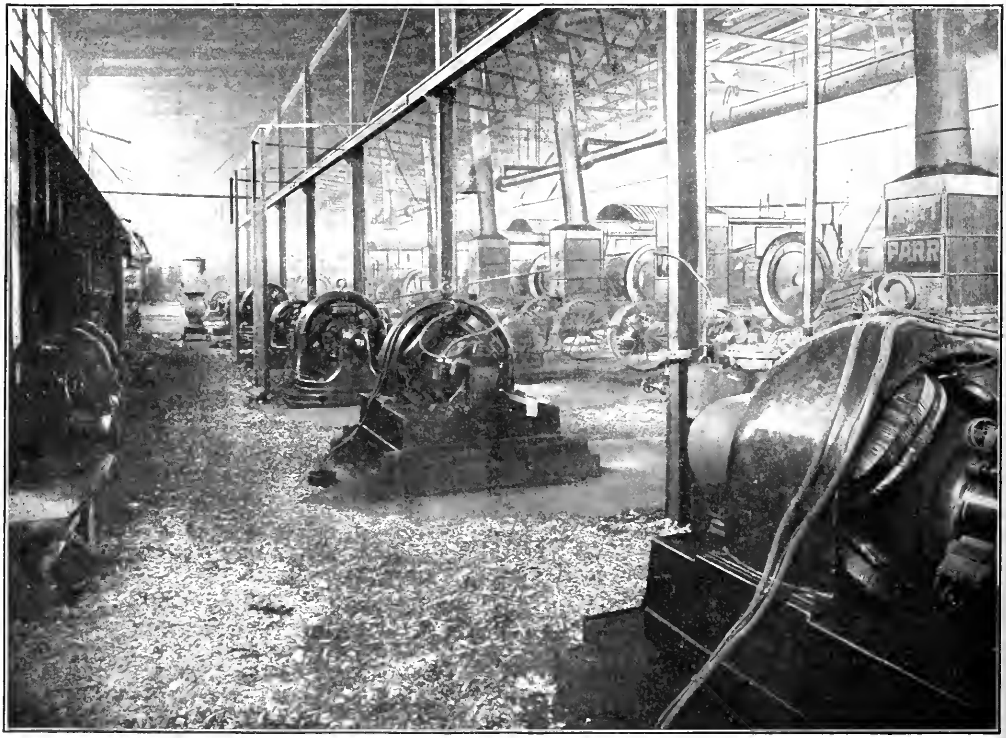

Fig. 1. Tractors Driving Generators

In the first plant power was furnished by a stationary engine belted to the line-shaft. This worked nicely until the buildings were enlarged and more machinery put in. It was then decided to use the tractors under test to drive 110-volt generators. Accordingly, a small power house was erected and one 110-volt generator installed. Some of the machines in the shop were motor-equipped, while others were belt-driven from lineshafts which were motor-driven.

With this plan the tractors were worked out in the yard and as soon as they were fit went into the power house to undergo a thorough test while furnishing power. As there was but one generator, tractors were generally changed during the noon hour. Shutdowns during shop hours came quite often, but the force was small at this time and there was no great loss.

The increasing demand for power soon made it necessary to install the second 110-volt generator. The two-wire system was continued, using the two generators in parallel. This made it possible to test two tractors at the same time and to change an engine without "dropping the load." There were times, of course, when a temporary heavy load caused a delay in changing engines.

The further demand for power was met by a third generator. It was then decided to change the distribution, using a three-wire system with two of the generators running in parallel. When the load was not too heavy only two of the three generators were run on the three-wire system. This allowed the use of 110- and 220-volt circuits at all times. The machines and lights were so connected that most of the 110-volt load was on one side of the system; hence the two machines in parallel carried considerably more than half of the load.

In order that any of the three generators might be used alone, double-throw switches were installed on the switchboard. By means of these switches, any two of the generators could be operated in parallel, with the third one running on the opposite side of the three-wire system. These generators were all compound-wound, but switches were put on them so that the series windings of the fields might be short-circuited when they were running in parallel.

When one of these generators played out, a three-wire machine was tried with indifferent success, and it was soon replaced with another 110-volt generator.

Usually, three dynamos were run during the day and up to 8 p.m., after which only two generators were used. In order to equalize the load after 8 p.m., one of the large 110-volt motors was fed by an individual circuit through a double-pole double-throw switch. When the three dynamos were in use this motor was fed from the two in parallel on the positive side, and when only two generators were running the motor was usually switched to the negative side to more nearly balance the load.

A single-pole double-throw switch was installed in the machine shop, so that an incandescent light circuit of some size could be switched as required. When this switch *S*, Fig. 2, was thrown to the right, the lights were on a two-wire circuit connected to the two dynamos in parallel. After 8 p.m. this switch was closed to the left, and the lights became a part of the three-wire system. All arc lamps were connected between the positive and neutral wires of the three-wire system, and the polarity of their supply was not changed.

When the motor and lights were switched to the negative side the load was nearly balanced.

The next addition was a larger 110-volt dynamo, of 600-amp. capacity (not shown in Fig. 2) for use with some 80-hp. tractors, although other tractors were used with it as well.

Soon after this, two 200-amp. dynamos were also installed in one end of the machine shop. These were arranged to be driven by one engine by the use of a double pulley on the first dynamo. They were also connected with double-throw switches so that they could be used in parallel or to feed the three-wire system. This outfit was very convenient, for small loads could be carried and it helped to keep the voltage quite steady when used to feed the three-wire system. After putting these machines in circuit all the dynamos were run with the shunt fields only.

Rapid increase in production, however, demanded more power, and it was decided that a new power house should be built and that 220-volt generators, with a balancer set, should be used.

It was not possible to get the power house ready for some time, so machines Nos. 1, 2, 3, 5 and 6 and two 220-volt dynamos, Nos. 7 and 8, were used for a considerable period. It was always necessary to start the 110-volt units first and then cut in the 220-volt machines. The double unit (5 and 6) was always cut in "against itself" (on opposite sides of the three-wire system) to prevent any possibility of mistake with 1, 2 and 3. One of the 220-volt dynamos was set up in the yard under a temporary shed, but whenever it rained the belt had to be removed. A temporary switchboard was set up in the new power house, and the other 220-volt machine was installed there.

It was a rather mixed-up power plant during the period just before the change-over. In the old power house there were three 110-volt dynamos and in the yard one 220-volt machine; in the machine shop were the big 110-volt dynamo, one 220-volt dynamo and the two 110-volt machines, combined in one unit. Two 220-volt dynamos were next set up in the new power house with a tem-

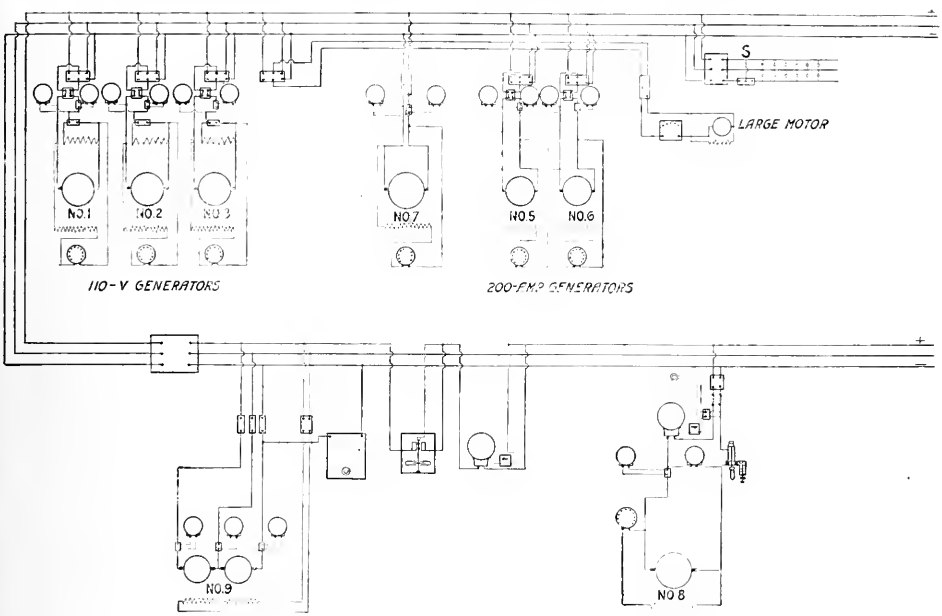

Fig. 2. Diagram of Generator Wiring

porary switchboard. It was at this time that the temporary balancer set described in POWER, July 14, 1914, was put in service.

This plan of operation continued for some time, though all the 220-volt generators were moved to the new power house. When at last the other 220-volt machines arrived and the new switchboard was set up, the 110-volt dynamos were taken out of service, the two 110-volt, 200-amp. machines being combined to make a balancer set.

In connection with generator No. 8 (Fig. 2) is shown the permanent plan of wiring the 220-volt generators, of which there are 10 at present. Each panel carries a wattmeter, an ammeter, a voltmeter, a pilot light, a circuit-breaker, a rheostat, and a switch with fuse blocks.

The unit system in this plant gives great flexibility and makes it possible to rush the testing of tractors during busy times. These tractors range from 30 to 80 hp. There is never any trouble regarding shift changes, for the care of the tractors requires but little time and all filling is done with hose connected to pipe lines. The power is cheaply developed, for the tractor motors use fuel at 4c. per gallon. Of course, the greatest advantage is the thorough testing of the tractors with little, if any, extra cost. All in all, the plant is very satisfactory and efficient, though the noise is not pleasing to the man who is accustomed to quiet-running Corliss engines.

Government Furnishes Cheap Electricity

By Herman B. Walker

SYNOPSIS—A hydro-electric plant which forms part of the Minidoka irrigation project in Idaho sells its surplus power to the community at such rates as to encourage the use of electricity for heating and various domestic purposes, a notable example being the high school at Rupert.

There is not more than one thousand population in each of the towns of Heyburn, Rupert and Burley, which are the post offices and marketing centers for the farmers on the Minidoka irrigation project, in the southern part of Idaho; but it is probable that few cities have adopted electricity for so many purposes. To irrigate this part of what used to be known as the Idaho Desert, the U. S. Reclamation Service built a dam 600 ft. long and 50 ft. high across the Snake River, forming an artificial lake covering 26 square miles, and at this dam installed a hydro-electric plant capable of producing 30,000 hp. The Government carries this power to the towns and farms scattered over the project, uses part to pump water to land too high to be irrigated by gravity, and sells electricity to farmers, settlers and distributing companies in the towns, at rates as low as half a cent per kilowatt-hour.

The lowest rates are made for power and for heating purposes. In the winter the power from the government plant is not needed for pumping water, and the low rates offered have resulted in many of the houses and business buildings being heated by electricity at a lower cost than they could be heated with coal, which in this section (Wyoming bituminous) is worth about $6.25 a ton.

Nearly every house and many of the barns on the Minidoka project are lighted by electricity, while the farmers' wives do their cooking on electric ranges, and the farmers run their pumps, grindstones, cream separators, churns and other farm machinery by electricity.

Last year the town of Rupert built a $50,000 high school, and after figuring on costs, left off the chimneys and put in an electric heating plant. This schoolhouse has probably the most modern equipment of any in the United States, if not in the world. When the janitor desires heat for the building he throws a switch instead of shoveling coal, and when he leaves for the night he throws out the switch instead of banking his fires. The building is a three-story brick structure, desigued to accommodate 600 children, and the electrical installation exceeds 435 kw. The heating plant has a connected capacity of about 400 kw. and consists of eleven units, which makes it possible to regulate the heat with ease. Each unit has a capacity of 36.5 kw., on 400 volts, and consists of a stack of grid resistances.

The air is drawn in through a two-way damper which permits it being taken from either inside or outdoors. A fan with a capacity of 20,000 cu.ft. per min., located beyond the heaters, forces the hot air into the plenum chamber, the floor of which is dropped a few inches below the rest of the basement and is kept flooded with water. The hot air is blown across the surface of this water before entering the flues leading to the various rooms. About forty gallons of water a day is evaporated and carried to the rooms with the hot air, thus keeping the atmosphere moist. Foul air is exhausted through ventilating shafts leading to the roof.

An hour or two before school opens in the morning, the janitor starts the fan, turns on as many units of the electric heaters as he thinks necessary, and turns the air damper to draw the air from inside the building into the heating chamber. When the temperature has reached about 70 F., he turns the damper to draw the air from outside. When the building is closed at night, the two-way dampers are turned to exclude the outside air, the heating units are all switched onto 220-volt transformer taps, the fan is shut down and the air is allowed to circulate by natural current during the night. This keeps the temperature high enough to make the warming-up process in the morning quick and easy. The heating installation is designed to heat 20,000 cu.ft. of air per min. from zero to 70 deg. F., and has worked satisfactorily.

It has cost somewhat more for current than it would have cost for coal to heat the school, but the school authorities are convinced that the saving in the cost of installation, fireman's wages and depreciation has more than made up the difference, and that the electric plant under the existing conditions is actually more economical in the long run than furnaces or boilers. Furthermore, there is the greater elasticity of operation and the ease of adjustment to meet varying weather conditions.

Power for this heating is supplied by the Government at a flat rate of $1 per kw. per month, based on the maximum demand for the month, with the stipulation that the maximum demand for the season must be paid for at least four months out of the year.

In addition to the electric heating, the school has a complete domestic-science department with an equipment of individual electric hot-plates for twenty pupils. There is also a large electric range for baking and for cooking the dishes supplied to the school cafeteria, where the pupils are supplied with hot meals at cost. An electric water still which not only furnishes distilled water for the school, but also supplies the local drug store, where the water is exchanged for the chemicals used in the school laboratory, is another unusual equipment. Water for the toilets, the shower baths in the gymnasium, dishwashing in the domestic-science room and for the laboratory, is heated by a 3-kw. circulating heater connected to a 250-gal. hot-water tank. The machinery in the manual-training room is operated from the 10-hp. variable-speed motor which drives the ventilating fan. A 450-watt stereopticon is a part of the school equipment.

On this project, in summer, the government power plant sends current to several points to pumping plants, and pumps water for irrigating approximately 50,000 acres of farms, mostly alfalfa fields, the average pumping lift being 66 feet.

The Government is required to allow a certain amount of water to pass through the dam at Minidoka, as there are interests further down the stream which have prior water rights. The water passed on for use below is dropped through 10-ft. penstocks and drives five main generating units of the vertical type, each of 2000-hp. rated capacity under a head of 46 ft., and two 180-hp. turbine-driven exciters. The power is transmitted at 33,000 volts over 40 miles of transmission lines to the pumping stations and transformer stations for town use. The average cost of generating electricity and delivering it at the pumping plants on the project, including 10 per cent. on the investment for depreciation and other items, has been about 0.6c. per kw.-hr. The cost of pumping water for irrigation has been about $1.40 per acre per season.

The rates charged to consumers on the project are:

FLAT-RATE LIGHTING

	Per Month
For 20 incandescent 15-watt lamps	$1 50
Per additional lamp	0 05
For 5 incandescent 15-60-watt lamps	1 50
Per additional lamp	0 25
Per light over 60 watts, for each 60 watts or fraction thereof	0 25
Per arc lamp, 700 watts, to 10 p.m.	2 50
Per arc lamp, 700 watts, all night	4 00

HEATING RATES

Per device, per 1,000 watts, winter	1 50

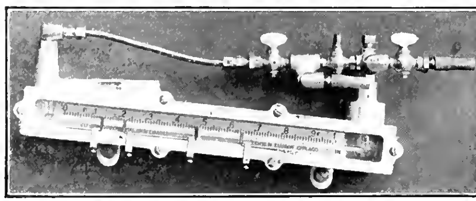
New Ellison Combination Differential Draft Gage

The accompanying illustration shows the latest addition to the long list of Ellison gages. By the application of a simple system of cross-connecting, the cover-type differential draft gage, the flue draft, the furnace draft or the differential between the flue and the furnace, indicating the variations of the air supply, can all be indicated on a simple gage, over the full length of the scale. The fittings are of brass and the tubing of copper. Each connection is furnished with a piece of rubber tubing for a ⅛-in. pipe, serving as a flexible joint for relieving the gage from pipe strains and from shocks when the pipe lines are accidentally struck with the fire tools. By means of the elbows with locknuts, the combination can be turned to the right, left, or up.

The tube at the right connects with the flue piping on the boiler side of the damper, or with the last pass, and the connection at the left with the furnace piping in the usual manner. To indicate the flue draft the flue cock is opened and the other two are closed, the cock



NEW ELLISON COMBINATION DIFFERENTIAL DRAFT GAGE

at the left being pinned at quarter turn and so vented that when closed, the zero end of the gage is open to the atmosphere.

To indicate the furnace draft the outside cocks are closed and the middle cock opened, the economical range of furnace draft being maintained between the pair of pointers at the left, which are set as directed on the cover-type differential draft gage.

To give a continuous indication of the variations in the air supply, for which the gage is chiefly intended, the outside cocks are opened and the middle one closed. The reading is maintained between the second pair of pointers, which are set to check with the furnace pointers, the right being red, beyond which the liquid should not pass except under excessive overloads. The object of the pointers is to maintain the liquid as nearly as possible to zero and still carry the load without producing CO.

To establish the liquid at zero all cocks are closed and the plug over the chamber unscrewed until the vent in the threaded portion stands out of the fitting.

Manifolds can be furnished in place of the flue nipple, for connection with various flue-gas passages, while a pressure nipple can be furnished with an ashpit connection, for indicating the blast or the differential between the ashpit and the furnace. The scale of the gage is divided into hundredths of an inch, and the movement of the fluid is magnified ten or fifteen times. The inventor and maker of the gage is Lewis M. Ellison, 6238 Princeton Ave., Chicago, Ill.

Why Direct-Current Motors Fail to Start—II

By F. A. Annett

SYNOPSIS—The effects of open field circuits and how to locate the trouble; also the use of a water rheostat as a substitute for a starting box.

The causes of direct-current motors failing to start as described in Part 1 (Feb. 9, 1915) will not affect other parts of the apparatus, such as causing the fuses to blow, the starting box or other parts of the machine to heat, etc.

A break in the field circuit will produce several different effects, depending upon the winding, the setting of the brushes, and whether or not the machine is loaded. If series-wound it will not start, for the field winding is part of the armature circuit. If shunt-wound and the brushes are set at the neutral position the motor will not start, but shifting the brushes off neutral will cause rotation in the direction in which the brushes are shifted, provided the machine is not loaded. A compound-wound machine with the shunt field winding open will usually start whether loaded or not, but unless heavily loaded it will usually race. If the series field winding is open it will have the same effect as in a series machine.

In the shunt field circuit a break may occur anywhere between the first contact point on the starting resistance around to where the field coils and armature leads connect to the line wire, as indicated by the arrowheads in Fig. 1. As the no-voltage release coil on the starting box is located in an unprotected place, it is usually one of the chief sources of open circuit in the shunt field circuit; therefore, it should be given first consideration.

Assume a condition as illustrated in Fig. 2 where the no-voltage release coil is open at *X*. This interrupts the shunt field circuit, but leaves the armature circuit complete, and may cause any one of the effects enumerated. Where an attempt is made to start a shunt- or compound-wound motor with the shunt field circuit open, if it starts it will run at high speed, the starting resistance will become very hot, and if an attempt is made to cut out the resistance the fuses will blow and the machine will spark badly at the brushes and commutator.

A simple test for this defect is to disconnect the armature lead *A* on the starting box, close the switch, and bring the arm upon the first contact. If the field circuit is closed, a spark will occur when the arm is allowed to drop back to the off position; if open, no spark will occur. To locate the defect in the starting box, disconnect the armature and field connections, close the switch and bring the arm upon the first contact; then test with a lamp, as at *L* and *L'*, Fig. 3. When the lamp is connected to terminal *A* it will light, for the circuit is completed through the starting resistance, as indicated. When connected to terminal *F* it will not light, for the circuit is open at *X*; the coil may then be tested by connecting the lamp first to one and then to the other terminal, as indicated at *a* and *b*. If the lamp lights at *a* and not at *b*, as in this case, it indicates that the circuit is open between the two terminals of the coil, which may be removed and again tested to make sure that the trouble has been properly diagnosed.

If the defect cannot be located and repaired and the coil has to be rewound, it does not necessarily mean that the motor has to be shut down until the repairs have been made. This difficulty can be temporarily overcome by connecting terminals *a* and *b* with a piece of wire. However, it will now be necessary to tie the starting arm or remove the spring, to keep it in the running position. For a more detailed explanation on open circuits in field coils see Power, Aug. 4, 1914.

Sometimes it is necessary that the starting box be taken to the shop for repairs, or it may have been completely burned out and a new one is required. In such cases, if a duplicate starter is not at hand the motor must remain shut down unless some substitute is provided for starting. One of the most convenient substitutes is a water rheostat. This is made up of a common 10- or 12-quart pail, a wood or pulp pail being preferable, as there is less danger of a short-circuit. Two electrodes must be provided; one a flat plate which rests on the bottom of the rheostat and connects to one side of the line, the other any piece of metal that is at hand and connects to the armature. The pail is filled with water containing a handful of common salt to increase its conductivity. This size of rheostat will be sufficient for starting a 25- or 30-hp. 230-volt motor under full load, or a 100- to 150-hp. motor under light load.

Fig. 4 illustrates the proper method of connecting the rheostat in circuit for starting a shunt motor. In making the connection care should be taken to get the rheostat in series with the armature only and the field connected directly to the line, as shown. If the field is connected to the armature wire leading to the movable element of the rheostat, the motor will have a very weak torque at starting. To start a motor with a water rheostat proceed as follows:

See that electrode *a*, Fig. 4, is removed from the rheostat; then close the line switch and lower *a* slowly into the pail. As soon as it is immersed in the liquid the machine should start. Continue to lower *a* gradually until it comes in contact with electrode *b* at the bottom of the pail. To insure good contact while the machine is running, a single-pole switch *S* may be used to short-circuit the rheostat after the machine has been brought up to speed. This short-circuiting switch must be open when the line switch is closed to start the motor, or the fuses will blow. If difficulty is experienced in getting the motor to start properly through the rheostat, more salt may be added.

The proper method of connecting a compound motor is shown in Fig. 5, which is practically the same as for a shunt machine. If a metal pail is used electrode *b* may be dispensed with and the line wire connected directly to the pail.

A short-circuit in one or more of the field coils of a multipole machine will prevent it from attaining normal speed. However, it will start with a good torque, but as the speed increases sparking will occur at the commutator and brushes and excessive current will be drawn from the line; and by the time three or four points of the starting resistance are cut out, conditions will become so bad as to necessitate shutting the machine down, or the fuses will blow.

A ground in two or more field coils if the system is insulated, or a ground in one field coil where the frame of the machine and one side of the line are grounded, will have practically the same effect as a short-circuit in one of the field coils. A method of locating these defects was described in POWER, Sept. 1, 1914.

Another defect which will prevent a motor from attaining full speed is a short-circuit of a group of armature coils. This will cause the machine to start with a jerky effort, and before the armature has accelerated very much it will act as though heavily overloaded; and if an attempt is made to cut out the starting resistance the fuses will blow. The method of locating this defect was treated in POWER, Nov. 17, 1914.

Two grounds in the armature winding will have practically the same effect as short-circuiting a group of coils. One ground in the winding, combined with a ground on the external circuit, will cause the fuses to blow.

If the brushes are shifted so that they are equidistant between the neutral points, the machine will not start, but will draw an excessive current from the line and blow the fuses if the starting resistance is cut out.

To set the brushes on the neutral point when the machine is standing still, follow out the leads of the armature coils located between the polepieces and set the brushes on the segments to which these leads connect. The proper position for the brushes is usually opposite the center of the polepieces or opposite the center of the space between them. In most modern machines it is opposite the center of the polepieces.

If the machine is compound-wound a short-circuit between the series and shunt field coils will have about the same effect as a short-circuit in the field coils of a shunt machine. This condition is illustrated in Fig. 6, where a short-circuit is indicated at X between the shunt and series field coils on polepiece B. On account of the low resistance of the series field winding, the current through the shunt field coils will take the path indicated by the arrowheads, short-circuiting the shunt field coils on polepieces C and D and part of the coil on B.

A quick test can be made for this defect, as shown in Fig. 7. Open the connection between the series and shunt fields at the motor and the armature connection A at the

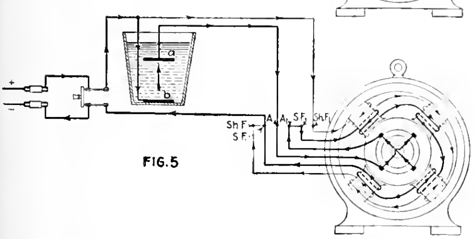

FIG. 5

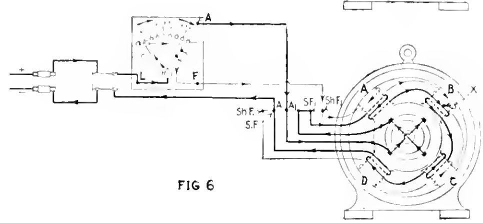

FIG. 6

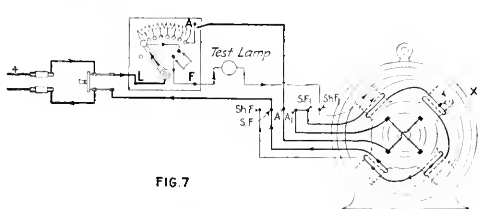

FIG. 7

TESTING FOR BREAK IN CIRCUIT AND STARTING MOTOR BY MEANS OF WATER RHEOSTAT starting box. Connect a test lamp in the shunt field circuit as indicated, close the switch and bring the starting-box arm upon the first contact. If the lamp lights it denotes a short-circuit between the series and shunt fields, as shown by the arrowheads. The defective coil may be located by opening the connections between the field poles and then testing between the series and shunt coils on each polepiece with a lamp or voltmeter.

In locating trouble never forget to test the machine and the controlling device for grounds, as a combination of grounds on a motor and controller sometimes produces some very puzzling and, at first thought, unaccountable effects which are easily explained after the trouble has been located.

Boilers for Isolated Plants

By Charles L. Hubbard

SYNOPSIS—A brief treatise on the selection of boilers for isolated plants, together with the more important matters to be considered in connection with boiler design and operation.

Selection of a Boiler

Among the governing factors in the selection of a boiler are the pressure to be carried, size and number of units, available space, and cost. To these may be added details of construction, relating especially to accessibility for inspection, cleaning and repairs.

When the boilers are furnished by builders of established reputation, it is not usually necessary for the engineer to prepare detailed drawings and specifications. General requirements as to pressure, amount of heating and grate surface, and type of furnace and setting are furnished the builder, from which he, in turn, prepares specifications for the approval of the engineer and which are submitted with his bid. This applies especially to water-tube and patented boilers, of which there is a great variety. In the case of fire-tube boilers of the horizontal type, the engineer often furnishes specifications, particularly where any departure from standard construction is required.

The boilers most frequently used in isolated plants are the horizontal return-fire-tube and the standard makes of water-tube boilers. Vertical fire-tube, locomotive and marine boilers are also used in special cases. In the matter of fuel consumption for a given capacity there is little choice in the different types of equal grade, hence adaptability and cost are the governing features in making a selection.

Return-tubular boilers are rarely used for pressures over 150 lb. or for sizes much above 125 hp., because of the thickness of plate required, which in general should not exceed ½ or ⅝ in., owing to its exposure to the hottest part of the fire. Within these limits they are an efficient type and are especially adapted to low basements. The first cost of a return-tubular boiler is somewhat less than a water-tube boiler, which is sometimes a deciding factor.

For larger units and higher pressures some form of water-tube boiler is usually selected. Boilers of this type are also frequently employed in small- and medium-sized plants on account of greater safety, and special designs are constructed for locations where headroom is limited.

Boiler Capacity

The capacity of a boiler is based upon the weight of steam which it will furnish in a given time under specified conditions; the standard of measurement being the weight of dry steam evaporated per hour from and at 212 deg. The performance of a boiler operating under other conditions may be reduced to this standard by the use of a table of "Factors of Evaporation," which may be found in most handbooks. Table 1 gives the factors of evaporation over a small range and in a condensed form merely for present purposes.

TABLE 1. FACTORS OF EVAPORATION

Temperature of Feed Water, Deg. F.	Gage Pressure in Pounds per Square Inch								
	100	110	120	130	140	150	160	170	180
50	1.208	1.210	1.212	1.214	1.215	1.217	1.218	1.220	1.221
60	1.198	1.200	1.202	1.203	1.205	1.207	1.208	1.210	1.211
70	1.187	1.189	1.191	1.193	1.194	1.196	1.197	1.199	1.200
80	1.177	1.179	1.181	1.183	1.184	1.186	1.187	1.189	1.190
90	1.167	1.169	1.170	1.172	1.174	1.176	1.177	1.179	1.180
100	1.156	1.158	1.160	1.162	1.164	1.165	1.167	1.168	1.170

Example—A boiler supplied with feed water at a temperature of 70 deg. generates 4000 lb. of dry, saturated steam per hour at a pressure of 180 lb. gage. What is its equivalent evaporation from and at 212 deg.?

The factor for the above conditions from Table 1 is 1.2, hence the equivalent evaporation under standard conditions is $4000 \times 1.2 = 4800$ lb. of steam per hour.

The heat required to evaporate one pound of water from a temperature of 212 deg. into steam at atmospheric pressure is 970.4 B.t.u.

One boiler horsepower represents the capacity to evaporate 34.5 lb. of water per hour from and at 212 deg., which process requires $970.4 \times 34.5 = 33{,}479$ B.t.u. In practical work this is commonly taken as 33,000, which gives results on the side of safety.

What is commonly known as heating surface includes all the plates and tubes exposed to hot gases on one side and water on the other. Surface coming above the water line and exposed to hot gases on one side and steam on the other is called superheating surface.

The effectiveness of the various heating surfaces depends upon their location and character, but in all computations relating to boiler capacity, it is customary to assume a uniform value for the entire heating surface which shall represent a fair average under ordinary working conditions.

For power work an evaporation of 3 to 3.5 lb. of water per sq.ft. of heating surface per hour may be taken, which calls for $\frac{34.5}{3} = 11.5$ sq.ft. per hp. in the first case and $\frac{34.5}{3.5} = 9.9$ sq.ft. in the second.

Builders usually rate their boilers on a basis of 10 sq.ft. of heating surface per hp. for water-tube boilers and 12 sq.ft. for return-tubular boilers, but as no uniform rule is followed in this respect, the engineer should always specify the amount of heating surface required rather than the horsepower. Some engineers call for a guaranteed evaporation under standard conditions as to feed-water temperature, steam pressure and coal consumption.

In the case of return-tubular boilers, it is well to state the diameter and number of tubes for a given diameter of shell, as the efficiency is lowered by crowding them too closely together. Table 2 gives tube data as recommended by the Hartford Steam Boiler Inspection & Insurance Co.

TABLE 2. TUBE DATA

Diameter of Shell, In.	Diameter of Tubes, In.	Number of Tubes
48	3	44
54	3	54
54	3½	46
60	3	72
60	3½	64
66	3	90
66	3½	78
66	4	62
72	3	114
72	3½	98
72	4	72

Efficiency

The efficiency of a boiler plant is made up of the combined efficiencies of the furnace and boiler and is expressed by the ratio:

$$\frac{\textit{heat absorbed by water in boiler per lb. of coal, as fired}}{\textit{calorific value of one lb. of coal, as fired}}$$

When oil fuel is used or mechanical appliances are provided for feeding the coal or creating a draft, the heat required per pound of fuel for this purpose must be deducted from that delivered by the boiler in the form of steam for useful purposes in order to obtain the net efficiency. The heat absorbed by the water in the boiler per pound of coal equals

$$\frac{970.4 \times W \times q \times f}{w}$$

in which

W = Apparent weight of water evaporated, in pounds per hour;

q = Quality of the steam;

f = Factor of evaporation for the conditions of feed temperature and steam pressure during the test;

w = Weight of coal burned, in pounds per hour.

The calorific value of coal varies with the kind and the locality from which it comes, and should be determined in each particular case for accurate results. For approximate work, the following values may be used:

TABLE 3. CALORIFIC VALUE OF AMERICAN COALS.

Kind of Coal	Calorific Value in B.T.U. per Pound
Anthracite.........	13,200
Semi-anthracite.......	13,800
Semi-bituminous.....	14,700
Eastern bituminous......	13,600
Western bituminous.......	12,300

In general, the efficiency will run from 50 to 70 per cent., averaging about 60 per cent. in well designed and carefully operated isolated plants of good size. This applies to boilers working under normal conditions. When forced beyond the capacity for which they are designed, the efficiency falls off somewhat, although not so much as was formerly supposed.

Boiler Performance

This relates to the various results obtained in the practical operation of steam boilers, such as rates of combustion and evaporation, coal per horsepower-hour, etc.

The weight of coal burned per square foot of grate per hour depends principally upon the kind of fuel, the type of furnace and the strength of draft. Table 4 gives about the average for different grades of coal burned under natural draft. These figures, however, may vary 2 or 3 lb. either way, according to local conditions.

TABLE 4. RATES OF COMBUSTION WITH NATURAL DRAFT

Kind of Coal	Pounds Burned per Sq.Ft. of Grate per Hour
Anthracite buckwheat No. 1. .	9–12
Anthracite pea....	12–15
Anthracite nut...	14–18
Semi-anthracite, screenings..	14–18
Semi-anthracite, run of mine... ..	18–22
Semi-bituminous, screenings... .	18–24
Semi-bituminous, run of mine.....	18–24
Bituminous, slack. .	18–24
Bituminous, screenings.....	20–26
Bituminous, run of mine..	20–28

With mechanical draft the rate of combustion may be greatly increased if desired, but is not usually carried much over 30 lb. in stationary plants of medium size. With certain types of stokers, however, the best results are obtained with small grate surfaces and high rates of combustion, but for average practice with hand-fired furnaces, the figures given should be generally followed.

The rate of evaporation depends partly upon the grade of fuel and partly upon the boiler and furnace efficiencies, which in turn are influenced by the character and arrangement of the heating surface and its relation to the grate area. Table 5 gives the pounds of steam evaporated per pound of coal for different calorific values and efficiencies within the usual range in isolated plants.

TABLE 5. POUNDS OF STEAM FROM AND AT 212 DEG. PER POUND OF COAL

Combined Efficiency of Boiler and Furnace	Calorific Value of Coal in B.T.U. per Pound 12,000	13,000	14,000	15,000
50 per cent	6.2	6.7	7.2	7.7
60 per ceot...	7.4	8.0	8.6	9.3
70 per cent..	8.6	9.4	10.1	11.8

The pounds of coal per horsepower-hour is found by dividing 34.5 by the rate of evaporation obtained in any given case. Table 6 has been prepared for the same conditions of boiler efficiency and calorific value of fuel as Table 5 and gives the pounds of coal required per boiler horsepower per hour.

TABLE 6. COAL CONSUMPTION PER BOILER HORSEPOWER-HOUR

Combined Efficiencies of Boiler and Furnace	Pounds of Coal per Boiler Horsepower per Hour Calorific Value of Coal in B.T.U. per Pound 12,000	13,000	14,000	15,000
50 per cent..	5 6	5 2	4.8	4.5
60 per cent.	4 7	4.3	4.0	3.7
70 per cent	4 0	3.7	3.4	3.2

Boiler Capacity for Power—All power requirements should be reduced to indicated horsepower. This, multiplied by the water rate of the engine, reduced to an equivalent evaporation from and at 212 deg. and divided by 34.5, will give the boiler horsepower required. Expressed as a formula, this becomes

$$b.hp. = \frac{i.hp. \times W.R. \times f}{34.5}$$

in which

$b.hp.$ = Boiler horsepower required;

$i.hp.$ = Indicated horsepower to be supplied;

$W.R.$ = Water rate of the engine under given conditions of feed-water temperature and steam pressure;

f = Factor of evaporation for given conditions.

Example—What boiler capacity will be necessary to supply power for a factory requiring 500 i.hp. at the engine? Power is to be furnished by a low-speed engine using 20 lb. of steam per indicated horsepower per hour. The average feed-water temperature is 60 deg. and the steam pressure 100 lb. gage. In this case

$i.hp. = 500;$

$W.R. = 20;$

$f = 1.198;$

which, substituted in the formula, calls for

$$\frac{500 \times 20 \times 1.198}{34.5} = 347 \textit{ boiler horsepower}$$

This gives simply the boiler power for supplying the engine. If steam is required for other purposes, such as the driving of pumps, heating, ventilating, etc., the capacity should be increased accordingly.

Boiler Capacity for Heating, Ventilation, etc.—The general method employed in this case is the same as above described. All heating requirements are reduced to pounds of steam per hour and the result divided by 34.5 to find the boiler horsepower.

Paint for Engineering Purposes

By E. N. Percy

The writer had occasion recently to investigate the principles of paint making, because his employers were not satisfied with the results in the upkeep of painted surfaces in their various power plants. The results of these inquiries may be of interest to practical men.

There are many ways of making paints, but only a few for good paint. There are also many ways of using paint, but only a few for getting good results. Nothing goes further toward improving the appearance of a power plant than the judicious use of paint and varnish, and a man need not be a highly trained painter to get fairly good results if the underlying principles are known.

Protective coats may be divid l into three general classes, viz., paints, varnishes and dips.

Paints consist of a body, which is to be the protective coat, and the solvent in which the body is dissolved. The solvent in some paints evaporates and leaves the body; in others, it oxidizes and hardens with the body. In addition to these two ingredients, it is customary to add coloring matter, unless the body is already of the color required.

Varnishes consist of a body and solvent, and are used to give a glazed finish, impervious to the elements. Varnishes are sometimes used as fillers, prior to the application of paint; again, they are used as a protection to the paint, particularly if the paint is of an expensive and highly ornamental character. Dirt may be washed from varnish, whereas it sticks more or less to paint. Varnishes may be colorless and transparent, or may be stained to any desired color.

Dips are protective coatings into which articles may be dipped, after which the coating is hardened to the desired texture by cooling, baking in an oven or by further dipping in another compound. Such coatings include lacquer for brass, cast iron, copper or wooden pipes, etc.

Well known combinations for paint are white lead and linseed oil and coloring matter, kerosene or gasoline and lampblack, or linseed oil and lampblack.

Without doubt, there is no paint known that equals pure white lead and boiled linseed oil for general protection. For white coats, it may be used without other ingredients; for any other color, the pigment may be procured at any paint shop. It is almost impossible to get contract work done with pure white lead and pure boiled linseed oil; but this is the only way to have high-grade work done. The writer has had to go to the greatest extremes, with inspectors, chemical tests, etc., in order to compel contractors to use pure white lead and linseed oil, because of their high cost. The usual substitute is zinc, and even this is often mixed with chalk or lime.

Red lead is an excellent protection for steel work; it does not show the dirt and is much cheaper than white lead.

Cheaper paints are made with asphaltic and tar products dissolved in gasoline, distillate, benzine, benzol, linseed oil or kerosene.

Varnishes consist mostly of rosins or tree gums dissolved in turpentine, alcohol, gasoline or boiled linseed oil. The solvent then evaporates (known in this case as a spirit varnish) or hardens by oxidation (known as an oil varnish). Among the cheaper varnishes are shellac, inside finish, etc. The more expensive varnishes are those intended to endure stress of weather, like automobile finish, etc. The pyroxylin or celluloid varnishes are made from cellulose. The celluloid is dissolved in wood alcohol or in amyl acetate (banana oil), and may then be mixed with coloring matter or heavier bodies, such as a solution of asphaltum in gasoline. It then imparts a high, glossy finish. It has been found, however, that the pyroxylin varnishes do not withstand the elements and are therefore suitable for inside work only.

The pyroxylin varnishes are suitable for finishing and protecting metal surfaces, provided the metal is not highly heated. They also prevent oxidation, and preserve highly polished surfaces. A fine grade of pyroxylin varnish may be made by dissolving moving-picture films in wood alcohol. The film can be secured from any large film exchange, as they always have quantities of worn-out films on hand, which are merely burned up as so much waste. A thousand feet of film, unwound and stuffed into a ten-gallon drum, may be covered with wood alcohol and the drum closed. It should be left for a week, and the drum turned over every day. Then the liquid may be drawn off and will be found to be a good grade of varnish. The drum may be filled again, as the film will last for months. The emulsion settles to the bottom as a sort of mud, and one must be careful to decant the liquid so as to leave the settlings in the barrel.

The varnish is ideal for glossy, metallic surfaces, particularly those that tarnish, such as brasswork, metallic paint, copper pipes, etc.

The metallic paints consist merely of finely divided metal mixed with some oil or body which will cement them together and to the surface, and then the liquid portion will either oxidize or evaporate. The metals consist of gold, silver, bronze, brass, copper, aluminum, iron, and sometimes zinc. These paints must not be confused with ordinary paints, which are compounds, such as lead oxide (white lead; red lead is another lead oxide), white zinc (zinc oxide) or copper ship paint, which is copper sulphate as a rule. The finely divided metals which go to make metallic paints are secured partly by grinding, partly by electrolysis, and others are byproducts of some other process or industry. The cheaper gilt paints are, of course, imitations, but the more expensive ones are pure gold leaf. The leaf is so very thin as to be reasonably cheap, since it takes thousands of them to make a pile one inch high.

Dips are very important to the engineer, because they are the principal method of protecting pipe, brasswork, etc. Most dips are applied hot. Pipe dips are mostly black, and must withstand the action of water, air, weather, soil and heat. The coating must be hard and glossy, but must not chip or crack, nor run or flow when subjected to moderate heat. Such results may be obtained with certain grades of coal-tar products, also asphaltum. The coal-tar products are affected more easily by heat than the asphaltum, but it is important to get the proper grade of asphaltum. Probably the most satisfactory is a medium grade of air-blown stock of such hardness as will be determined after a few experiments. This asphalt should be dissolved in boiled linseed oil in a vat over a fire until the mixture contains two parts of molten asphaltum to one of linseed oil. Care must be taken not to get the mixture too hot, as the asphaltum will be brittle if burned. A fair dip is obtained with only 10 per cent. of linseed oil, but the coating is more likely to chip.

Lacquer for brass work is made in numerous ways, but a fair coating can be obtained by dipping in a hot mixture of pure linseed oil and pure white rosin melted together. Care must be taken that the bath does not take fire.

The Purchase of Coal

By Morgan B. Smith

SYNOPSIS—Some factors which ought to be considered by the consumer when purchasing coal.

In connection with the purchase of coal two questions arise, both of which may seem odd but which nevertheless bring forward intensely practical answers. The first is, *why* does the consumer purchase coal? and the second, *how* does the consumer purchase coal? The first question may be answered by the simple statement that the coal is bought for heating purposes. This answer is ready and straight to the point; but how about the second question—can this be answered as readily as the first? Unless the purchaser has been through the mill thoroughly he will state that he buys coal from his dealer at so much per ton, plus freight charges, and then puts it in storage in field or bunkers, or perhaps burns it at once in the furnaces.

It is worth while to consider the answer to the second question. There is more involved in the purchase than mere tonnage. The purchaser himself admits that it is heating value which he desires. Therefore, he should look for heating value per ton of coal bought and also for nonheating properties in the coal.

Stop to consider, then, some of the factors to which the consumer ought to give attention when purchasing coal for his plant. In the first place, he is forced by current practice to buy "tons of coal," regardless of the true value to him, unless he is in a position to insist upon "heating value per ton of coal."

What does this mean to the consumer? It means that he is paying for mere weight of coal, for freight on mere tons, for handling at the plant of mere tons, for crushing mere weight, for storage of weight only, for burning weight only and for handling ashes—all based upon mere avoirdupois rather than upon heat value. Is this common sense or good judgment? Hardly.

Supposing that he is in a position to insist upon heating value in every ton of coal which he purchases, and to make his insistence strong by means of the proper tests on all coal received at the plant. What then? The purchase of coal then becomes a matter, not of mere tons, but of heat units per ton or per pound, a measure of the coal's real value.

When the purchaser has reached this position regarding coal, he can then go ahead and by comparative tests select the coal best suited to his plant equipment. That coal which is by its characteristics best adapted to the conditions of the plant and the load is the highest grade usable, regardless of cost.

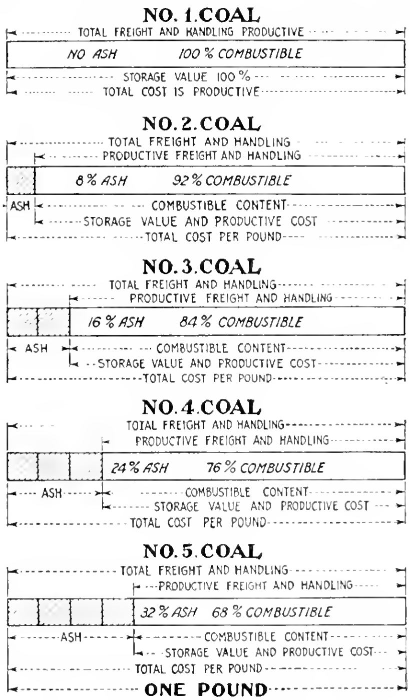
It is customary to state the heat value of coal in terms of heat units per unit of weight, generally stated as British thermal units per pound (B.t.u. per lb.) based on the sample dried at 105 deg. C. for one hour. Unless the exact characteristics of the coal are known, a pound of it may have diverse meanings to the buyer. To make this clear, the accompanying diagram has been made to illustrate graphically how "one pound of coal" may have great significance when all costs and efficiency in the plant are considered.

Assume the initial cost at the mines to be the same for each of the five coals shown. How much of the total cost is productive? Only that portion represented by the heat content of the coal purchased. How much of the total cost is loss? The difference between the total cost and the productive cost. The content of fixed carbon and volatile matter is a measure of the productive cost, whereas the ash content is the nonproductive cost. Which is wanted, heat value or ash?

No. 1 coal is a purely hypothetical coal, not found in nature, but shown here for the sake of comparison only. Coals Nos. 2 to 5 are representative of coals on the market and show a common range of characteristics. Which of these coals will give the best results in cost and efficiency in the plant, from mines to bunkers and ultimately to the ash dump? Does storage value mean anything when, through strikes at the mines or stoppage of transportation by floods, the plant is threatened with a shutdown? If so, which of the four coals would it be preferable to have the bunkers or field filled with in such an emergency?

The cost does not stop with the original price per ton plus freight, for handling, crushing, storing charges on the coal and also handling of the resultant ash must still be covered. It is generally conceded that coal high in ash and sulphur is harder on all handling apparatus than a coal of lower ash and sulphur content. The costs for upkeep of apparatus will then be in proportion to the wear and tear upon such equipment. In the furnaces evolution of heat is the desired output and will vary directly with the heat content of the coal used. The higher the heat value, the greater the amount of heat liberated, all other conditions being similar. Finally there are the charges for handling the ashes produced. These costs vary directly with the ash content of the original fuel burned.

In general, it may be said that the higher the quality of coal which the plant will handle economically, the lower will be the costs and the greater the efficiency of the plant. It is not necessary that the dealer be held to a strict specification of properties of the coal purchased, although it is wise for the purchaser to acquaint himself with such characteristics and for his own satisfaction



Diverse Meanings of One Pound of Coal to Consumer

formulate a specified analysis. He will find that daily tests on all coal received at the plant, or possibly weekly averages, will afford him valuable data, and if he sends copies of all such tests to his dealer, he will find himself possessed of powerful ammunition with which to convince the dealer that it is to his interests, as well as those of the purchaser, to furnish the coal desired. Such an arrangement tends toward mutual satisfaction since it places both parties to the contract on an equitable footing.

The tests which should be made regularly are those to determine the heat value per pound of coal as fired, ash content as fired and percentage of sulphur. These tests give all the required data. Other tests may be made, often of value to the consumer, such as the determination of fixed carbon and volatile matter. Moisture must always be determined in order to calculate the coal to the condition "as fired" or net weight of coal burned. These are simple tests, and the apparatus is not expensive when the results are considered. By all means adopt the oxygen-bomb type of calorimeter for determining the heat value of coal. Other calorimeters are at best only approximate in their results, although cheaper in first cost.

The purpose has been to point out the real meaning of "coal" to the purchaser and consumer and to emphasize the fact that only by knowing the fuel can the user reach that degree of standardization in his fuel purchase and combustion which has been the real factor in producing the high efficiency of the modern power plant. It is a fact that uniform fuel means uniform and economical operation in the plant.

Good Specifications

A specification or written contract should be a binding agreement that will hold good in law, and should also define or describe so clearly that no doubts can arise, when examined in detail, as to the meaning, scope and intention of the agreement. Simple, direct and comprehensive language alone will fulfill these needs. No matter how complex the idea, some way of expressing the meaning that will be clear to all parties is always to be found. Yet it is the rule, rather than the exception, on contract jobs for owners, engineers, inspectors, contractors and mechanics to be hindered one or more times by a dispute over the interpretation of some clause of the specification.

At such times it seems as if the ideal contract will never be written. Each of the interested parties is able to show good reasons for his contradictory interpretation of the meaning. The owner justifies his effort to get the best class of service and material for the least possible expenditure, and the contractor, on his side, strives to make the contract call for the least material and labor. These opposing interests of owner and contractor are the reason for the binding character of the agreement, and the frequent ambiguity of meaning may in many cases be traced to over-anxiety on the part of the writer to produce a document binding in law.

At the same time these opposing interests call no less for clear unambiguous specifications than for legal safeguards for the protection and control of both parties. Probably the best way to obtain such specifications is to have them written by some disinterested third party who is thoroughly familiar with the work to be done, the legal demands, and the necessity for perfect clearness. Another method of obtaining clear specifications and one which has been receiving considerable attention is the use of a uniform standard specification. Where applicable, this method appears to be best, the standard form being adapted from time to time to agree with an ever widening experience.

An Engineer Needs Judgment

It is the engineer's judgment that counts, not only in the performance of his duties in the engine room, but in his administrative position as the head of an important department.

His vocation is unique in that there is no well defined term by which to designate it. If it were only a matter of keeping boilers and machinery in operation, starting and stopping, and looking after details, he might be called an attendant, but if he is to be truly successful he must have more than the ability to do these things. He must have mechanical ability as a workman, as well. This part of his work savors of a trade. He must also have a knowledge of mathematics, physics and chemistry before his calling takes on the characteristics of a profession.

Then there are the things learned by experience; they are peculiarly the property of the engineer. They increase his knowledge and better his judgment in his routine work, and that is a strong point, but his knowledge cannot stop here. It must extend to the executive end of his duties and covers what is now a very important part, and what is fast becoming more important—the business part of his work. To know what is best in his plant to get results, that is what the employer wants, and it requires a knowledge of uptodate equipment of apparatus, appliances and devices, as furnished by trade papers, circulars and catalogs and by personal investigation, and finally, it requires good judgment in the selection of those best suited to the conditions of his own plant.

A man may have all this at his command, but the "what" and "when" in the matter figure largely. He must work in harmony with the powers that be. A proposition that might not receive encouragement at one time might be sought for at another. The management has other things to look after besides the power end, and the engineer must use good judgment in his relations therewith. Knowledge and experience improve judgment, and they are both valuable assets to the engineer.

Engineering Points in Court Decisions

The doings of the civil courts are thought by many engineers to be about as uninteresting as any human activity can be. That this is a mistake will be discovered by anyone who will take the trouble to glance through a few volumes of decisions handed down by the supreme court of any state having a large industrial population. Scattered through the pages of these publications are many absorbing "stories" of both human and scientific interest, and the engineer who has never made the acquaintance of opinions of this kind will do well to look into the subject the next time he is in a public library or within visiting range of a courthouse.

Naturally, the chief engineering interest centers in those decisions which bear most directly upon accidents, except in the findings of the Federal courts, where patent decisions of the most absorbing technical significance may be found. By and large, these decisions contain clear-cut statements of the circumstances surrounding accidents in the plant and on the field which are often instructive in suggesting ways of avoiding the recurrence of trouble, and which almost invariably assign responsibility in a way which appeals powerfully to men with the reasoning powers of engineers. It is surprising how soon one can acquire the knack of scanning decisions of this kind for material of technical importance from the engineering or operating standpoints, and the excellent indexes which these volumes generally have are most helpful.

Without attempting to list the topics treated in the findings of the higher courts, it may be noted that these include explosions, short-circuits in electrical generating equipment, accidents on transportation and distributing systems, failures of material due to defective manufacture, the results of negligence in dealing with high-tension conductors, omission of safeguards on and around machinery, failure to live up to the terms of contracts, oversights in the erection and use of structures, tools and forms for concrete molding, the value of new ideas in equipment design and arrangement, and a host of other matters which make very interesting reading, entirely apart from the discussions of legal problems which necessarily go with the setting forth of facts and the interpretation of their relations to one another. Especially in the patent cases is one likely to find engineering points of note, since expert testimony is usually brought into the proceedings and the analysis of equipment designs carried to extraordinary lengths.

The study of court decisions bearing upon engineering questions is well worth the while of men of technical training and occupation, and it is a pity that so many engineers fail to realize the interest and instructive value of the material hidden away in such opinions. Court decisions will never rank among the "best sellers," but no greater mistake could be made than to assume that they are too dry to be worth scanning except in cases with which one has personal associations. If one does nothing further we would advise at least the reading of the digests of cases of engineering interest which appear from time to time in our department, "Recent Court Decisions."

Analyzing the Plant's Condition

It is always gratifying to the editors to know that readers have made practical use of matter which has appeared in POWER's pages. Under the same heading as this editorial, on page 239 is the report of a reader on his plant, as examined according to the questions in the foreword, "A New Year's Letter," which appeared in the issue of January nineteen.

Incidentally, Mr. Hawkins is to be complimented on the excellent showing which his plant made. We are satisfied, however, that it was not for the purpose of eliciting praise for himself or his plant that he sent us this report with his permission to print it, justifiable as may be his pride in the condition found. Rather do we believe that he is sincere in hoping that the idea may be of value to others who would take it as a suggestion to measure their own plants, not so much to discover how well they have done, but wherein they may make improvements.

In his own case it would appear that Mr. Hawkins has been frank in his criticism of things that are not all that they might be, and it is in this direction that we feel he and all who try the test will derive the most benefit. In fact, it was our purpose in printing the New Year's letter to have it bring to mind all of the points upon which an examination of a plant is desirable. While most of them would occur to any painstaking engineer, a few might easily be overlooked.

The scheme of marking or grading the condition by percentages for each question was rather original and has its value to any individual, as it affords comparable figures. It would not, however, serve as a basis for comparing different plants, at any rate not unless the marking were done by the same person, on account of the personal factor entering in. No two people would judge alike. Further, as Mr. Hawkins pointed out, the average percentage of the plant as a whole is not fair while equal weights are allowed to each question and answer. To carry out that plan relative importance of one thing to another should be taken into consideration. It is also evident that two different plants could not be justly compared without some modification of the marking system. The scheme does have value, however, in comparing the condition of the same plant from year to year.

We believe that good may come from a discussion of the idea and will welcome suggestions for elaborating or improving upon the method of plant analysis.

Soot

Soot lowers the heat-absorbing efficiency of boiler-heating surfaces! Soot obstructs the passage of the products of combustion! Soot is a direct cause of corrosion! And soot is smoke! Altogether, soot is the undesirable of the boiler plant, an enemy of efficiency that is always present and cannot be entirely eliminated, but must be limited if economy in steam generation is to be realized.

As a destroyer of boiler efficiency, soot is more potent than would be five times the thickness of asbestos spread over the heating surfaces. In obstructing the passage of gases it not only reduces the area of free passage, but the soot clinging to the heating surface has a marked retarding effect on the flow of the gases in proximity to the heating surfaces, thus further reducing the rate of heat transfer to boiler contents. Corrosion of boiler tubes and surfaces is accelerated by deposits of soot, either through electrolytic action or the eating away of the metal by the sulphur constituents that are present, to some extent, in all soot. Then soot contains, or is, practically all the visible, wasteful and objectionable constituents of smoke. Within the furnace, boiler and flues soot is merely soot; issuing from the chimney it is black smoke.

Suppose that, as some claim, one thirty-second inch of soot on the heating surfaces produces as great a loss as blowing out a pound of steam for every ten pounds generated. Steam escaping into a boiler room at any such rate would soon make it impossible for the fireman to remain near his boiler and would be such an evident sign of waste that it would not be countenanced in any plant, no matter how slipshod its operation. Nevertheless, a mean thickness of one thirty-second inch of soot may be found on the heating surfaces of many a boiler—it will frequently collect in ten hours' operation. Again, assume that a three-sixteenth-inch coating would be as detrimental to efficient operation as throwing away seven pounds of steam for every ten pounds generated, which, if allowed to escape into the boiler room, would quickly scald to death the boiler-room force or bring about their asphyxiation. Three-sixteenths inch of soot is rarely found clinging to all heating surfaces, it is true, but such accumulation is not unknown in out of the way corners of the boiler, corners that are difficult to cleanse of soot.

Perfect combustion of fuel would be the only way of eliminating soot. This being impossible of realization, every means of improving combustion must be taken and the heating surface of the boiler frequently cleaned. Too great efforts to prevent soot accumulation cannot be made, for it surely and continually settles on every surface that lies in the path of the products of combustion.

Correspondence

A Short Cut in Packing

One way to cut down Sunday work is to have packing ready cut and prepared to fit each gland. It should be kept in boxes labeled with the size and the rod it is cut for. It is also a good plan to keep the packing hooks on a rack in the same locker, then with a good heavy pair of gauntlet gloves an extra ring of packing can be slipped in during the noon hour. When a job of this kind is to be done in a limited time, it is most important to have everything ready before the machine is shut down. Then, just as soon as the machine is stopped, get busy. The heavy gloves protect the hands, and with all the tools laid out within reach and in order, the job does not take long.

Cleveland, Ohio.

Analyzing the Plant's Condition

As I read the "New Year's Letter" on the first page of the issue of Jan. 19, I mentally answered the questions asked, as they applied to our own plant, and after finishing the letter the question arose in my mind, "Assuming the best practical operating conditions to be 100 per cent., what percentage, as an average, will our plant show?" The result of this self examination was interesting, and the method in which it was made may be of use to others desiring to make the same test. Each question was considered on its own merits, keeping in mind as a standard the best practices as advocated in the columns of POWER during the past year.

	Per Cent.
1. Are our boilers clean? Yes	98
2. Is the brickwork in good condition, and are all cracks and unnecessary openings air-tight? Some cracks in setting	98
3. Is the feed-water heater clean and working efficiently, and is the water as hot as possible? The heater is clean, but not of an efficient type. Exhaust is also used for heating the building, and hotter feed water would mean more live steam for the building. Could be improved in summer	94
4. In water-tube boilers do we know that the baffling is tight and that the gases are not short-circuited directly to the stack? Yes	100
5. Are we sure that all blowoff valves are tight and that we are not blowing down too much? Yes	100
6. Are our dampers working, and do we use them instead of closing the front doors on hand-fired boilers, allowing cold air to filter through the brickwork, etc., or on stoker-fired boilers allow the fires to burn down too low? No. Dampers are not properly used. Draft is controlled by speed of stoker engine and fan, and is unsteady	80
7. Are we carrying a steady maximum steam pressure? Yes	100
8. Are all our grates, gages, flue cleaners and other boiler- and engine-room tools and auxiliaries kept in proper condition? Yes	100
9. Have the soot and ashes been cleaned out of the base of the stack and combustion chamber? Yes	100
10. Do we know that our draft is the maximum possible under the existing conditions? It is too high	98
11. Are we using a minimum amount of labor to properly perform the work in both engine and boiler rooms? Yes.	100
12. Are the engines operated as economically as possible under the existing conditions? Yes	100
13. Do the pistons leak? No	100
14. Do the valves leak; are they properly set? There is no leakage, and they are properly set	100
15. Is there any undue loss of pressure between the boiler and engine? No	100
16. Is there any steam loss from leakage in steam lines? No	98
17. Is the back pressure on the exhaust a minimum? Could be lower in winter, but would give no better economy, as engines are not intended to operate on a vacuum	98
18. Are all steam traps in good condition, or are valve seats cut, floats collapsed or other parts defective? Holly drain system is used, with very few traps; these are in good condition and do not leak	100
19. Are all exposed surfaces subjected to loss of heat by radiation covered? Yes, except pipe flanges	94
20. Do we know that all valves on steam lines and all drain valves are tight and in good condition? Yes	100
21. Are all drains from oil separators, heaters, piping, etc., clear and in good order? Yes	100
22. Are we using the proper auxiliaries to keep the feed-water temperature at a maximum, and are motor-driven auxiliaries operated under a maximum efficiency? In winter, yes. In summer we could do better with a more efficient type of feed-water heater, as the exhaust is wasted and the temperature of feed-water in summer is low	85
23. Have we the maximum vacuum possible with the present temperature of water, barometric head, and water supply? No, a higher vacuum could be carried in winter, but more live steam would be used. In summer engines run noncondensing	96
24. Do we keep the maximum load factor on all apparatus in use? Yes, on boilers, but engines operate a great deal of the time underloaded. Have one more unit than is needed and smallest unit is too large for the light load at night. Only one is used at a time	80
25. Do we try to keep down the cost of supplies such as lamps, oil, waste, packing, etc.? Yes	100
26. Do we know that our apparatus and station light and wiring are in safe condition? Yes	100
27. Have we fire extinguishers and fire hose on hand and properly connected? Yes	100
28. Have we taken all precautions to prevent accident by protecting all openings by railings, inspecting ladders to see that they are safe, looking after all weights or other heavy parts that may be suspended from above, seeing to it that all pulleys, blocks, tackle chains, and other tools are in proper order? Yes	98
29. Are there any oily or slippery places in or around the plant, or any piping or apparatus in use that is showing signs of strain? No, except high pressure in feed line due to leaking pump governor	98
30. Are high-tension apparatus, switchboards and all exposed wiring properly guarded and danger signs used where necessary? All wiring is protected by guards except front of generator switchboard, and wide space back of distribution switchboard is used for storage of lamps, wire, etc	90
31. Have we prepared for extreme weather conditions in the way of ice, floods, lightning, etc.? Yes	100
32. Have we taken care of the effects of high wind and rains on our stacks, windows, roofs, etc.? Yes, except main sewer from building is too small and causes water to back up through plumbing fixtures on basement floors during very hard and long rains	95
33. Do we keep accurate records of the operation of the power plant and other machinery? Yes, but could be improved	98
34. Is the operation of the plant harmonious, the men satisfied with their work and with each other, and with the salary received? Yes, as a rule	98
35. What is the general appearance of the plant; is it kept clean, with bright work polished, floors clean and all machinery clean? Yes	100

Adding the percentages for each item and taking the average, we get a general average of 97 per cent., or in other words, the general condition of the plant taken as a whole has a rating of 97 per cent. of the best practical operating conditions that could be obtained in a plant of this character. The nature of the work is that of an office-building plant. We have a greater engine capacity than is required and could get along just as well with one less engine. The other equipment is all required to provide continuous operation. The lowest percentage of any part of the equipment is in the furnaces, which could be improved by installing a better means of controlling the draft and by operating the blower continuously at a uniform speed, with the dampers partly closed at times. There are some other changes that could be made to improve the efficiency, but would require a change of the equipment in use at present.

This test, if honestly made, is interesting, and of benefit in checking the general condition of the plant at the end of the year. If it were made at the beginning of each year it would give the engineer an efficient means of telling whether the condition of the plant was getting worse or better, as compared with previous examinations.

It has the disadvantage that a low percentage in the boiler efficiency would be more expensive than a low percentage in the condition of the fire extinguishers, for instance, but would not show in the general average unless the several percentages were multiplied by their relative importance.

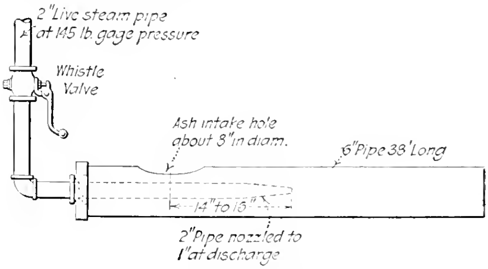
I would like to know what other engineers think of this self examination, which I admit is not absolutely correct from all points of view, and what they would suggest to improve it.

J. C. Hawkins.

Hyattsville, Md.

Live-Steam Ash Ejector

In regard to the unsatisfactory ash ejector described in the issue of Dec. 22, 1914, p. 889, I would suggest that if Mr. Clark will advance his steam nozzle to about 16 in. beyond the intake of his ejector, or, in other words,



Nozzle for Ash Ejector

beyond the bottom of the ash hopper, and use a 2-in. steam pipe nozzled down to 1 in. at the discharge instead of a bell nozzle, and entirely close the end of his larger pipe where the steam pipe enters, he will undoubtedly eliminate his ejector troubles.

In a plant where I was once employed we had almost the same trouble, and changed it to something like the inclosed illustration, and the ejector worked very well; but it did not have the capacity needed for the four boilers, which it was intended for, so we made two of them and the trouble was ended.

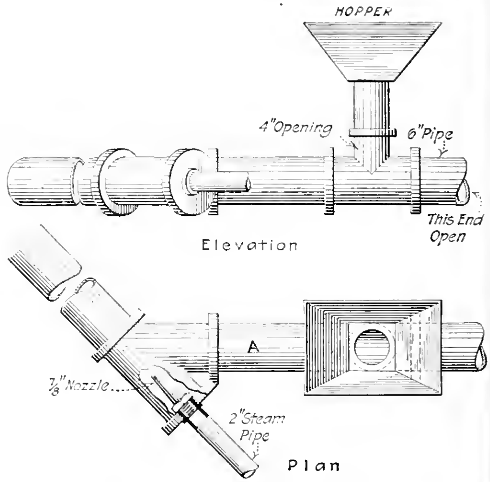
H. L. Burns.

Oran, Mo.

I think if E. H. Clark would change the plan of piping a little and increase the size of the steam pipe the ejector would probably be a success. In his arrangement I believe the steam helped to clog the pipe instead of clearing it.

In the arrangement shown in the accompanying illustration, the steam jet creates a suction in the pipe *A*, which pulls the ashes from the hopper, and they have a high velocity when they reach the nozzle which blows them on through the pipe. If the end of the pipe were not open the ashes fed into the hopper would clog up.

I know of an arrangement similar to this one, which is in successful operation, and I think it is worth a trial, as it would only require a Y-fitting in the present line



Another Steam Ash Ejector

a few feet ahead of the hopper and a larger steam pipe with a single nozzle—one made of brass I think is the best. The pipe line must be air-tight back of the nozzle except at the open end, as noted.

G. Clevenstine.

Pottstown, Penn.

Motor Had One Terminal

Where motors or generators may be required to operate in either direction, both the armature terminals and the field terminals are brought to the outside of the frame for convenience in connecting. Shunt- and compound-wound machines may have four, three or two terminals brought to the outside. Where there are four, all connections are to be made outside, and where there are three,

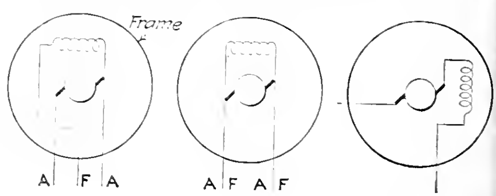


Fig. 1. Fig. 2. Fig. 3.

one armature terminal and one shunt-field terminal are connected inside, as indicated in Fig. 1. This connection may be found on generators, the rotative direction of which has been specified. Where there is but one pair of leads issuing from the frame, it means that the armature terminals and field terminals have been paired and connected inside the motor, as indicated in Fig. 2. Such a connection is never found on machines as received from the makers, because, in the case of a motor, it would require starting with the shunt field short-circuited by the armature; and, in the case of a generator, there would be no convenient way of cutting in the field rheostat.

The limit in terminal economy was reached in the case of a series motor operating a line of shop shafting. The motor apparently had but one terminal; that is, only one terminal issued from it. This condition had passed unnoticed until the motor developed an open circuit which had to be located. The motor was supported by an iron shelf bolted to the iron building, traversed by the car tracks and, upon disassembling, it was found that one armature terminal had been connected to one end of the series field and the other armature terminal was brought out for external connection, as indicated in Fig. 3. Instead of the other end of the series field being brought to the outside of the motor, it was connected to one of the iron field shells with a bolt and the connection taped over, so that it could not be seen. The open circuit was due to the bolt having loosened and burned off.

Compressor Gaskets

In the Nov. 10 issue, Christian L. Hern inquires for a suitable gasket for ammonia-compressor valves. I have had satisfactory results with gaskets made from pure tin or from solder, half tin and half lead. Make this up in the shape of a cylinder by forming up sheet metal an inch or so larger in diameter than the gasket and six or eight inches long. Inside of this use a mandrel about ½ in. smaller than the gasket. After pouring, chuck in a lathe, bore and turn to the inside and outside diameters of the gasket and then cut off to the proper thickness. These gaskets have always made tight and lasting joints for me.

Muncie, Ind.

Safety-Valve Specifications

The article in the Jan. 19 issue, page 81, under the above heading, brings out a number of interesting points in the proposed boiler code of the A. S. M. E. It would appear that these specifications, formulated by the manufacturers of safety valves, represent the best modern practice embodying the combined experience and judgment of those who have had the best opportunities for studying the subject. While in the main the specifications cover the subject in an excellent manner, there are several points which, looking at the matter from a practical standpoint, seem a handicap to the code and impossible of fulfillment.

Assuming that the code is adopted and placed before the legislature of a state, the promoters of the bill will have a hard enough row to hoe to convince steam users and other taxpayers of the desirability of legislation along these lines as a public safeguard. It will be hard to convince legislators in states where boiler laws similar to the proposed code are now in force that anything will be gained by discarding the present rules in regard to safety valves and adopting the code rules. Other states which might be favorably disposed toward this legislation would await the action of the states which now have boiler rules and, undoubtedly, would act along the same lines as the pioneers. It would seem, therefore, that in loading the code with fine-spun theories and lofty ideals the safety-valve manufacturers have not given full consideration to the practical side of the matter.

In the proposed code the size of a pop safety valve for a boiler is based on the discharge capacity of the valve. To determine this capacity it is necessary to take into consideration the total weight, in pounds, of fuel burned per hour at time of maximum forcing, the heat of combustion in B.t.u. per lb. of fuel used, diameter of the valve seat in inches, the vertical lift of the valve disk measured immediately after the sudden lift due to the pop, and the absolute boiler pressure per sq.in., or gage pressure plus 14.7 lb.

A study of these requirements suggests many interesting questions which affect the practical application of this rule. How can it be determined when a boiler is being forced to its maximum capacity? Take, for example, a hand-fired return tubular boiler on which a good fireman with high-grade fuel is having a struggle to maintain steam pressure. Now, if an automatic stoker were installed on this boiler, more work could be obtained from it before the same conditions would obtain. It might be that several types of stoker would be tried out, each doing a little more work than the one preceding it, before the right one was found. In each case, however, the boiler or, rather, the furnace would have reached its maximum capacity and, undoubtedly, the safety valve would have been changed each time. Take the case of a locomotive, in which the maximum capacity is only attained when the engine is being worked. In this case the greater part of the steam goes through the engine and the safety valves are never called upon to take care of the maximum evaporation of the boiler.

The heat of combustion of the fuel would, of course, be determined by calculations from a chemical analysis or by burning a sample in a calorimeter. If fuel is tested today there is no assurance that subsequent tests would not show a higher value, possibly to such an extent that a change of valves might be required to conform to the code. A great many steam plants have no coal-storage capacity, and the coal is delivered day by day as required, and many an engineer can tell without a calorimeter that the heating value of the coal varies load by load.

In the case of a number of paper mills in the Middle West, the principal fuel is "hog feed," or wood chips. The boilers are equipped with stokers which are always ready to go into service automatically if the supply of wood fuel decreases and the steam pressure tends to fall. In one of these plants they have six 90-in. by 20-ft. tubular boilers, and burn about five tons of coal a week in addition to the wood fuel. Now, under the code the safety valves would have to be proportioned, not on the normal conditions, but on the theory that the boilers were being forced at all times to their maximum with coal as fuel. Many similar instances could be cited where it is frequently found necessary to make a quick change in the nature of the fuel.

The vertical lift of a safety-valve disk can be determined by a laboratory test involving delicate registering and recording instruments. If the valve lifts a certain amount, expressed in thousandths of an inch, today, what assurance is there that it would not lift a few thousandths of an inch more or less tomorrow, making the test valueless?

At the top of page 39 of the code, a table of values is given, which may be assumed as the heat of combustion of various fuels. If it is fair to assume this value, why not assume a value for each of the other variants in the rule or formula, which would bring us back very closely to the rule now in use in Massachusetts and Ohio? This could be modified, if necessary, by the addition of the paragraph in the rules of Ontario and other Canadian provinces which provides that, when considered necessary, the safety valves shall be tested under full steam and full fires for at least fifteen minutes with feed water shut off and stop valve closed; if the accumulation of pressure exceeds 10 per cent. of the working pressure of the boiler, a larger safety valve must be substituted.

By this means the whole purpose of a safety valve would be fulfilled and steam users, inspectors, and boiler manufacturers would have a reasonable idea as to where they stood on the safety-valve proposition.

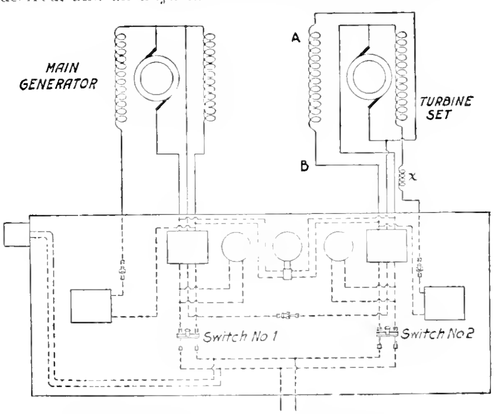
Neglected to Change Field Connections

In taking off some indicator diagrams from an engine we had occasion to put on an additional load. For this purpose it was decided to run a small turbine set as a motor. The main generator and the turbine set had been so arranged that they could be connected in parallel if desired, and an adjustable resistance was inserted in the



CONNECTIONS BETWEEN THE TWO MACHINES

armature circuit of the turbine set at X to limit the flow of current when starting as a motor.

When switch No. 2 was closed and the resistance gradually cut out, the resulting current flow was so great that the belt driving the main generator began to slip; finally, it came off. The trouble was at once laid to a short-circuit in the turbine-generator circuit running to the switchboard. Testing out showed the circuit to be free from shorts, and after carefully looking over the field connections of the turbine set, it was found that the series field connections A and B had not been reversed for operation as a motor.

The turbine-generator had a large series field effect. When the switch was closed and the resistance was being cut out, the current, flowing through the series field in an opposite direction, produced a differential action and neutralized the flux produced by the shunt field. As the torque is the product of the field strength and that of the armature, and the starting torque required was large, the armature revolved very slowly. Hence, the counter-electromotive force was low and permitted abnormal current through the armature.

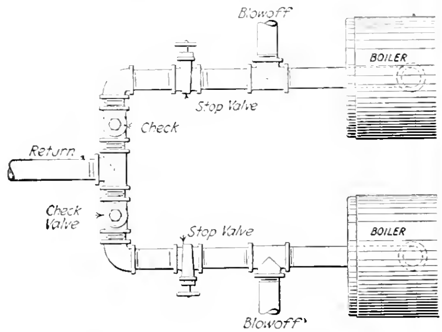
After the necessary changes were made no more trouble was had and the engine tests were made with excellent results.

CARL E. EISMANN.

Rexford, N. Y.

Lack of Synchronism in Check-Valve Action

Referring to the article in the issue of Jan. 12, page 48, under the above caption, it appears that the final arrangement, which gave satisfactory results, was to leave the four heated vessels connected to a main return line with only one check valve in the same.



PROPOSED HAND-REGULATED RETURNS

As regards the Massachusetts rules, which propose to require a separate check valve in each return line for heating boilers connected two or more in a battery and fired independently, it would seem that there is no analogy between this proposed method of connecting boilers and the boiler in question, which furnished four unfired vessels with steam.

In the case where one check valve is used on the main return line, if one boiler is furnishing most of the steam, while the fire under the other is banked, the water will tend to flow through the return connection away from the boiler which does the work, due to the slightly higher steam pressure. The function of separate check valves in each return line is to prevent this. The illustration shows how the connections should be made. With separate checks in each return line, the water level in the boilers will vary with the rate at which each boiler is forced, but would, however, be controlled by the stop valves shown, similar to the ordinary feed valve, so that if the check valves did not work in synchronism it would make no material difference, for the water level would be controlled entirely by the stop valves.

A. W. MACNABB.

Newark, N. J.

[Regulating the water level by stop valves as suggested, would require someone in constant attendance, which is not often the case with small heating plants.—EDITOR.]

Record Keeping in the Power Plant*

SYNOPSIS—The importance of keeping accurate daily records and the necessity of analyzing and comparing them. Losses which would otherwise go by undetected are discovered and the saving in the course of a year is well worth the trouble.

Occasionally one finds a plant in which fairly complete daily records are kept and a capable man in the capacity of supervising engineer to make daily comparisons of operation of the furnaces, boilers, engines, generators, etc., but it is probably an exception to the rule, particularly in the smaller or medium-sized plants.

It is usually difficult, and frequently impossible, for an engineer to persuade his manager to furnish him with the necessary instruments and devices to make daily tests on operating conditions, and the necessary printed forms on which to record the data for purposes of comparison and for detecting the location, or even the existence, of preventable losses. Yet the writer's experience with several plants has proven that the savings made in one month as a result of the daily tests and records frequently will pay for all the additional expenses incurred within a year.

In nearly all plants managed by the writer he has insisted on installing scales to weigh all coal as used and the ashes daily, a water meter in the boiler feed line to measure all water fed to the boilers, a kilowatt-hour recording meter to measure electrical output, and suitable printed forms on which to record the daily records of pounds of water evaporated per pound of fuel, pounds of refuse from furnaces and its percentage to the total fuel, pounds of fuel consumed, rate of combustion, electrical output, pounds of fuel per kilowatt-hour, boiler output in horsepower hours of operation, steam pressure carried from recording gages, and similar data which local conditions would suggest.

These records should be as complete as the nature of the plant justifies; some types of plant naturally require more data than others, but in all cases sufficient data should be recorded to make daily comparisons of value in detecting losses which may arise within the course of a few hours.

From these daily records suppose it is noticed that the boilers evaporated 6 lb. of water per pound of fuel today, while yesterday 7 lb. was evaporated; there is a cause for this difference, and the right kind of a man will not be satisfied until he finds it. It may be due to a new car of fuel, the quality of which is not as good as the former car; perhaps the firemen were "too busy" to scrape the boiler flues. Show them how to be more systematic, so that they will always have time for this work and show them conclusively that you know what is going on in the boiler room and cannot be fooled. Perhaps the load was lighter—then take the matter up with the works manager and try to persuade him to balance his operating conditions to better advantage. Some boiler plants are so located with relation to adjoining buildings that when the wind is from certain directions the draft is affected, materially reducing the furnace efficiencies. Notice from the records if this applies to your case; if so, estimate the losses during a month from this cause and then figure out how long it would take the possible savings to pay for an addition of 50 ft. to the stack. Then put it up to the general manager. There is always a cause for every effect; the records show the effect, and it is up to you to locate the cause and remove it as soon as possible.

Suppose the records show the number of pounds of fuel per kilowatt-hour to have been six yesterday and four for the day before; why this difference? Assuming the load conditions and the boiler evaporation to be the same for the two days, there evidently has occurred a change in the engine economy. This may be due to one or several things; get busy and find the cause.

It is not always easy to locate the immediate cause of these variable losses, but daily analysis of operating performances will soon make a man quick in running down the trouble and will train him to take the necessary steps to prevent their recurrence.

The knowledge that someone is daily going over the operating records also has a decided effect on the engineer and fireman. At first these men usually resent the idea of being so closely watched, but by taking them into your confidence, showing them the various records, complimenting them upon securing better results, and consulting with them in the effort to locate undue losses, they soon learn and realize that this watching is of personal benefit to themselves and adds to their store of knowledge. Usually, there will be voluntary competition between shifts and between neighboring plants to see who can get the most work out of a pound of fuel.

Of course, the writer has found men who resorted to tricks to fool him. One fireman thought that blowing off the boilers at light-load periods and letting in fresh water would raise the rate of evaporation. It did slightly, and sufficiently to start an investigation of the steam consumption of the engine, as at first it appeared that it was taking more steam than ordinarily. The engineer, of course, was notified of an apparent loss of economy in his engine, and after checking the rate carefully he became busy in trying to solve the peculiar problem of the boilers' apparently generating more steam than the plant was consuming. He found the cause and discharged the fireman.

Another fireman was complimented when his rate of evaporation showed an improvement. By permitting the safety valve to open frequently he raised the rate of evaporation, but wasted fuel in doing so. Two or three days' record were sufficient to put a stop to this practice.

The writer believes in frequent testing for line-shafting losses. The tests are simple and inexpensive, especially in case the plant is group-driven by electric motors. The daily hunting for preventable losses is less expensive than the ignoring of them. The load conditions seriously affect the efficiencies of furnaces, boilers, and practically all engines. It is desirable to pay attention to this point and attempt to persuade the works manager to better balance his production departments. One hour or day the power plant may be seriously overtaxed, while the next hour or day it may be carrying a decided underload. Usually, these conditions can be avoided or at least improved upon.

A few years ago the writer took charge, as supervising engineer, of an isolated plant which was entirely too large for the work required. The load factor at that time was about 18 per cent. of the engine and generator rating, and as a result the losses were large. The engine was a simple Corliss, belted to an alternating-current generator, and the boilers were of the regular horizontal return-tubular high-pressure type. The engine was operated at 108 r.p.m., but an order was issued immediately for the proper pulleys for the generator, engine and governor to drop the speed to 82 r.p.m. The result was a saving of 25 per cent. in coal consumption. The only apparent solution for better economy was more load. The shop was fully equipped with men and machinery, so there was no chance for more load here. The rate of evaporation of the boilers was approximately 3 lb. of water per pound of coal. Evidently, then, there was a chance for improvement in the boiler room.

Gas was used for heating the baking ovens in the japanning department, and the writer designed and built in the shop an electric oven. It was so successful that six more were built within a short time. This electric-oven load was just what was needed to bring the load factor up to 41.4 per cent. of the plant rating, and gave the boilers more work to do, with the result that the evaporation increased to 6.5 or 7 lb. of water per pound of fuel. As the rate of evaporation more than doubled with this increased load, it required actually less fuel to operate the plant and saved between five and six dollars for gas per day.

There was still a loss not located, and it was logical to expect it to be in the furnace. Each furnace had 30 sq.ft. of grate area, and tests showed that the rate of evaporation was highest, other things being equal, when from 18 to 20 lb. of screenings were consumed per square foot of grate per hour; a decrease in this rate of combustion, or an increase, lowered the rate of evaporation, the latter showing a greater loss.

Previous tests on the boilers showed that their evaporative efficiency fell rapidly from half load to no load, while the curve of evaporation from one-half to 1¼ load was fairly flat. As the load was sufficient to require in one boiler a combustion rate of about 35 to 40 lb. of fuel per square foot of grate, the furnace efficiency was low. If both boilers were operated to gain in furnace efficiency, the boilers were so underloaded that they showed poor efficiency. Evidently, it was a question of increasing the height of the stack, using forced draft, or adding to the grate area.

A higher stack or a suitable forced-draft system would have increased the economical rate of combustion, but the in-

*From a paper by S. J. H. White presented at the annual convention of the Indiana Engineering Society in Indianapolis, Ind., Jan. 21 to 23, 1915.

crease in grate area seemed worthy of trial, and new grates having an area of 36 sq.ft. were installed in one furnace. This resulted in some saving during the daytime, but at night, when the load was light, the losses were greater than with the smaller grate area. The net gain, however, was considerable.

At this time the company was contemplating moving to another city, so that the writer did not recommend a higher stack, which, after all, was the proper solution of the problem, as it is in a great many plants.

The daily losses detected and removed by a careful survey of the records amounted to over $1000 per year on coal costs alone, with an output of approximately 231,000 kw.-hr. This reduces to 4.3 mills per kw.-hr. and is about 31 per cent. of the total cost of production, including fixed charges, or about 70 per cent. of the cost per kilowatt-hour for fuel, labor, oil and waste only. The cost per kilowatt-hour during 1913 in this plant, including fixed charges of 14 per cent. on the investment, fuel, labor, oil and waste, was $0.014. In view of the fact that the load factor was only 31.4 per cent. of rating, the writer considers this an excellent record, and one which it is possible to make only by the closest supervision.

The weighing of coal proved to be valuable in another way. The management closed a contract for coal with a certain dealer. The writer detected a decided difference in the quality of the coal and a shortage of weight after the third car had been shipped on this contract. He reported the matter and made complaint, but the matter was not attended to as it should have been. Inside of a short time the company had been billed with 70,000 lb. of coal which it had not received. In other words, the weights on the bills had apparently been raised 10,000 lb. per car, and further, the coal was not shipped from the mine specified in the contract. The daily records showed this up clearly. Without them, how much would have been lost on short weights alone in a year's time, to say nothing of the losses resulting from the rate of evaporation dropping from 6.5 to 4.5 lb.? The contract was canceled, and coal was purchased elsewhere of a much better quality on a square-deal basis.

The facts given show that it pays to keep records. Never be satisfied with results which may seem good, but which may possibly be improved upon. In all lines of work continual digging is the only successful way to secure the best results.

Watt-Hour Meter Accuracy*

By D. D. Ewing

While approximately one-half the states have passed laws authorizing the creation of public-utilities commissions, many of the commissions are as yet in the formative stage and have not passed any regulations on watt-hour meter accuracy and meter testing. The percentages of error allowed by the commissions of several states are:

State	Permissible Error, Per Cent.	Remarks
New York	4	Meter must not creep on 110 per cent. voltage.
New Jersey	2 fast, 4 slow	
Connecticut	4	
Maryland	4	
Indiana	4	
Massachusetts	5	
Wisconsin	4	
Washington	4	

The following requirements, abstracted from the rules of the Wisconsin commission, have been widely copied in other states:

(a) No electric meter which registers upon no load shall be placed in service or allowed to remain in service.

(b) No electric meter shall be placed in service or allowed to remain in service, which has an error of registration in excess of 4 per cent. on light load, half load or full load.

(c) Each service meter shall be tested at least once each year, the test to be made by comparing the meter while connected in its place of service, with suitable standards on light-load, half-load and full-load rate of operation.

(d) Each service meter shall be tested and adjusted for accuracy at the time of its installation.

(e) A complete record shall be kept of all tests made on electric meters.

(f) Each company supplying electrical energy on constant-potential systems shall adopt and maintain a standard average value of voltage, as measured at any consumer's cutout, which shall remain constant from day to day, and vary during any one day by an amount not more than 6 per cent. of the minimum value.

It is interesting to note, in this connection, that the permissible error in gas meters, as defined by the regulations of most of the above named states, is only 2 per cent., despite the fact that electrical quantities are capable of more precise measurement than is the flow of gas.

The question may be asked: How near do the meters on the market conform in accuracy to the requirements of the regulations? Manufacturers of direct-current meters usually claim that their meters will register within 2 per cent., plus or minus, from 5 per cent. of full load to 50 per cent. overload, the meter being capable of carrying the overload continuously. Some makers place the lower load limit at 10 per cent. instead of 5. The lower load limit with alternating-current instruments varies from 2 to 5 per cent. of full load among the different manufacturers, the accuracy and overload limits being the same as for the direct-current meters.

The initial accuracy, or accuracy when new, of most modern meters is largely a matter of adjustment. In fact, by careful adjustment a good meter may be made to give an initial registration within 1 per cent., plus or minus, from 2 per cent. load to 50 per cent. overload, and a registration within ½ per cent. from 10 per cent. load to 50 per cent. overload. Such very careful adjustment is hardly a commercial feasibility, however, as it would make the first cost of the meter too high. Moreover, the maintenance charges would be excessive if such a high grade of adjustment were maintained.

Most types of meters are fairly accurate when new, but permanency of calibration is one of the most important of the features that distinguish the good meter from the poor one. In the modern meter increase of friction is the factor that most often affects the permanency of calibration. Also, the variation of the meter friction from instant to instant makes it difficult to secure consistent results in light-load tests. The effect of increased meter friction is to make the meter run slow. With a well designed and constructed meter, it is the exception rather than the rule that the percentage registration increases as the age of the meter increases. While increased friction tends to make the meter run slower at all loads, the effect is most marked at light loads.

Evidently, no power company would care to keep in operation a meter in which the friction had increased enough to even slightly affect the full-load registration. With meters of lower torque ratio than 200 to 1, the errors will be greater, other things being equal. However, if a well designed and constructed meter is properly installed, the friction does not increase very rapidly.

A comparison of the rules above abstracted with the operating characteristics of the meters leads one to believe that in general the regulations cover the ground fairly well. There are several points, however, that merit further discussion. Rule (d) is hardly specific enough and, as it stands, is capable of broad interpretation. It does not specifically state that the test is to be made either on the consumer's premises, with his load or a load having similar characteristics, or elsewhere under conditions approximately similar to those on the consumer's premises, and be in service a year before the error in calibration was discovered. In rules (b) and (c) light load is not defined. If a meter is adjusted so that it is registering within the limits of permissible error, as fixed by the rule, at 10 per cent. load, the error at 2 or 3 per cent. load may be anywhere from 5 to 15 per cent.

The ruling that electric meters may have an allowable error of plus or minus 4 per cent. does not seem consistent with the 2 per cent. ruling for gas meters. It seems that a ruling allowing the permissible error on 5 per cent. load to be 6 per cent., and the error on half and full load to be 2 per cent. would be much better. Such a ruling would protect the consumer far more than does the straight 4 per cent., because with the latter all meters can be adjusted by the power company to be approximately 4 per cent. fast at the higher loads, because meters have a tendency to slow down with age rather than to speed up. At the same time such a ruling would not work any particular hardship on the public-service companies because the light-load error passes the 6 per cent. point long before the error at full load would pass the 2 per cent. limit. Also, some time would be saved in meter testing, because the variable friction of the meter makes it difficult to secure consistent results at light loads, and with a wider range of permissible error at light load, meters would not have to be tested so often.

*From a paper read before the Indiana Engineering Society at Indianapolis, Jan. 21 to 23.

In conclusion, the writer believes the efficiency of the commission rules above abstracted would be increased if:

(1) They specifically stated that meter tests made on the customer's premises be made either on the customer's load or a load whose characteristics were known to be approximately the same.

(2) Meter tests made elsewhere than on the customer's premises should be made with the conditions of voltage and power factor as near like those existing on the customer's premises as is practically possible.

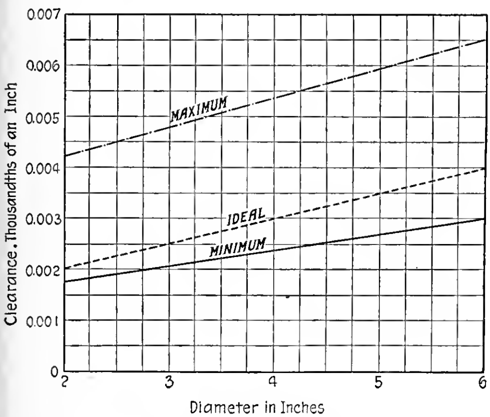
(3) The light load should be defined as 5 per cent. load.

(4) The permissible errors should be taken as 6 per cent. at 5 per cent. of full load and 2 per cent. at half and full load.

Allowances for Piston Fits*

By E. W. Weaver

The piston being the part first affected by the impulse of the explosion, friction at this point decreases the efficiency of the engine to a greater extent proportionately than at any point farther on. Therefore, it is of prime importance that its fit in the cylinder be the best obtainable and that it be sufficiently free to allow for the necessary oil film and for slight distortions under heat, yet close enough to prevent "piston slap."



Maximum, Ideal and Minimum Clearances

The problem is not like that of a solid plunger operating in a cylinder of heavy body and under such conditions as to insure an unchanging form and permit of copious lubrication. Instead, it is that of a comparatively delicate piston working in a cylinder with walls as thin as the designer dares make them and subject to extreme variations of temperature at different points.

The ideal allowance will be considered apart from that of manufacturing tolerances. Some engineers make the piston 0.001 in. small for each inch of diameter of the cylinder bore. The writer prefers to allow from 0.002 to 0.0025 in. for each inch of diameter above 2 in. This is shown in the chart.

As it is impossible to manufacture commercially parts that are all exactly alike, due allowance must be made for variations. The engine builder has the choice of three methods—(1) putting limits on the drawings and holding the inspection to such a point that any piston will work in any cylinder; (2) sorting and assembling the cylinders and pistons according to size; (3) making all the pistons a closer fit than they are expected to run at and lapping them to the proper fit, each in its own cylinder.

Only the first method, that of strictly interchangeable production, will be considered. The fixing of the limits to which the work is to be done is very important, as it directly affects the cost of the product. The drawing should represent what the engineer expects, what the shop will guarantee and what the company is willing to pay for.

Considering the cylinder first, a permissible variation between maximum and minimum size of 0.0015 in. is absolutely necessary—0.002 in. is the ordinary allowance—and the cylinder must not be tapered or "out of round" to exceed the given allowance. A variation of 0.001 in. between the maximum and minimum size for the piston is the usual allowance. If wider limits are given, more care must be exercised in assembling or the quality of the engine will be lowered.

As the head of the piston is exposed to the intense heat of the explosion, it must be made considerably smaller than the skirt. The amount is usually fixed at from 0.002 to 0.0025 in. smaller for each inch in diameter.

The fit of the piston ring in the groove is another important point. The ring must be loose enough to operate freely and close enough to prevent gas from leaking past. The minimum safe allowance is 0.0005 in., and the tolerances on both ring and groove must be given in such a way that this allowance is not diminished. The closest limit that is being worked to commercially is 0.0005 in. variation between the minimum and maximum of both ring and groove width. This would be expressed on the drawing as $\frac{\text{"}0.2500\text{"}}{0.2485}$ for the width of the groove and $\frac{\text{"}0.2490\text{"}}{0.2485}$ for the ring. Allowance must also be made between the ends of the piston ring for expansion under heat. From 0.006 to 0.015 in. is the usual amount.

The fit of the pin in the piston is the final point at which great care must be exercised, the proper allowance being 0.001 in. The hole in the piston, being reamed or broached, can be held from exact size to 0.0005 in. under size. In the case of a 1-in. piston pin, the hole in the piston would be dimensioned from 1.000 to 0.9995 in., while the pin would be given as 0.9990 to 0.9985 in., thus insuring a minimum allowance of 0.0005 in. and a maximum allowance of 0.0015 in.

It should be stated in conclusion that the suggestions in this paper apply particularly to water-cooled engines.

*From a paper presented at the annual meeting of the Society of Automobile Engineers, New York, Jan. 6 and 7.

Petroleum Developments

The world-wide activity in the search for petroleum deposits of commercial importance which characterized the year 1913 continued unabated during the early part of 1914. During the later part of the year, development in proved areas was greatly curtailed and exploration work postponed on account of the European war and the enormous overproduction of oil in the United States and Mexico.

The following paragraphs are from a statement by John D. Northrop, of the United States Geological Survey, discussing the petroleum developments in foreign countries in 1914, which has just been made public by the Survey.

NORTH AMERICA

CANADA—The productive fields of Ontario and New Brunswick continued to furnish the declining petroleum output of the Dominion. Though considerable effort was made to extend the boundaries of the productive areas, new production sufficient to offset the decline in older wells was obtained only in a few places. Good gas wells continue to be found in the Tilbury district, Ontario, but attempts to retard the declining oil output were unsuccessful.

MEXICO—Early in 1914 field operations in the oil districts of Mexico were very active—more so in the northern fields at Panuco and Topila than in the southern fields, where the work was interrupted by the belligerent political factions. The bringing in of an enormous gusher by the Corona Oil Co. (Dutch-Shell) at Panuco on Jan. 11 became the signal for a pronounced increase of work in the northern fields, where, as in the southern fields, the lack of adequate storage facilities tended to hamper developments greatly. Work in all districts was abruptly curtailed and in many places terminated in April. Late in the year the resumpton of local oil consumption by the Mexican railroads and mining industries served to revive activity to some extent.

Of more than passing interest was the fire which raged about the famous Potrero del Llano No. 4 well of the Mexican Eagle Oil Co., during the latter part of the year. Seepages of oil escaping to the surface after the well had been capped were ignited by lightning on Aug. 14, and up to the close of the year the fire, though confined to a small area, had defied all efforts to extinguish it.

SOUTH AMERICA

COLOMBIA—The discovery of petroleum and natural gas at Tubara, near the important Caribbean seaport of Barranquilla, indicates the development of an important oil field in close proximity to the Panama Canal.

BOLIVIA—Geologic investigations have shown the presence of a considerable area of prospective oil land south of Sucre, and the reported acquisition of petroleum concessions in that region indicates that the area will be thoroughly tested.

Relative Costs of Steam and Hydro-Electric Power

The question of relative efficiency and cost of installation and operation of hydro-electric and steam plants brought out some marked differences of opinion among experts at the recent hearings before the U. S. Senate committee while the Ferris water-power bill was under consideration.

Paul M. Lincoln, president of the American Institute of Electrical Engineers, advised that increased efficiency and lower unit cost of installation in the steam plant within recent years altered the hydro-electric situation materially, and that the value of potential water powers had perhaps been overrated because of failure to consider this fact.

"There is much public misconception," Mr. Lincoln declared, "as to the profits of hydro-electric companies, which are generally considered as very large because of the idea that water power costs nothing and the cost of operation is small, while the company's income is large." "On the contrary," he stated, "the interest, sinking-fund charges, taxes and depreciation on the larger initial cost of water-power installations are comparable with the cost of coal in a steam station. The invested capital in a water-power plant is so much greater than the public realizes that with interest charges at not more than 5 or 6 per cent., in a majority of cases from 70 to 80 per cent. of a water-power company's income is absorbed. This return to capital is not profit."

"When the cost of installation for water-power development amounts to $100 per kilowatt capacity against an installation cost of $50 per horsepower for steam," declared Mr. Lincoln, "it is always a serious question whether the steam plant is not likely to be more economical and profitable."

Several other electrical engineers testified along the same lines, urging the discrepancy between steam- and water-power installations and the growing efficiency in steam generation of power, to such an extent that advocates of the water-power bill intimated the possibility of an organized effort on the part of the electrical engineers and water-power companies to affect the pending legislation by depreciating the potential and actual value of water powers in the minds of the committee.

In support of his argument Mr. Lincoln said that engineers have claimed it would be cheaper to install a steam plant in St. Louis to furnish light and power in that city, than to transmit hydro-electric power from the Keokuk dam. An auxiliary steam plant, he claimed, could undoubtedly be installed in Buffalo to take the peak of the load for that city while the Niagara Falls Power Co. carried the main part of the load, and the combination would give Buffalo cheaper power than is now being furnished by the Niagara Falls company. In other words, the cost of the hydro-electric installation to carry a high peak is disproportionate to the return from this peak. He admitted, however, that, considering the entire load factor, the Niagara water power transmitted to Buffalo was developed cheaper than power could be generated there by steam. When questioned about Western power development and costs, he suggested that if water-power installation cost more than $150 per kilowatt capacity in Los Angeles, it would probably be found that steam power could compete with it.

Both O. C. Merrill, chief engineer of the Forest Service, and George O. Smith, director of the U. S. Geological Survey, attacked the statements of Mr. Lincoln and other engineers who testified along the same line. Mr. Merrill declared that Mr. Lincoln's statement that steam and hydro-electric production cost on the average about the same was startling, but wholly incorrect, and proceeded to quote figures from plants in operation. According to these figures the actual switchboard cost of power sold by the New York Edison Co. (Waterside No. 2 station) is approximately five mills per kilowatt-hour. This cost includes labor, fuel, supplies and repairs. On the basis of power generated, where 24.9 per cent. is lost in distribution, the Edison station cost is approximately four mills per kilowatt-hour. Fuel and labor costs of generation at steam plants in California were quoted as 0.336c. for Long Beach and 0.372 for Redondo, while the generation cost at the Pacific Gas & Electric Co.'s Borel hydro-electric plant was only 0.033c., or, with transmission cost added, 0.128 cent.

"On this basis," declared Mr. Merrill, "it would be as profitable to invest $380 per kilowatt capacity for installation at the Borel plant, considering the load factors in each instance, as to invest $50 per kilowatt capacity at the Long Beach steam plant; while the fact that this steam plant was being operated on a 20 per cent. load factor and the hydro-electric plant at 69 per cent. load factor, justified even a larger discrepancy in installation cost."

"In general," said Mr. Merrill," hydro-electric installation costing eight times as much as steam, instead of three times as much, might be considered economical and profitable."

Dr. Smith attacked the water-power engineers for having made much of the increased efficiency of steam production without having mentioned the equal increase in efficiency of hydro-electric production. Quoting from a report of Samuel Insull, president of the Commonwealth Edison Co., of Chicago, he showed that within the last ten years this company, with its steam plant, had quadrupled its investment and increased its output fifteen-fold. In 1903 a one-dollar investment in the Chicago plant yielded 3 kw.-hr., while in 1913 the one-dollar investment yielded 10 kw.-hr. Chicago, all steam, now shows a per capita consumption of a little over 300 kw.-hr. and an average income of a little more than 2c. per kw.-hr., while San Francisco, part steam and part hydro-electric, shows about the same average consumption, and an average income of a little less than 2c. per kw.-hr.

As compared with the showing of the Chicago steam plant of 10 kw.-hr. per dollar of investment, the San Francisco plant had shown 6 kw.-hr. to each dollar of investment in 1911, while the ratio for the Montana Power Co. (all hydro-electric), where the average consumption was as large as 1000 kw.-hr. per capita, was 15 kw.-hr. per dollar of investment.

Undeveloped Power in Eastern Rivers

The rivers of the northeastern and middle eastern portions of the United States are the best known in the country and the earliest in point of development, and their usefulness as sources of power and centers of industry has been demonstrated for several generations. Nevertheless, it has been shown by the work of the United States Geological Survey during past years and is demonstrated in one of the reports of the Survey that in spite of the long familiarity of manufacturers and industrial men in general with most of these rivers, the water resources they afford have not yet been appreciated and by no means developed to their fullest extent. In fact, there are very few rivers in this great region in which the development of water power has come anywhere near the maximum possible degree of usefulness.

The report mentioned, "Water-Supply Paper 261," contains records of flow during several years of the principal rivers in the section referred to, which empty into the Atlantic Ocean. In developing a water supply enormous sums of money may be uselessly expended unless observations of this kind are made throughout the various stages of stream flow.

Water Resources of Connecticut

The rapid industrial development of this state in recent years has given rise to numerous problems relating to water-supply. With an annual rainfall of 45 in. both surface and ground waters in Connecticut are large in amount, but the rainfall is sometimes deficient through periods of several weeks or months. Consequently, farmers must endure periods of drought, manufacturers must provide against fluctuating water power, and congested districts must arrange for adequate water-supplies. With increasing population conflicts of interest arise between water-power users and domestic consumers, and towns dependent on the same streams. With the development of irrigation and drainage another set of interests is making demands.

To meet the present situation and to provide for the future the first step in the solution of the water problem is a comprehensive study of the facts as regards both surface and underground supplies. How much available water is stored in the gravels and sands and bedrock of the state? How much does the amount fluctuate with the seasons? What is its quality? How may it best be recovered in large or small amounts? What is the expense of recovering it? How much water may the streams of the state be relied upon to supply? How much is polluted? How may the pollution be remedied? To what use should each of the various streams be devoted? What is the equitable distribution of ground and surface waters among the conflicting industries and communities?

Realizing the importance of such studies to Connecticut, the state joined forces with the Federal Government in order to carry on the work. In 1911 a coöperative agreement was entered into by the United States Geological Survey and the Connecticut Geological and Natural History Survey for the purpose of obtaining such information. The work in 1911-13 was done by A. J. Ellis and that in 1914 by H. S. Palmer, both of the United States Geological Survey.

The five areas first chosen for study represent more or less typical geologic conditions in different parts of the state.

Reports, including detailed maps, of the Hartford, Stamford, Salisbury, Willimantic, Saybrook, and Waterbury areas have been completed and will be published at the expense of the Federal Government, as water-supply papers for free distribution. Similar reports on the Pomperaug and Plainville areas are in preparation, and tentative plans contemplate covering the other towns in the same manner in order to obtain a detailed and authoritative inventory of the ground-water resources of the entire state.

Efficiency and Size of Steam Turbines

At a meeting of the West of Scotland Iron and Steel Institute, J. Golder, in a paper on "The Steam Turbine," said that as regards efficiency, the Elberfeld turbine in 1902 gave 62 per cent. A Chicago machine is guaranteed to give 74 per cent. A 35,000-kw. turbo set for New York is guaranteed to give 75 per cent. efficiency. As regards size of unit, so far as the turbine is concerned, there is room for still further increase, and 50,000-kw. sets are projected for the Greater London scheme; 10,000 kw. is getting quite common. A line of advance for which the turbine has long been waiting is the combination of high power with high speed. Ideal conditions for this are found in the case of the direct-coupled turbo-compressor, and some remarkable machines have been made.

For example, a Rateau turbine capable of 3000 hp. at 4000 r.p.m. has been installed in the Midlands. Generator makers, realizing the possibility of this compact and cheap prime mover, have risen to the occasion, and 3000-kw. at 3000 r.p.m. Rateau machines have been successfully installed. Fraser & Chalmers have built a mixed-pressure turbine nominally of 2000 kw. at 3000 r.p.m., but as this machine does its full load with low-pressure steam, it follows that the design is safe for a pure high-pressure turbine of about double that capacity. Continental builders are said to have made a 6000-kv.-a. set at 3000 r.p.m., and a 20,000-kw. set at 1000 r.p.m. The Chicago set of 25,000 kw. runs at 750 r.p.m. Rateau sets are under contemplation for an output of 15,000 kw. at 1500 r.p.m.

Public-Utility Legislation in Washington

Representatives of light and power companies have presented their arguments to the joint legislature of the State of Washington, favoring a bill which provides that a company desiring to found competing power plants must procure certificates of necessity from the public-service commission on a showing that the company already in the field is unable to furnish adequate service or is charging unreasonable rates. A further provision legalizes indeterminate franchises subject to public-utility commission authority as to rates and service, leaving plants subject to municipal purchase as going concerns by condemnation. Municipalities granting franchises retain jurisdiction over original construction of plants or systems. If the city and the company are unable to agree upon terms in thirty days, the public-service commission is empowered to grant the franchise. This power is also conferred upon the commission in disagreements where one company is serving two cities or desires to pass through one not served.

Representatives of the Stone & Webster Corp. addressed the body on the proposed bill and urged its adoption, which is practically assured. They stated that public service had reached a point where it was no longer possible to attract the capital needed for further development of power and light projects, due to the fact that many franchises are now entering upon the last year and the statutes give no security in renewals upon which to base future bond issues for extensions.

Another argument urged by the light and power men is that the state, through the public-service commission, has regulated their operation and fixed limitations of how much they may earn on such investments, but has provided no protection for the companies from irresponsible and ruinous competition. They ask the enactment of the pending law as a measure of protection to offset restrictions imposed by state regulation of rates and service.

Model Will Show How Rivers Are Measured

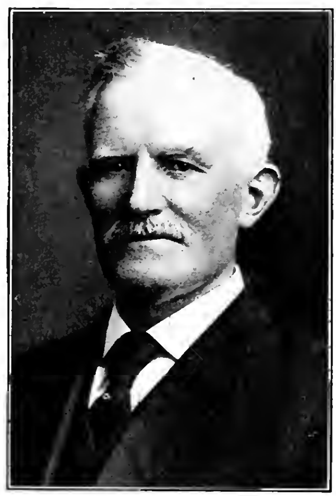
To show the way in which rivers are gaged—that is, how the volume of running streams is measured—by the United States Geological Survey, the exhibit maintained by the Survey at the Panama-Pacific Exposition, in San Francisco, will include a display of automatic gages, run by electricity, which record the fluctuating heights of water of an artificial river—one flowing through a tank.

The work of measuring the flow of the various streams of the United States every day in the year and some of them several times a day affords an invaluable basis for the study of our water resources. Upon the data thus obtained engineers depend in working out plans of water-power development, irrigation, drainage—in fact, every project in which running water is a factor.

OBITUARY

JOHN QUINN

John Quinn, efficiency engineer of the Mingo Steel Works & Furnaces, died on Saturday, Jan. 30, 1915. He was at his desk at the usual hour on Saturday morning, but complained of a sharp pain in the chest. He left the mill about 11 a.m. for his home, and passed away quietly at noon. He is survived by the widow, two sons (Robert S., master mechanic, and Herbert L., assistant master mechanic, Mingo Steel Works & Furnaces), and four daughters.



JOHN QUINN

Mr. Quinn was born in Ireland in 1850 and came to this country at the age of 20. He worked in a printing office in Cleveland for a short time and then entered the employ of the Newburgh Furnace, now the American Steel & Wire Co. He moved to Mingo Junction, Ohio, in 1882, as chief engineer of the Junction Iron & Steel Co., and upon the consolidation of the Laughlin Steel Co. and the Junction Iron Co. in 1884 he was made master mechanic, holding this position through the various changes made in this company until 1911, when he was made efficiency engineer.

He was a man of sterling character, high ideals and unquestioned ability in his chosen profession. His advice and counsel were eagerly sought, not only by the men in his employ, but by his superiors.

Mr. Quinn was actively interested in the religious, charitable, educational, industrial and financial life of the community, being president of the board of stewards of the M. E. Church, a member of the publishing committee of the Pittsburgh "Advocate," a member of the Ohio Valley Hospital Association, president of the Board of Education, efficiency engineer of the Carnegie Steel Co. and president of the First National Bank of Mingo Junction, Ohio.

In his long association with the Carnegie Steel Co. he made many friends among steel men and the allied industries, who will learn with regret of his sudden demise.

PERSONALS

Francis W. Hoadley, well known to mechanical engineers the country over from his long connection with administrative forces of the American Society of Mechanical Engineers, and since connected with the "Engineering Magazine," "Cassier's," and other publications, has accepted a position upon the staff of "Safety Engineering."

Clifton Reeves, head of the Reeves-Cubberly Engine Co., of Trenton, N. J., has been chosen by Secretary Wilson, of the Department of Labor, as a member of the Federal Board of Arbitration, for duty in the South. He has gone to Washington to receive further instructions and proceed to his appointed field. Mr. Reeves' appointment to this important board is the result of his interest and activities in labor matters. For 10 years he was secretary of the Employers' Association, during which time he assisted in the adjustment of several labor differences. He has resigned his position with the association, but will continue with the engine company.

B. F. Grout, consulting engineer, of Pittsburgh, Penn., and at one time professor in the School of Mines of the University of Minnesota, has recently been engaged by the Minneapolis General Electric Co. in connection with the tests of the efficiencies of its turbines in the Coon Rapids plant. Mr. Grout, in connection with his work at Massena, N. Y., investigated very fully what is known as the chemical method of measuring the volume of water flow. In this method a solution of salt is introduced into the penstock above the water wheels, and samples of the water issuing from the draft tube below give a measure of the quantity of water passing through the wheels. Mr. Grout, on Saturday, Jan. 30, gave a talk on the subject of these chemical tests before the Engineers' Club of Minneapolis, at a dinner held at the University Club.

ENGINEERING AFFAIRS

Louisiana Engineering Society—At the annual meeting of the Society held Jan. 9, 1915, in New Orleans, the following officers were elected to serve for the ensuing year: President, L. C. Datz; vice-president, Samuel Young; secretary, W. T. Hogg; treasurer, E. H. Coleman; director, Ole K. Olsen (to serve 3 years). The other members of the Board of Directors holding over are A. T. Dusenbury, W. B. Gregory and W. H. Williams.

Boiler Inspectors—At a recent meeting of the American Institute of Steam Boiler Inspectors of New York City, E. Haggerty was elected president; J. H. Pollard, secretary; and J. Turnbull, vice-president. The annual dinner will be held Feb. 20 at Rector's, Forty-eighth St. and Broadway. Prominent guests will attend, and with a star toastmaster in charge, it is promised that the dinner will eclipse any of the previous ones.

Equitable Dinner—In celebration of the completion of their part of the work on the new Equitable Building in New York City, about sixty mechanical and electrical material men gave a dinner to William Gordon, superintendent of mechanical and electrical equipment of the Thompson-Starrett Co., at the Hotel Claridge, Friday evening, Feb. 5. The committee of arrangements consisted of Paul H. Brangs, of the Heine Safety Boiler Co., who acted as toastmaster and George L. Gillon, vice-president of the National Metal Moldings Co., who was master of ceremonies.

International Engineering Congress—The technical success of the International Engineering Congress at San Francisco, Sept 20-25, is now well assured. From 200 to 250 papers and reports, covering all phases of engineering work, will be contributed by authors representing some eighteen different countries. The Congress will, therefore, be truly international in scope and character, although the representation from the warring countries will naturally be less than originally planned. The papers now rapidly coming in indicate that the proceedings will form an important collection of engineering data and a broad and detailed review of the progress of engineering art during the past decade. The Committee of Management is inviting all important engineering societies to send delegates, and the presence of a considerable body of them is well assured. Membership in the Congress, with the privilege of purchasing any or all of the volumes of the proceedings, is open to all interested in engineering work. For full particulars apply to W. A. Cattell, secretary, 417 Foxcroft Building, San Francisco, Calif.

BUSINESS ITEMS

The Terry Steam Turbine Co., Hartford, Conn., has appointed E. F. Scott representative for the State of Georgia, with offices at 702 Candler Bldg. The Pittsburgh office in charge of H. A. Rapelye is now located at 1624 Oliver Bldg.

The Terry Steam Turbine Co., Windsor St. at Windsor Ave., Hartford, Conn., is sending out a 64-page bulletin giving details on various turbo-pump applications. Anyone interested in any kind of pumping problem can have a copy for the asking.

The Builders Iron Foundry, Providence, R. I., has published a new bulletin—No. 142—which contains much interesting and valuable information on many important waterworks systems throughout the United States and Canada. It is sent free on request.

The Bruce Macbeth Engine Co., Cleveland, Ohio, has recently received orders for one 150-hp. natural gas engine from the Magnolia Petroleum Co., Fort Worth, Tex.; one 60-hp. artificial gas engine direct connected to generator, from the Ingersoll-Gaukler Co., Detroit; one 90-hp. natural gas engine from the Solar Electric Co., Brookville, Penn.; one 90-hp. natural gas engine from the Empire Marble Co., Cleveland; one 40-hp. natural gas engine direct connected to generator, from the Alhambra Theater, Sandusky, Ohio.

CONTRACTS TO BE LET

Bids received until Feb. 25, 1915.

Water Meters and Machinery

BUREAU OF ENGINEERING
DEPARTMENT OF PUBLIC WORKS.

Chicago, February 3, 1915.

Sealed proposals will be received by the City of Chicago until 11 a.m. Thursday, February 25th, 1915, at Room 406 City Hall, for manufacturing and delivering to the City of Chicago Water Meters, made according to designs prepared by the City of Chicago. The following quantities of water meters are desired:

1,500 ¾-inch meters.
2,000 1-inch meters.
750 1½-inch meters.
750 2-inch meters.

The city will furnish detail drawings and one set of patterns of each meter. The contractor is to turn over to the city upon completion of his contract special machinery, tools, dies, jigs, etc., used in the manufacture of the meters, according to plans and specifications on file in the office of the Department of Public Works of said city, Room 406 City Hall.

Proposals must be made out upon blanks furnished at said office, and be addressed to said department, indorsed "Proposals for Water Meters," and be accompanied with One Thousand Dollars in money or a certified check for the same amount on some responsible bank located and doing business in the City of Chicago, and made payable to the order of the Commissioner of Public Works.

The Commissioner of Public Works reserves the right to reject any or all bids.

No proposal will be considered unless the party offering it shall furnish evidence satisfactory to the Commissioner of Public Works of his ability, and that he has the necessary facilities, together with sufficient pecuniary resources, to fulfill the conditions of the contract and specifications provided such contract should be awarded to him.

Companies or firms bidding will give the individual names as well as the name of the firm with their address.

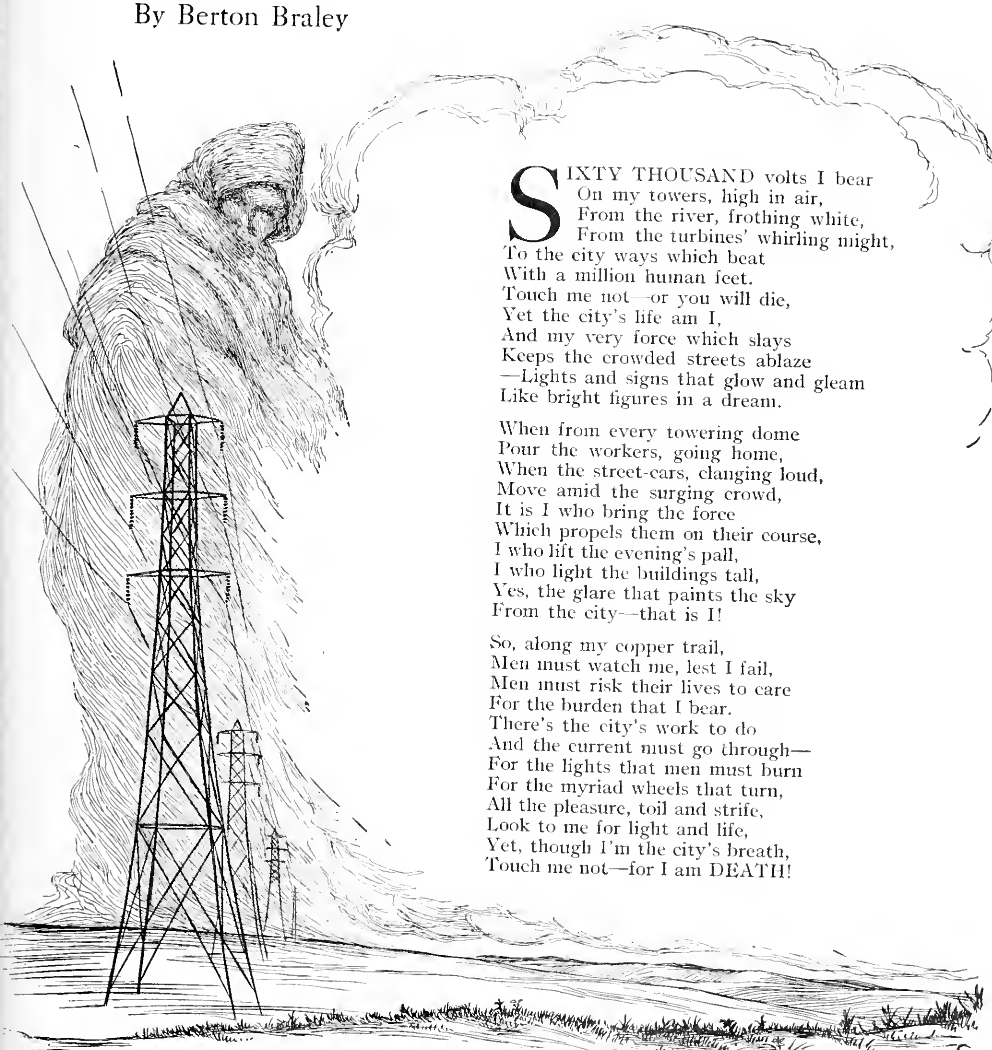
L. E. McGANN,
Commissioner of Public Works.

POWER

Vol. 41 NEW YORK, FEBRUARY 23, 1915 No. 8

The Transmission Line

By Berton Braley



SIXTY THOUSAND volts I bear
On my towers, high in air,
From the river, frothing white,
From the turbines' whirling might,
To the city ways which beat
With a million human feet.
Touch me not—or you will die,
Yet the city's life am I,
And my very force which slays
Keeps the crowded streets ablaze
—Lights and signs that glow and gleam
Like bright figures in a dream.

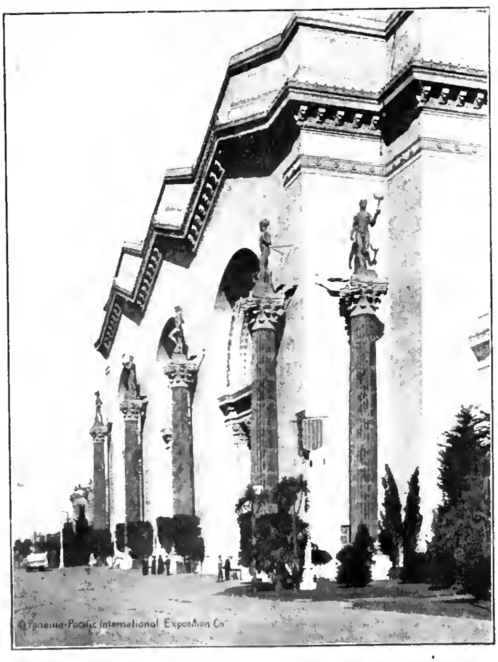
When from every towering dome
Pour the workers, going home,
When the street-cars, clanging loud,
Move amid the surging crowd,
It is I who bring the force
Which propels them on their course,
I who lift the evening's pall,
I who light the buildings tall,
Yes, the glare that paints the sky
From the city—that is I!

So, along my copper trail,
Men must watch me, lest I fail,
Men must risk their lives to care
For the burden that I bear.
There's the city's work to do
And the current must go through—
For the lights that men must burn
For the myriad wheels that turn,
All the pleasure, toil and strife,
Look to me for light and life,
Yet, though I'm the city's breath,
Touch me not—for I am DEATH!

The Panama Pacific International Exposition

Race Track, Aviation and Athletic Field State and Foreign Pavilions Education Food Products Agr
Drill Grounds Stock Exhibit Fine Arts Horticulture Libera

Third of its class held in the United States and twelfth of its class held anywhere in the world, the Panama-Pacific Exposition was officially opened when President Wilson touched the button last Saturday. Contrary to the usual international expositions, it is not the celebration of an anniversary of some past event, but commemorates a modern achievement—the completion of the Panama Canal. In its exhibits it is intended to show particularly the advance which has been made in the last ten years, or since the Louisiana Purchase Exposition. There being less of history in it than is usual, it is especially interesting to contrast some things contemporaneous with the years of the various World's Fairs. For example, in the steam-power field, we have, as typical of their respective times, the big Corliss walking-beam engine at the Centennial Exposition at Philadelphia in 1876 the quadruple-expansion 2000-hp. Corliss engine at the Columbian Exposition at Chicago in 1893, a 5000-hp. angle compound engine and a steam turbine of 2000 kw. at the Louisiana Purchase Exposition at St. Louis in 1904, with turbines as large as 5000 kw. built at that time, and now 35,000-kw. turbines, though none of that size will be exhibited at San Francisco, for the Panama-Pacific Exposition does not generate its own power for lighting and the operation of moving exhibits, but purchases its current from the Pacific Gas & Electric Co. which has over 90,000 kw. in hydro-electric installations and approximately 100,000 kw. in steam installations, the steam plants being boosters or auxiliaries in case of breakdown of the hydro-electric stations. Three-phase, 60-cycle, alternating current of 11,000 and 1000 volts will be furnished in amount up to 9000 kw. between 5 and 7:30 in the afternoon of any day or up to 15,000 kw. at any other time. The 18,000 kw. steam plant of the Sierra & San Francisco Power Co. is held in reserve, ready in case of interruption of the Pacific Gas & Electric service. The exposition's secondary distribution is at various voltages—117 for lighting, and 230 and 440 for power. Direct current by conversion through motor generators is available at 250-125 volts. The Centennial engine drove the machinery by means of lineshafts gear-driven from the engine and extending throughout the building.



Front End of the Palace of Machinery

The Centennial Engine

This engine was really a pair of beam-engines and formed the most prominent exhibit at the Centennial. They operated condensing and were supplied with steam at 80 lb. pressure. The valves and valve-gears were Corliss and the cylinders were 40 in. in diameter with 10-ft. stroke. The beams were 27 ft. long by 9 ft. deep and weighed 11 tons each. They were connected at right angles to a shaft carrying the flywheel, which was a cut gear wheel 30-ft. diameter and 2-ft. face, and was the heaviest cut wheel that had ever been made up to that time. It geared with a 10-ft. pinion on an underground shaft 256 ft. long running across the building. This lineshaft at each end and two intermediate points was connected by 6-ft. bevel gears to transverse shafts extending lengthwise of the building. These shafts were belted to eight overhead shafts, each 658 ft. long. The engine made 36 r.p.m., giving a piston speed of 720 ft. per min. The peripheral speed of the spur gears was 3384 ft. per min. The engines were rated at 1400 hp., but could develop 2000. The cylinders were jacketed with live steam.

San Francisco, California, Feb. 20 to Dec. 4, 1915

Tower of Jewels — Transportation — Manufactures — Varied Industries — Mines and Metallurgy — Festival Hall — Machinery — The "Zone" Amusement Concessions

Steam was supplied by twenty vertical boilers furnished by Corliss, which also supplemented the steam supply to the Pump Annex. Each boiler contained 48 tubes 3 in. in diameter in a shell 4 ft. in diameter by 14 ft. high. The total heating surface of the twenty boilers was given as 13,000 sq.ft.

Columbian Fair Engines

A heterogeneous collection of engines was to be seen at Chicago—horizontal and vertical, high-speed and low-speed—and no one type can be taken as representative of that time. The largest engine shown was a 2000-hp. Allis (Reynolds-Corliss) engine with 20-, 40-, 60- and 70x72-in. cylinders and 60 r.p.m. The flywheel was 30 ft. diameter by 76-in. face and carried two belts 6 ft. wide, each driving a Westinghouse 10,000-incandescent-light dynamo. Another notable engine was the 1250-hp. four-cylinder triple-expansion Buckeye engine with its distinctive valve-gear. Its cylinders were 20, 32 and 36x48 in. The flywheel was 20-ft. diameter by 72-in. face and it also

drove through a 6-ft. belt. It has since developed that fewer cylinders and larger ratios are better and even triple-expansion engines are not warranted except with the higher pressures used in marine service.

Louisiana Purchase Exposition Engines and Turbines

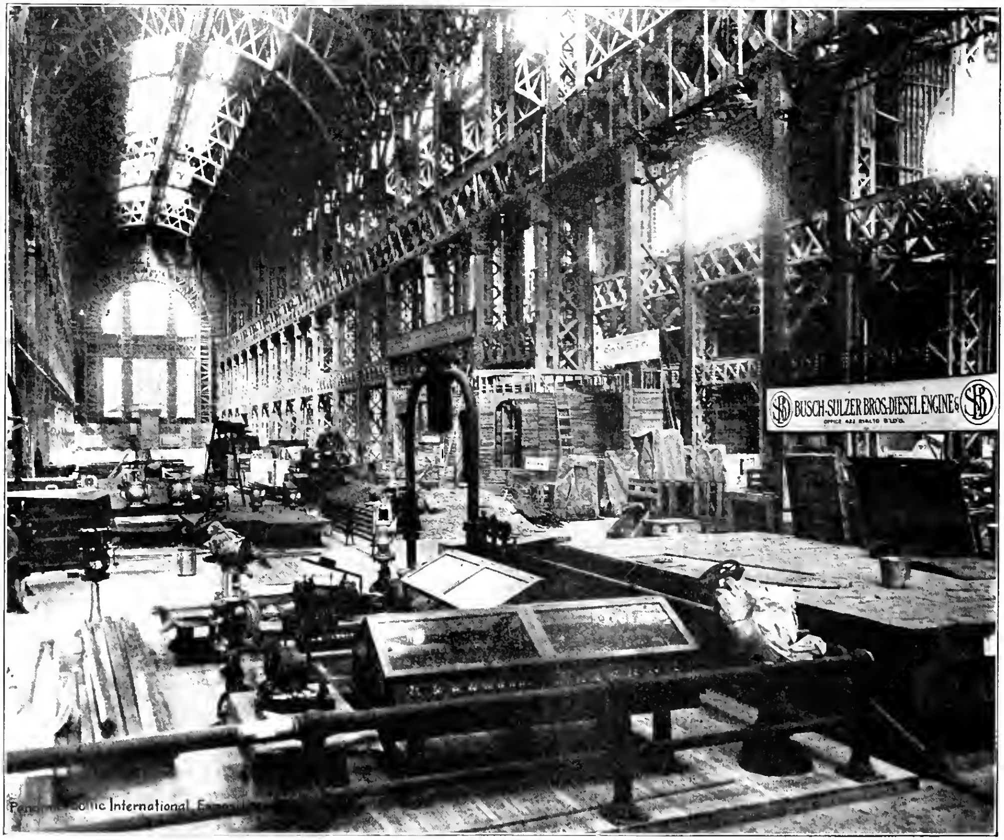
At this time (1904), the struggle between the turbine and the reciprocating engine was on and the advantage of the former, even in large units, was yet to be established. The largest turbines of their day were 5000-kw. Those exhibited were a 2000-kw. Curtis, a 1000-kw. Hamilton-Holzwarth, and a 400-kw. Westinghouse-Parsons. There were 21 engines, of which the 5000-hp. Allis-Chalmers angle compound was the largest, most impressive and most typical of the art and time. It had cylinders 44 and 94x60 in. and drove a Bullock generator by direct connection at 75 r.p.m. Four three-cylinder vertical compound 3000-hp. Westinghouse engines driving 2000-kw. generators were really not exhibits, but a part of the outfit bought by the Exposition.

Present-Day Prime Movers

At San Francisco, as the exhibits are not furnishing power for any considerable part of the exposition's needs, there was no occasion to install a prime mover of the size that must be taken as representative of this period for large capacity. Such a one, however, is the 35,000-kw. turbo-generator now being completed for the Philadelphia Electric Co. This unit, with its condensing equipment, will occupy a floor space of 1355 sq.ft., which is in marked contrast with the 2376 sq.ft. required for the Centennial engine. The horsepower output of the two units per square foot of area occupied is 34.6 for the new turbo-generator and 0.6 for the Centennial engine. The respective weights are 1,200,000 lb. and 1,400,000 lb., and the speeds 1200 and 36 r.p.m.

Centennial and Panama-Pacific Machinery Buildings Compared

The machinery buildings of the Centennial and Panama-Pacific expositions furnish a number of striking comparisons and contrasts as shown on the two accompanying pages. These give, by a few illustrations and tabulated data, a comparison of general dimensions and a few important features of these two great buildings. The Centennial Machinery Hall was a larger building, both in length and floor area, than the present Panama-Pacific Palace of Machinery. But this must not be looked upon as a step backward, for at Philadelphia the building de-



Inside the Machinery Palace during the Installation of Exhibits voted to machinery included everything that could be brought under that general head. In keeping with our present tendency toward specialization, the exhibits at San Francisco have been divided so that printing presses, typewriters, and similar machines now go to the Palace of Liberal Arts, while locomotives and all means of transportation have a building of their own.

One of the striking contrasts between the two buildings is in the materials of construction, for strange as it may seem, more metal was used in the Machinery Hall of Philadelphia 40 years ago than in the present Palace of Machinery in San Francisco. The two pages of illustrations give a hint as to the kind and quantity of these materials.

Another contrast worthy of mention lies in the provisions made for installing exhibits. In Philadelphia there was a total absence of crane service—not a single crane of any kind was used. At San Francisco there are two 30-ton cranes in the middle bay, with one 20-ton crane in each of the two principal side bays. The skids, rollers, and tackle of 1876 have given way to the traveling cranes of 1915.

General Features of the Present Fair

The grounds are in the city limits of San Francisco and face north on the bay. There are 2¾ miles of buildings, covering an area of 635 acres. While this area is only about half that occupied by the St. Louis Fair (1240 acres) and not even quite as much as the Chicago Fair (733 acres), this is an advantage rather than otherwise, for it means that the tiring distances to be walked are less. It cost more, however, than any exposition to date, for it represents an investment of $58,000,000, whereas the Louisiana Purchase Exposition cost $50,000,000, the Columbian Exposition $20,000,000 and the Centennial Exposition $8,000,000. For the present fair nothing was contributed by the Government as in the cases of the Chicago and St. Louis expositions. The palaces cost more than $12,000,000. Another distinguishing feature of this Fair is that the structures were finished three months before the opening, and it was the first international exposition to be considered completed on time.

White does not predominate in the buildings. The walls are of an ivory tint, and the roofs generally red and flat, with great domes and lofty towers of blue and gold, and green-latticed windows. Add to this the effect of the myriads of flowers, palms and trees, and it is evident that there is here no lack of color.

The tallest feature is the Tower of Jewels, 435 ft. high. On either side of it are the main exhibit palaces, 14 in number. Height in general marks these buildings as compared with the previous fairs, for the walls of the palaces are as high as the average six-story city block. Just east of the group is the amusement section known as "The Zone," to which there has been devoted 65 acres. To the west of the group are the pavilions of the 42 states and 38 foreign countries participating. In addition there are the parade grounds, live-stock pavilion, life-saving stations and the aviation and athletic field.

Eight exhibit palaces subdivided by courts make up the main group, seemingly under one roof and appropriately called "The Walled City." The buildings are in a rectangle, their walls being interconnected and broken only by archways and entrances giving access to the courts between the buildings. The buildings are all of the same height and the architecture generally similar. The courts dividing them north and south are known as the Court of the Universe, the East court, or the Court of Abundance, and the West court, or the Court of the Four Seasons. These eight central palaces are: Mines and Metallurgy, Transportation, Agriculture, Food Products, Varied Industries, Manufactures, Liberal Arts, and Education.

Palace of Machinery

Flanking this group on the east is the Palace of Machinery, in which centers the most of interest to Power readers and of whose exhibits more will be told in later issues. It cost approximately $650,000, and is the largest wooden building in the world. It was the first of the exposition palaces to be completed. Ground was broken on New Year's Day, 1913. The architecture is Roman, and the decoration is classic in form, but modern in expression and suggests machinery and invention. Inside, the building, is divided into three north and south aisles, each 101 ft. high and 75 ft. wide, extending the length of the building which is 967 ft. long. On each side of the main structure are side aisles 70 ft. wide covered with shed roofs 41 ft. high to the soffit of the trusses. The total width of the building is 367 ft. and the total floor space 370,000 sq.ft. In other words, it is about three blocks long, 8½ acres in size and as tall as a 13- or 14-story building. Lincoln Beachy, the aviator, flew from one end of it to the other under the roof. This was the first time an aëroplane flight was attempted indoors.

To facilitate the installation of heavy exhibits there are two 30-ton traveling cranes with 5-ton auxiliary hoists in the middle bay and a 20-ton traveling crane in each of the two principal side bays, all operating the length of the building. Railroad tracks enter and cross the building at the center at right angles to the crane travel, so that shipments received by rail can be unloaded from the cars directly by the cranes.

The first machinery exhibit was installed May 27, 1914, nine months before the opening of the Exposition. This was a Busch-Sulzer Diesel engine of 500 hp. The occasion was celebrated with fitting ceremonies attended by exposition, state and city officials and several hundred engineers. The exhibit is to be seen in one of the illustrations herewith.

Wherever possible, the exhibits are to be in operation, and many of them will also embody the exhibition of safety devices being arranged by William Doolittle, safety inspector of the National Metal Trades Association. To increase the convenience of viewing the building's exhibits electric chairs operating on tracks are provided, so that visitors may go from place to place by the pressing of a button and thus may spare themselves the fatigue which is such a drawback to exposition sight-seeing.

The sculptural feature of the Machinery Palace are three figures typifying the Triumvirate of Power, which are repeated in rotation at the tops of the 60-ft. columns flanking the entrances. These are called "Electric Power," "Inventive Power" and "Steam Power" and are the work of Haig Patigian, an Armenian by descent, but a resident of San Francisco. They are 16 ft. high and of a deep-golden color. Electric Power shows a man controlling a lightning bolt with his right hand, and dominating earth under his left foot. Inventive Power is symbolized by a heroic figure wearing the wreath of achievement and holding in his right hand a globe from which rises in flight a winged man. The power of steam is typified by a man in the act of creating motion with a driving rod of a steam engine attached to a crank which gradually blends with the earth.

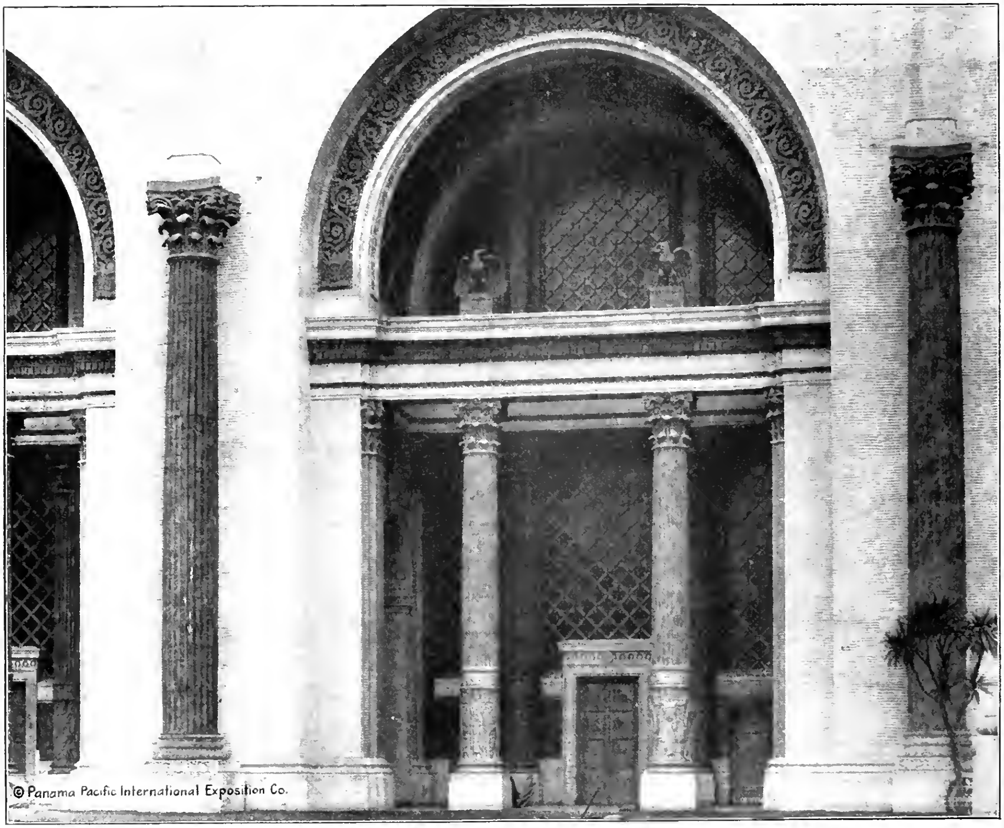
Other Buildings

Flanking the central group upon the west and separated from it by a lagoon, which it partly encircles, is the Palace of Fine Arts. The Palace of Horticulture covers approximately five acres and has as its most prominent feature a steel dome 186 ft. high and 153 ft. diameter, surmounted by a half-sphere 26 ft. high, weighing 26 tons. It is planted with flowers and at night is one of the most spectacular features of the illumination. Festival Hall will be the rendezvous of conventions, among them the Engineering Congress next fall. Nearly all of 350 congresses and conventions will be held here.

Methods of indirect lighting are used for out-of-door effects for the first time at any exposition. The palace walls are flooded by light from high-power arcs, concealed or shaded from the eyes of the spectators by ornamental metal shields or banners. Domes are illuminated from within by powerful searchlights arranged to give varying colored effects. Architectural features are accentuated by the use of "jewels" of polished crystal.

Of the nations which committed themselves to participate before the war, none has withdrawn. They include Argentina, Australia, Austria, Bolivia, Brazil, Canada, Chile, China, Costa Rica, Cuba, Denmark, Dominican Republic, Ecuador, France Guatemala, Haiti, Holland, Honduras, Italy, Japan, Liberia, Mexico, New Zealand, Nicaragua, Norway, Panama, Persia, Peru, Portugal, Salvador, Spain, Sweden, Turkey, Uruguay and Venezuela.

Visiting the Exposition has been facilitated as much as possible by the railroads and local hotels. Rates are being offered on all lines and the hotel men have formed an association, binding themselves to adhere to reasonable prices. In addition numerous boarding houses are available, so that accommodations within the means of all are claimed to be provided in abundance. Still, it is urged by the management that prospective visitors secure their reservations in advance to forestall any chance of disappointment in getting just what they desire.



One of the Three Main Portals of the Palace of Machinery

One of the most important features of the Exposition will be the series of congresses, conferences and conventions. As the material exhibits will show world progress on all lines, so will the congresses gather together the experience of the ages in education, science, art, industry and social service.

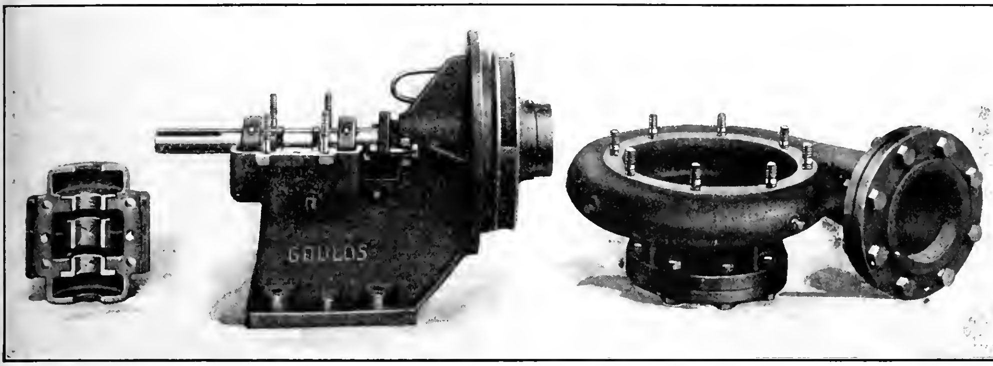
All in all, the Exposition holds attractions that cannot but make it worth while to any who can find the opportunity, to see it, and this aside from the advantages of viewing the country there and on the way.

Goulds Single-Stage Centrifugal Pump

The illustration shown herewith is that of the Goulds horizontal single-stage, single-suction, inclosed-impeller centrifugal pump with the casing and bearing cap removed. This pump is designed for directly connecting with electric motors, and is intended to run with different speeds for different capacities and heads.

bearing upon babbitted surfaces. These collars also serve to space the impeller properly in the casing. The waterway, or volute, is proportioned to convert the energy of the velocity of the water leaving the impeller into pressure, with a minimum of loss due to shock or eddies.

The casting forming the stuffing-box cover of the casing contains two bearings and carries the complete pump when assembled. The outboard end is split horizontally; the bearing cap is held in alignment with the bearing by



Centrifugal Pump with Casing and Bearing Cap Removed

The casing is of the volute type, supported on the bedplate so that it can be swiveled in any one of eight positions. This is a convenient feature where space for pipe fittings is limited, and also allows a discharge elbow to be dispensed with.

The impeller is of the inclosed type and is hydraulically balanced against end thrust. The slight amount of end thrust occurring in operation is taken up by shaft collars

the taper dowel pins and studs with locknuts. An opening with a hinged lid is provided in the top for inspection of the oil rings. Between the inboard end of the bearing and the face of the stuffing-box there is provided a drip pocket with a drain hole, which catches the necessary drip from the gland and is piped to a sewer.

This pump is manufactured by the Goulds Manufacturing Co., Seneca Falls, N. Y.

Will Quizz, Jr.

SYNOPSIS—Will Quizz, Jr., in looking on while a hydrostatic test is applied to a boiler, sees a demonstration of how the spoils system usually works out. Will, however, derives some benefit from his experience by consulting Chief Teller.

"While away on my vacation, Chief, I found time to peep into some of the boiler rooms in my home town; it has a boiler-inspection law. The inspector is in reality appointed by the mayor and the civil-service part is framed up afterward.

"While the members of the local examining board know nothing about boilers and engines, they are supposed to know how to judge and certify as to the fitness of the candidate after the mayor has appointed him.

"I happened to be chatting with John Starch, who fires at the laundry, when the boiler inspector came in. His method of applying a hydraulic test to the idle boiler puzzled me. The boiler is supposed to be good for 100 lb. and the inspector said he was going to test it for 50 per cent. over-pressure. I watched the gage and he ran the water pressure up to 200 lb., when the shell leaked like a sieve. One of us has this percentage business twisted. What is a 50 per cent. over-pressure, Chief, and how do you figure it? I want to know which of us was wrong."

"I am glad you got some practical information during your vacation, Will, by seeing how other plants are operated. Per cent. means 'by the hundred.' Your problem is easily illustrated by our decimal money: A dollar is 100 cents, and one penny or centum is therefore 1 per cent. A dime is ten one-hundredths, or 10 per cent., and half a dollar is 50 per cent. One hundred represents the base and 50 per cent. added would, of course, be a total of 150.

"You say the boiler is intended for 100 lb. steam pressure, and that it was to be tested to 50 per cent. over-pressure. Fifty per cent. of 100 lb. is 50 lb. Then the total test pressure should be

$$100 + 50 = 150 \textit{ lb.}$$

By putting on 200 lb., or doubling the working pressure, the inspector added 100 per cent., incidentally showing an extremely low percentage in his knowledge of percentage."

Spark-Plug Ignition Systems

By Albert H. Israll

SYNOPSIS—Explanation of the induction coil and magneto, as well as the operation of the common systems of spark-plug ignition.

Simple Induction Coil

The air gap across which is sent the ignition current offers a very high resistance to its passage. For this reason a current of low voltage from a battery or a low-tension magneto is unable to jump the gap. To transform this low-potential current to one of very high potential, amounting to many thousand volts, a device known as the induction coil is employed.

In its simplest form, the induction coil is composed of several layers of coarse wire (the primary) wound around a core of soft-iron wire and surrounded by many layers of fine wire (the secondary). The core tends to concentrate the lines of force and becomes an electromagnet when the coil is in use. In Fig. 1 is shown such a coil, with only one layer of each winding, for simplicity.

When a current is sent through the primary a magnetic field is set up around it, the lines of which pass through the core parallel to the axis, coming out at one end and entering at the other after passing through the layers of the secondary winding. A current is thereby induced in the secondary, the potential of which depends on the relative number of primary and secondary turns. When the current through the primary has reached a constant value, the induced current in the secondary ceases to flow. The magnetic field set up by the primary also tends to retard the current flowing through it, so that it takes longer for the field to build up from zero to maximum than to drop from the maximum to no field when the flow of current ceases. The voltage of the current generated in the secondary winding depends also upon the rapidity with which the intensity of the magnetic field changes. For this reason the current generated in the secondary is of much higher potential when the circuit through the primary is broken than when closed.

No current can be induced or generated in the secondary winding unless the intensity of the magnetic field is either increasing or decreasing. Thus there are two impulses of current in the secondary, one when the primary circuit is closed and the other when it is opened; but, as previously stated, the current induced at the break of the circuit is the only one of sufficient voltage to be utilized.

Induction Coil with Vibrator

The simple coil just described is used in a system explained later, where the make-and-break occurs once for each explosion and where only one spark is produced. There are systems, however, in which a series of short sparks are produced for each ignition. These add a small mechanism to the simple coil, called a vibrator (see Fig. 2). A current sent through the primary produces a magnetic field, making the core an electromagnet. The tension of the spring tends to keep the two platinum points together, thereby keeping the primary circuit closed; but when the core becomes magnetized it exerts enough force to attract the spring and open the circuit rapidly. As soon as the circuit is opened the core becomes demagnetized and the spring flies back, again closing the circuit. This making and breaking of the circuit by the vibrator occurs at the rate of about one hundred per second, depending on the adjustment. Each time the primary circuit is broken a small current of high potential induced in the secondary jumps the air gap of the spark plug.

As previously stated, a current is also induced in the primary winding each time the circuit is broken, and unless a condenser is employed to take up this current, considerable arcing will occur at the two platinum points, preventing a rapid break of the primary circuit and burning away the points in a short time.

The condenser consists of layers of tinfoil separated from each other by a waxed- or varnished-paper insulation. No connection is made between the two sides of the condenser within itself. The action is such that the current generated in the primary winding when the circuit is broken is absorbed by the condenser, but as soon as this induced current ceases to flow the condenser discharges again. The discharge current, however, flows back through the primary in the opposite direction to that of the battery current, thereby quickly demagnetizing the core. Therefore, the condenser not only does away with the undesirable sparking at the points, but also lessens the

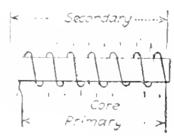


Fig. 1. Simple Induction Coil

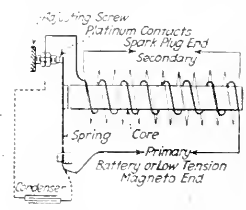

Fig. 2. Coil with Vibrator and Condenser

resistance to the flow of the battery current. It is generally inclosed in the box containing the coil.

Since the secondary current is of very high potential, there would be danger of the insulation being punctured if the circuit through this winding could not be completed. This might happen if a wire had been disconnected from a spark plug, if one of the secondary leads were broken, or if the ground connection became loose or had been left off. Therefore, to prevent the destruction of the coil from these causes, a safety spark gap is inserted in the system of each induction coil and high-tension magneto. The distance between the two points is greater in the safety gap than in the spark plug, hence the current will always jump the gap in the spark plug, except under the conditions mentioned.

The Magneto

In the induction coil just described the secondary wires remained stationary, while the lines of the electromagnetic field cut them as the intensity of the field was varied. If instead a stationary magnetic field be employed and the wires be moved through it, a similar result would be obtained. This is the principle employed in the magneto, the essential parts of which are the permanent magnets producing the magnetic field, the pole-pieces through which the magnetic lines of force pass before crossing the path of the armature, and the armature which consists of a core and windings. The core is generally of the shuttle type and the windings depend on the type of magneto; if low tension, the windings consist merely of heavy wire.

The current generated is not constant during one revolution of the armature, but whenever the armature winding passes through the strongest portion of the field, the maximum current is generated: this happens twice during each revolution. To obtain the best spark the maximum current must be utilized, and to do this the mechanism must be constructed so as to make this adjustment possible. The interrupter is generally on the same shaft as the armature, but the distributor arm is on a shaft placed above the armature shaft and is geared to the latter. The armature shaft and distributor shaft are so geared that when the interrupter acts to produce a spark the distributor arm will be in contact with or over one of the segments. To make clear the relation between the speeds of the shafts, assume a four-cylinder four-stroke-cycle engine. Two explosions occur per revolution of the crankshaft and, since two breaks occur at the interrupter points per revolution of the armature shaft, the speed of the two will be the same. There will be four segments, one for each cylinder, to distribute the high-tension current; thus the distributor shaft will make one-half a revolution for each one of the armature shaft.

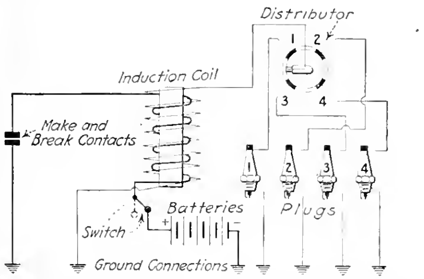

Fig. 3. Make-and-Break with Simple Coil and Spark Plugs

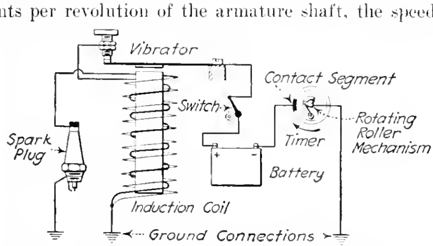

Fig. 4. Vibrator Induction Coil (Single Coil)

Difference between High-Tension and Low-Tension Magnetos

The chief difference between a low-tension and a high-tension magneto is that the latter is self-contained and very compact, while the former requires a separate induction coil. The high-tension magneto has wound on its armature, in addition to the layers of heavy wire, many layers of light wire which serve as a secondary winding. Instead of using a separate coil the armature serves both as a generator and as an induction coil.

The diagrams showing the different systems have been drawn to show the wiring and not the constructional details; therefore, the interrupter has not been shown on the shaft with the armature. Another thing to note is that the safety spark gap and the condenser have been omitted to prevent confusion.

Simple Coil (Make-and-Break)

When ordinary spark plugs are employed the make-and-break points are outside the cylinder. There are two systems in general use, one in which there is a long make and a second in which there is a very short make. The mechanism is so timed that it is mechanically operated whenever the spark is to occur. The break in the latter system occurs so quickly after the make that the eye cannot detect the two points in contact at all. The fundamental principle of operation is the same, however, in both (see Fig. 3).

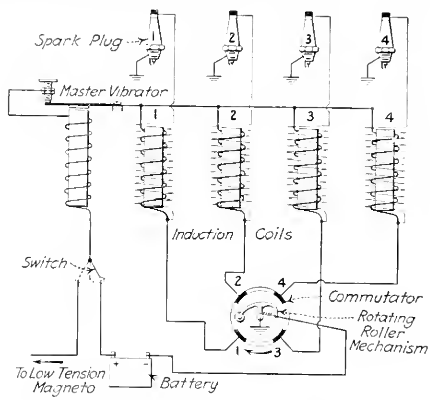

Fig. 5. Vibrator Induction Coil (Multiple Coil)

The current passes from the positive terminal of the battery through the primary winding when the points are in contact. This produces a strong magnetic field in the coil, and when it is allowed to shrink suddenly on the opening of the circuit, a current of high voltage is induced in the secondary. The latter flows through the distributor and jumps the gap in the spark plug, completing its circuit by way of the ground.

Vibrator Induction Coil (Single Coil)

In this system, which is shown in Fig. 4, a single induction coil is used. When the timer or commutator closes the primary circuit, which occurs when the roller is in contact with the segment, a current flows from the positive terminal of the battery through the vibrator, the primary winding, the ground and the roller to the negative terminal of the battery, thus completing the circuit. Each time the circuit is broken by the vibrator, a high-tension current is induced in the secondary, which jumps the spark gap of the spark plug. The spark produced at the gap is not merely one, but a series of sparks which succeed each other so rapidly that they appear continuous.

It should, of course, be understood that the roller mechanism of the timer is connected by shafts and gears to the crankshaft, so that there is a definite relation between the speeds of the two, and the spark is made to occur at a definite time.

Vibrator Induction Coil (Multiple Coil)

The wiring of this system (see Fig. 5) is so arranged that whenever a current passes through any of the induction coils, it must first pass through the master vibrator which is in series with each coil. This saves the use of a number of vibrators and gives a spark of the same intensity in all cylinders. Assume that the roller mechanism is rotating in the direction indicated by the arrow. When it touches segment No. 2, the circuit through the primary is closed, provided that the switch is on. The current then passes from the positive terminal of the battery, through the winding of the master vibrator, coil No. 2, segment 2 and back to the battery, causing the vibrator to act as before explained. Each time the circuit is closed

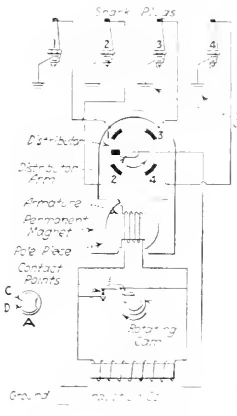

Fig. 6. Low-Tension Magneto

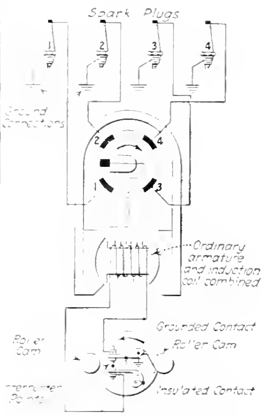

Fig. 7. High-Tension Magneto

and broken by the vibrator a magnetic field appears and disappears in the induction coil No. 2, and sets up a secondary current of high potential, which current jumps the air gap of No. 2 plug. The primary wire from each of the induction coils to the commutator also serves to ground the secondary wire on the respective coils, thereby eliminating four wires. In following out the circuits it should be noted that the roller mechanism is connected to ground.

Low-Tension Magneto

The system shown in Fig. 6 will operate in either of two ways, depending on the design of the rotating cam which operates the interrupter mechanism. With the cam as shown the system works as follows: The current generated in the armature of the magneto passes through the primary of the induction coil, except when the points of the contact-breaker come together. It is so arranged that the points come together while the maximum current is being generated in the armature. At this instant the major portion of the current passes through the interrupter. The sudden decrease in current flowing through the primary of the coil causes a rapid shrinkage of the field, which, in turn, induces a small current of high voltage in the secondary winding; this passes through the distributor, across the air gap in the plug and through the ground, completing its circuit.

When the cam shown at *A* is used the points of the interrupter are always in contact except during a short period preceding the production of the spark. The current from the armature of the magneto passes through the interrupter until the point *C* of the cam reaches the breaker arm. At this instant the points separate and the whole current is forced to pass through the primary winding of the induction coil. Although this induces a current in the secondary winding, it is not of sufficient potential to jump the spark gap. While the maximum current is being generated in the armature, the point *D* on the cam strikes the breaker arm and the contact points are instantly brought together again. The larger part of the current now flows through the interrupter again and the rapid decrease in the current passing through the primary winding causes a sudden shrinkage of the magnetic field. This induces a current in the secondary of sufficient tension to jump the spark gap.

High-Tension Magneto

The system shown in Fig. 7 is often called the true high-tension magneto system. The breaker or interrupter mechanism is on the shaft carrying the armature and rotates with it. The roller cams, on the other hand, may rotate on pinions whose positions remain fixed.

In the position shown, the grounded contact arm is about to be pushed inward by the roller cam; thus the interrupter points are about to separate. The armature is short-circuited through the interrupter points except when the spark is to occur. The mechanism is so timed that this takes place when the maximum current is being generated. When a spark is to occur the points are separated and the primary circuit is opened. The current immediately ceases to flow through this winding, causing the field to shrink very rapidly. This, in turn, induces a small current of high potential in the secondary winding on the armature, which passes through the distributor, jumps the spark-plug gap and completes its circuit through the ground.

Dual System

In this there are two distinct ignition systems which are generally not connected in any way, two sets of spark plugs often being employed. It is a combination of the systems shown in Figs. 5 and 7, namely, the vibrator induction coil and the high-tension magneto.

Duplex System

This system is the outcome of an improvement on the one shown in Fig. 7. The high-tension magneto is so designed that the armature may be used not only as an induction coil for the current generated in itself, but also for the current from a battery. Thus only the battery is added, but the wiring becomes more complex. An advantage is that without separate induction coils the engine may be started on battery current, which is generally easier than with the current from the magneto. This is due to the fact that the engine must attain considerable speed before the voltage of the current generated in the magneto becomes equal to that of the battery, namely, six to seven volts.

New Schlotter Blower

By Alfred Gradenwitz

A new type of blower has been brought out by Messrs. Siemens-Schukert Werke, of Berlin, Germany. Like all blowing machines of the screw type, the Schlotter blower, Fig. 1, requires but small floor area, is high-speed and

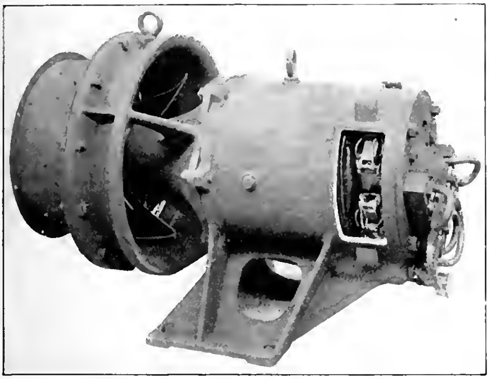

Fig. 1. Schlotter Blower, Motor Driven

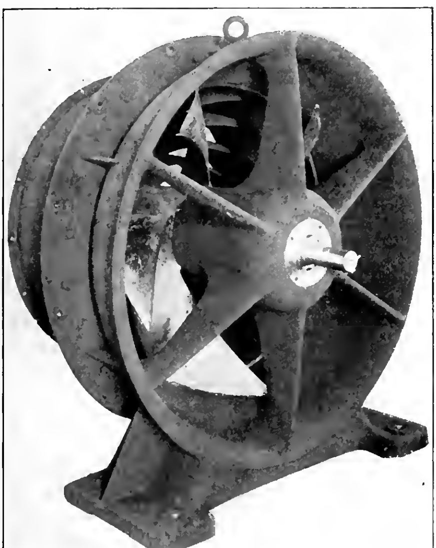

Fig. 2. Rotor and Casing

is reversible. Back pressures up to 11.5-in. water column are overcome by a single-stage blower, the maximum efficiency being upward of 80 per cent.

Each blower comprises a 5-vane rotor, Fig. 2, and a guide wheel, Fig. 3, at the outlet. The thrust surfaces of both wheels are of the screw type, that is, surfaces engendered by the rotation of a line and its simultaneous displacement along the axis of rotation. The feature of the guide-wheel principle is that the entrance edges of the guide wheel, so far from coinciding with the outlet edges of the rotor cross them at right angles everywhere. The air current issuing from the rotor is thus subdivided radially by each guide blade and is, at a given air supply, dealt with without a shock.

The curvature of the guide blades, which increases in the direction of rotation of the rotor, results in a con-

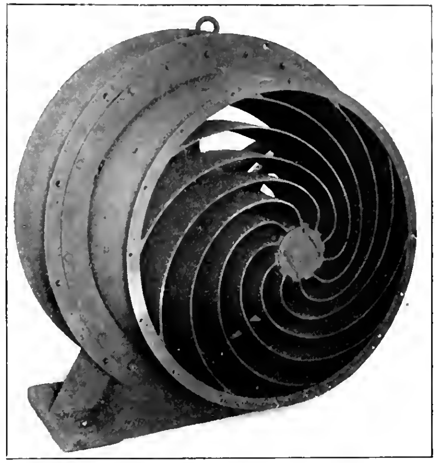

Fig. 3. Guide Wheel of Blower

traction of the air current and in a further acceleration of the resting guide wheel, so that a considerable portion of the axial thrust is engendered in the latter. Because of the inertia, the air currents on issuing are slightly rotating and convergent to the axis, so that the minimum cross-section of the jet in the case of a free motion of the air lies at about half the length of the diameter in front of the distributor.

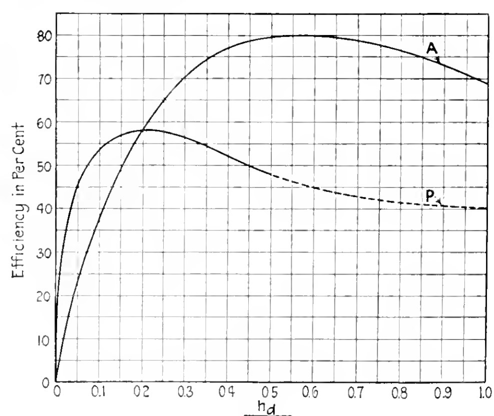

Fig. 4. Efficiency Curves of Schlotter and Centrifugal Fan of Usual Design

The efficiency of a blower depends mainly on the extent to which dynamic pressure in the adjoining tubings can be converted into static pressure. Tests have shown a maximum efficiency of about 80 per cent. to be obtainable in the most favorable case, when connecting the blower to a line of pressure pipes, and 75 per cent. can be reached with a short outlet tubing corresponding to an increase on cross-section of about 20 per cent., the efficiency decreasing in the case of a diffuser, according to the widening of the latter. These results have been confirmed by tests made on a number of middle-sized blowers, chosen at random, by Professors Brabbee and Kloss, of the Berlin Technical High School, the maximum efficiency found with a pressure pipe connected to the blower being 78 per cent.

An even more important factor than the high maximum efficiency is the fact that the efficiency curve of the Schlotter blower is flat, so that the efficiency remains high over a wide range of loads, from the highest back pressure down to a free escape. In Fig. 4, curve *A* shows the efficiency curve of a Schlotter blower as compared with that of a centrifugal fan of the usual design, as shown in the curve *P*.

Another advantage of the blower is that its power consumption for a given number of revolutions remains constant over practically the whole range of loads. This is valuable in case the back pressure of an installation cannot be predetermined exactly or when working conditions, with a given amount of air, entail variations in back pressure, such as, for instance, with the individual ventilating of mines, when using air pipes of variable lengths.

The annular cast-iron body of the blower is provided with a foot and comprises in its hollow hub the bearings carrying the shaft on the journal of which the rotor and the half coupling (belt pulley) are keyed overhung. Ball bearings are used. Water cooling is provided for the bearings when the blower is used with hot gases.

The standard design is modified in various ways to suit special requirements. The annular body may be fitted with a flange in the place of the foot, in case the blower is to be fixed to a wall. Since every blower is fitted with a thrust bearing to deal with the axial thrust, there is no objection to placing it in a vertical position. When the blower is to work through a conduit, a suction bend is joined to the annular body through which the driving shaft passes.

The rotors are cast either of some light metal (special aluminum alloy) or a high-grade bronze, according to their dimensions and numbers of turns and the gas temperature.

The blower is preferably driven through direct coupling with electric motors, steam, water or air turbines. The most important applications of the blower are for ventilators for boiler and engine rooms; for the individual and main ventilation of mines and tunnels; for air heating, drying and mist-dispelling plants; for forced-draft furnaces and for the removal of dust and shavings.

Designing Small Transformers

By Norman G. Meade

SYNOPSIS—Actual calculations in the design of a small transformer such as used for bell circuits or signaling devices.

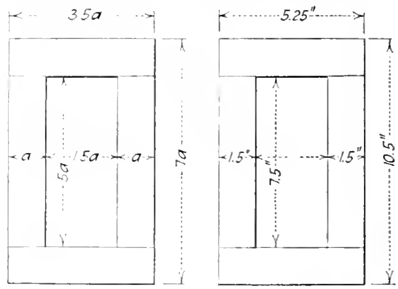
Small transformers with low-voltage secondaries are, to a large extent, replacing batteries for many purposes, such as the operation of electric bells, signaling devices, etc.; and where alternating current is available they are much more satisfactory, as they require no attention. As the secondary voltage is generally below 12 or 15 volts, ordinary bell wiring is sufficiently insulated for the secondary circuits.

The design of the small transformer involves the same calculations as transformers for lighting and power purposes. It is necessary to know or assume several quantities, such as the useful secondary output in kilowatts, the primary voltage, secondary voltage, and the frequency of the system on which the transformer is to operate. Let it be desired to design a transformer to operate from a 110-volt, 60-cycle circuit, which will have a secondary voltage of 10 and a secondary current of 10 amp.

$$Efficiency = \frac{watts\ output}{watts\ input}$$

For an output of 100 watts, assuming an efficiency of 85 per cent.,* the input would be $100 \div 0.85 = 118$ watts. Therefore, the total estimated losses are not to exceed 18 watts. These losses are made up of three components—hysteresis, eddy currents and copper losses. The copper or I^2R loss and the core loss (hysteresis and eddy currents) should be about equal. For intermittent service the copper loss can be somewhat the larger of the two; hence it will be taken as 10 watts and the core loss 8 watts.

Assume the density of the sheet-iron core to be 30,000 lines of force per square inch. For annealed sheet iron at this density, the hysteresis loss is 0.15 watt per cubic inch. The eddy-current loss should be small on account



Figs. 1 and 2. Core Dimensions

of the laminated core; therefore assume it to be 2 watts and the hysteresis loss 6 watts. The volume of the iron in the core will then be

$$\frac{6}{0.15} = 40\ cu.in.$$

The core must be proportionate with regard to the winding space and the length of the magnetic circuit. Let a represent the width of the core, as in Fig. 1, $7a$ the height of the core, $3.5a$ the total width, $1.5a$ the horizon-

*This efficiency is somewhat lower than would be obtained in a well designed transformer of this size under full load.—EDITOR tal inside distance between legs, and $5a$ the distance between the yokes. The cross-section of the core is a^2. Then the volume of the core is

$$V = (2 \times 3.5a + 2 \times 5a)a^2$$

or

$$V = 17a^3 = 40 \text{ cu.in.}$$

Whence, $a = \sqrt[3]{\frac{40}{17}} = 1.34$, approximately.

Let a be 1.5, on account of some loss of space due to laminations. Then the core dimensions will be as shown in Fig. 2 and the available winding space will be 2.25 in. between cores and 7.5 in. between yokes. Let the length of coil be 7 in. The secondary will be wound next to the cores so as to reduce the length of the heavier wire, and the primary will be wound over the secondary. The secondary current at full load will be 10 amp., and, as the primary and the secondary coils are wound in two sections, the secondary voltage for each coil will be 5 volts, but the conductor will carry 10 amp. Allow 1000 circ.mils per ampere. Then the size of the secondary conductor will be 10 × 1000 = 10,000 circ.mils, which corresponds nearest to a No. 10 wire.

The primary watts at full load are 118; hence the primary current will be

$$\frac{\textit{Primary watts}}{\textit{Primary voltage}} = \frac{118}{110} = 1.07 \textit{ amp.}$$

The power factor can be neglected and, as the magnetizing current is small, the primary current will be taken at 1.25 amp. The size of the primary wire will then be

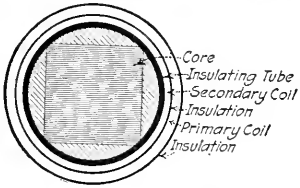


FIG. 3. SECTION THROUGH CORE AND COIL

1.25 × 1000 = 1250 circ.mils, which corresponds nearly with a No. 19 wire.

The relation between the maximum flux and the effective primary voltage is as follows:

$$V_p = \frac{4.44 N \times T_p \times n}{10^8}$$

where,

V_p = Primary voltage;
N = Maximum magnetic flux;
T_p = Primary turns;
n = Frequency.

The maximum magnetic flux equals the flux density, in the present case 30,000 lines per square inch, times the cross-section of the core in square inches; that is,

$$N = 30{,}000 \times 2.25 = 67{,}500 \textit{ lines.}$$

Substituting in the above formula,

$$110 = \frac{4.44 \times 67{,}500 \times T_p \times 60}{10^8}, \text{ and}$$

$$T_p = \frac{110 \times 10^8}{4.44 \times 67{,}500 \times 60} = 611 \text{ (approximately)}$$

To arrive at even numbers make the total primary turns 612, or 306 turns on each core. The number of secondary turns will be

$$\frac{\textit{Secondary voltage}}{\textit{Primary voltage}} \times T_p = \frac{10}{110} \times 612 = 56$$

or 28 turns to the coil. The arrangement of the windings on the core is shown in Fig. 3. The corners of the core are slightly rounded and it has four segmental blocks of hardwood on four sides. The wood should be well filled with shellac or insulating paint. The inside diameter d of the secondary coil figures 2.12 in., as illustrated in Fig. 4; but as the corners of the core are rounded, the inside diameter will be taken as 2 in.

From a magnet wire table it will be found that No. 10 wire has 8.54 turns to the inch and, as the length of the coils is 7 in., there is twice the space needed for the secondary winding of 28 turns per coil. Therefore, it will be

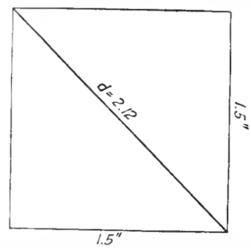

FIG. 4. ILLUSTRATING METHOD OF DETERMINING INSIDE DIAMETER OF SECONDARY COIL

necessary to wind a cord the diameter of the wire parallel with it, to make a good job. The secondary winding should be wound on a stiff insulating tube of the required diameter; a piece of mailing tube will do. Before winding, the tube should be thoroughly impregnated with insulating compound. For winding, the tube should be slipped on a wooden arbor and placed in a lathe. When the winding is in place the ends should be secured with cord and wrapped with two or three thicknesses of oiled cloth, then wrapped with webbing and painted or shellacked. The ends of the winding should be cut off about an inch from the core and flexible cord for the leads soldered on and the joints taped.

Each primary coil consists of 306 turns of No. 19 wire; there are 22.77 turns to the inch and 22.77 × 7 = 159.39 turns to the length of the coil, which will make about two layers for the primary coils. Flexible leads are soldered to the primary winding and the whole is bound lengthwise, that is, inside and out, with webbing and thoroughly painted. The coil should now be wrapped with oiled cloth.

In building up the cores the sheets of iron should be cut in different lengths. For example, referring to Fig. 2, cut half the sheets 7½ in. long and half 10.5 in. and assemble them with alternate strips, long and short; then securely rivet the bundle. The yokes should be assembled in like manner, which will allow the ends of the yokes and those of the cores to mortise. One yoke and two cores can be assembled and riveted, the coil slipped on and the second keeper placed in position and riveted. The coils should be so connected that the current flows in opposite directions in the two legs.

The I^2R loss should be checked after calculations are made and if too great, should be decreased by increasing the size of the wire. This is a cut-and-try method to secure the proper size of wire.

Just for Fun

[In the issue of Jan. 19 we asked for accounts of stupidity in a class with those printed in the same issue under the heading, "Some Original Ideas." Following are a few of the best stories which have been received.—EDITOR.]

The following method of laying up three 18-ft. by 72-in. return-tubular boilers was at least unusual. After pouring 18 gal. of cylinder oil through the top manhole, the boilers were filled and then slowly drained. The man in charge expressed an opinion that the boilers would be protected from rust indefinitely; in which I presume he was correct. The removal of the oil, however, upon resuming operations will call for another original idea.—*Ernest A. Tichenor, South Connellsville, Penn.*

A student taking an examination in steam engineering was asked what a "self-supporting stack" was. He answered that it was one which paid the interest on the investment by using natural instead of fan draft.

A turbine test man was sent to the stockroom for putty and came back lugging a 50-lb. keg of white lead and asked for some dry putty, as the new stuff was too soft. [This last joke looks "putty" thin to us.—EDITOR.]—*R. Blumenfeld, Brooklyn, N. Y.*

In a small town a short distance from New York City a town meeting was called to consider alterations to the steam-heating system in the high-school building, as it was not working properly. A member of the school board made a report, with recommendations, which was severely criticized by one of the Board of Aldermen, who made the following statement:

"The heating plant was not installed correctly in the first place, for the boiler is in the wrong end of the building, as it is now in the south end and should have been placed in the north end, because steam in pipes will flow better from north to south than from south to north."

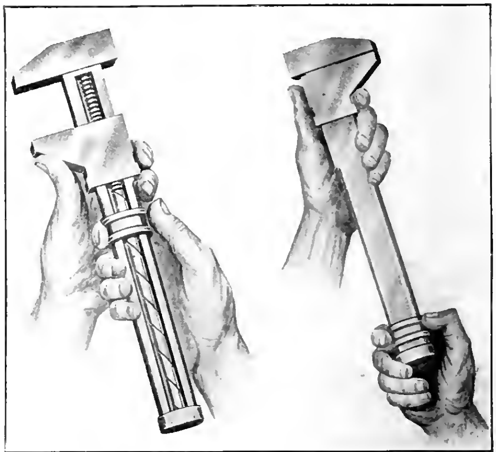
The above statement was actually made in public, and if desired, I will furnish proof of its authenticity.—*W. A. Armes, Norwood, Mass.*

During the recent cold spell I noticed a large bulged place on the brass plunger of a deep-well pump temporarily out of use for repairs, which resembled a snake after swallowing a large toad. On examining the piston it was found to be burst a distance of five inches, due to water leaking past the threads on the rod and freezing solid. On the same repair job it was necessary to take down a part of the discharge line which contained a three-inch gate valve. On removing the valve it was turned around several times. Anyone would have thought all the water had been spilled out, but such was not the case, and the result was a burst valve, but it was not noticed and was put back in the line.

When all was apparently ready the valve outside was opened to the tank pressure, and a large spray of water issued from the ruptured valve, of which a bystander and myself soaked up a good supply. The young man thought it was from over-pressure, and explained it to the fireman by saying that he saw it open up like a clam shell.—*W. H. Corbin, Sharples, W. Va.*

Bayer Quick-Acting Monkey-Wrench

A quick-acting and convenient monkey-wrench differing from the usual design has been placed on the market by the Bayer Steam Soot Blower Co., of St. Louis. The ordinary thumb-nut is replaced by a sliding collar which may be moved up and down the handle to operate the jaw. The motion of the collar is transmitted to the screw of the wrench by means of a pin attached to the collar and fitting into a spiral groove in the screw rod. Moving the collar toward the outer end of the handle closes the jaws and *vice versa*. When the collar is up against the movable jaw the wrench is wide open. In this position the



BAYER QUICK-ACTING MONKEY-WRENCH

wrench may be slipped over a nut. A pull on the collar will adjust the jaws, and pressure to do the turning may be applied at the same instant.

Including the cap at the end of the handle, the wrench is made up of five pieces: The handle and stationary jaw, the movable jaw, the collar, screw rod and cap. The handle is a solid steel forging of elliptical shape with a recess for the screw rod. The latter is thus protected so that there is little opportunity for bending it or getting it out of alignment. The collar is easy to move, and altogether, the wrench is a most convenient tool.

Heat Value Calculation—The combustion of a given element always results in the generation of a fixed amount of heat. Thus, when a pound of pure carbon burns completely (forming CO_2), 14,600 B.t.u. is produced. Consequently, the heat value of carbon is said to be 14,600 B.t.u. per lb., which is the unit of weight almost universally used in this country. When a pound of pure carbon burns incompletely (forming CO), only 4450 B.t.u. is produced. But if, in turn, the resulting $2\frac{1}{3}$ lb. of CO, which is a combustible gas, is burned, 10,150 additional B.t.u. is liberated, making the total heat produced equal to 14,600 B.t.u., just the same as though the pound of carbon had burned completely (to CO_2) in the first place. Hence, the heat value of CO is

$$\frac{10,150}{2.333} = 4350 \text{ B.t.u. per lb.}$$

The heat values for carbon and hydrogen were established by experiment and hence probably are not absolutely exact. In fact, some authorities give values for carbon as low as 14,220 and as high as 14,647, and for hydrogen as low as 61,816 and as high as 62,032, but 14,600 and 62,000 are the most widely accepted and used.

Step-Bearing Accumulator for a Vertical Turbine

By W. R. Bankhead

In the power plant at the Puget Sound navy yard there is a 500-kw. vertical turbine, the step bearing of which is supplied with oil by two duplex pumps capable of delivering oil at 800 lb. per sq.in. The oil passes through a baffle before reaching the bearing, which reduces it to a pressure sufficient to support the weight of the moving parts. This pressure varies from 155 lb. at no load to 190 at full load. These pumps also supply oil to the other bearings of the turbine and to a tank for a gravity system.

The step bearing has been burned out several times on account of the failure of the oil pressure. The pumps originally had no governor nor air chamber to steady the pressure. A failure for one second would cause the bearing to begin to cut, and the machine had to be shut down for repairs.

An accumulator of some kind was needed, and as the space was limited it was decided to install a vertical steel tube, into the bottom of which the oil should be pumped, compressing the air in the top of the tube, which acts as a spring to force the oil out to the step bearing in case the oil pump failed. This form of accumulator is cheaper to build than a weighted-piston type, costing only about one-half as much.

The tube is 11 ft. long, 12 in. inside diameter, and ½ in. thick, and is made of seamless rolled steel. In each end of the tube ¾-in. steel heads were welded by the oxy-acetylene process, and when tested to 2000 lb. hydrostatic pressure it was found to be tight; this is necessary to

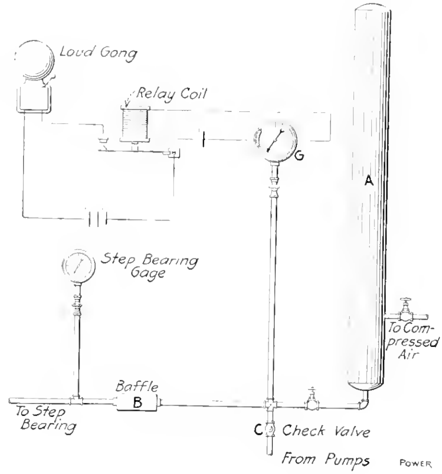


Fig. 2. Details of Alarm System

make such an accumulator successful. There is a check valve between the pumps and the accumulator and a gage

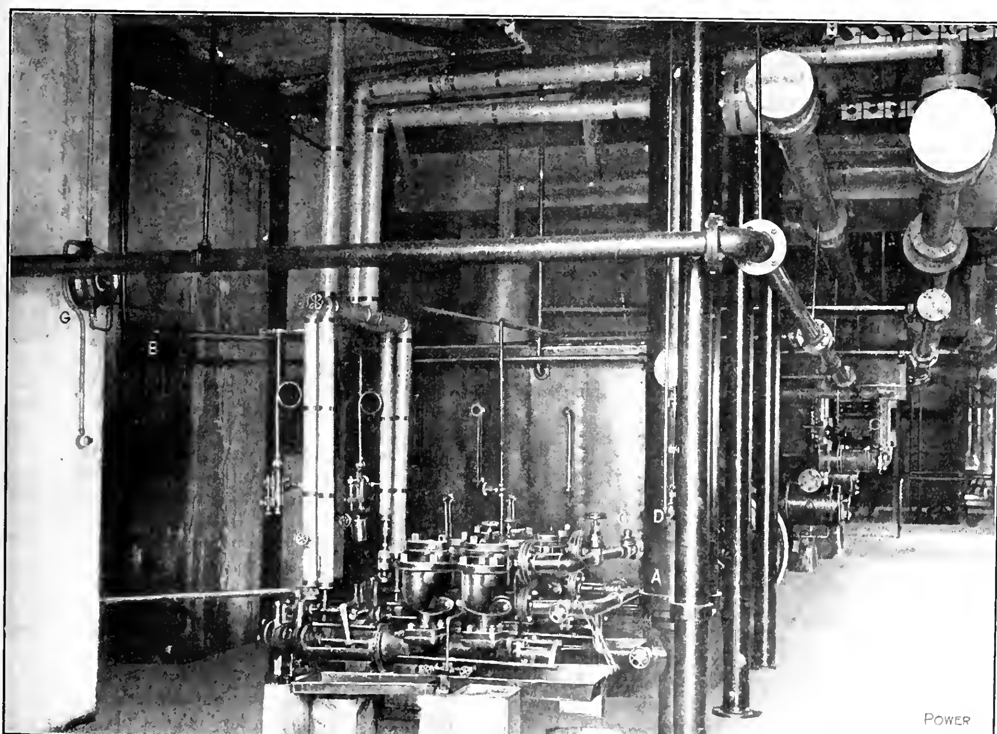

Fig. 1. Vertical Accumulator A in Limited Space near Oil Pumps

between the accumulator and the baffle. The gage is so fitted that when the oil pressure falls below 600 lb., a gong which can be heard all over the engine room announces the drop in pressure.

Fig. 1 shows the location of the accumulator *A*. The baffle *B* is at the base of the turbine foundation, and *C* is the check valve between the pumps and the accumulator. *D* is the connection to the compressed air. The high-pressure oil gage which closes the electric circuit is shown at *G*. The accumulator was first filled with compressed air at 100 lb. to insure a good supply and to reduce the quantity of oil necessary. Fig. 2 shows the details of the alarm system.

The primary purpose of this accumulator was to guard against a sudden failure and to give the operator warning in time to start another pump or to shut down the turbine. For 12 min. after the pump is stopped the accumulator will maintain a pressure sufficient to support the step bearing with the forced lubrication system still on, and for 23 min. to the step bearing only.

In practice it has proved better than was expected, as it keeps steady pressure and acts as a governor for the pumps, which can be run on a wide-open throttle.

The turbine has been running almost continually for eight months day and night without any step-bearing trouble whatever.

Instead of being an uncertain and unreliable machine, the accumulator has made this turbine one of the most dependable in the plant, and we have been able to "forget" the step bearing.

Setting the Valves of a Four-Valve Engine

By H. Wiegand

SYNOPSIS—Tells in a simple and thorough way how to set the valves of a four-valve engine to run either over or under.

In setting the valves of a four-valve engine the usual method of placing the engine on the center is used. A tram may be used to facilitate marking the different positions of the crosshead, crank, etc.

Turn the engine, which is supposed to run over, until the crosshead is at the point of the crank end release *R*, Fig. 1, which shows the positions of the crosshead, crank, throw of eccentric and rocker-arm in diagram form. As the crank-end exhaust valve must be line to line with the port to open and, when the crosshead is at *C*, begin to close for compression, it is evident that the rocker-arms must be in the same place at these two points of crosshead or crank position.

Therefore, it is not necessary to connect the valves until the right position of the eccentric has been found. Set the throw of the eccentric near the angle of advance point *B*, and mark the position of the rocker-arm line by a line across the pin and hub or hub and pin-boss; then fasten the eccentric with the setscrew or a false key and turn the engine over to the crank-end compression point

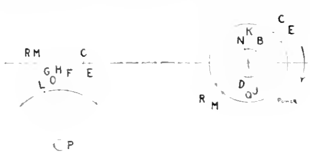

Fig. 1.

C. The throw of the eccentric will now be at *D* and the rocker-arm, instead of returning to *F*, will go beyond it to *G*. The eccentric must therefore be turned back until the rocker-arm reaches point *H*, central between *F* and *G*.

To accurately locate *H*, divide the distance between the marks on the hub and pin or pin-boss. The throw of the eccentric is now at *J* and the rocker-arm at *H*, with the crank and crosshead at *C*. Turned over to *R*. the throw of the eccentric will be at *K* and the rocker-arm will have moved to *L* and back to *H*. The crank-end exhaust valve can now be set line to line and the rods and valve lever put in the desired position. The latter may be fastened with a false key and a line drawn across the face of the lever and the valve stem to mark the position

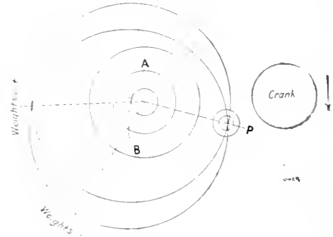

Fig. 2.

of the valve. The crank must now be turned back to *M*, the point of head-end compression, and the head-end exhaust valve connected and set line to line with the port. The eccentric will now be at *N*, the rocker-arm at *O*. Turned over to *E* or head-end release, the throw of the eccentric will be at *Q*, the rocker-arm at *O*, the crosshead at *E*, and the valve will begin to open for release. The eccentric and valve levers can now be marked for keyseating and the rods locked and marked for length. To set the admission valves, place the governor in its midway position and turn it so that with the weights "in," the throw of its eccentric is in line with that of the exhaust eccentric; then fasten it there. Next turn the shaft to its crank-end center and throw the weights of the governor out. With the valve-gear rods set at their proper lengths, set the crank-end admission valve line to line with the port and fasten the lever to the stem.

Now throw the weights in and note how far the valve has opened. The designer will give the lead and the lap of the valve at dead-centers. Suppose this valve should have $\frac{1}{4}$-in. lead and $\frac{1}{32}$-in. lap, it must move $\frac{9}{32}$ in. by throwing the weights out or in. If it does not move enough the governor must be advanced, or set back if the valve moves too much. The two large circles, Fig. 2, represent the greatest and the least travel of the eccentric. The diameters of the two smallest circles, Fig. 2, represent the greatest and least travels of the valves, the next larger one the bore of the wheel and the two large circles the positions of the eccentric with governor weights in and out. The arc AB drawn from the center of the pivot pin P marks the path of the center of the eccentric and

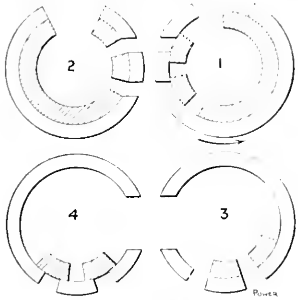

FIG. 3. POSITIONS OF VALVES

the two dotted lines drawn from the center of the wheel mark the throw of the eccentric at its greatest and at its least travel. It will be seen that the position of the governor is given by the distance between the two eccentric circles or the amount of valve motion at dead centers; also that the throw of the eccentric at least travel is opposite the crank and that it is impossible for the valves to open if they have lap at dead-center, while the governor weights are out. After finding the correct governor position the crank-end valve may be set to its proper lap and the engine turned over to the head-end center for setting the head-end valves in the same way.

Turn the engine over one revolution with the weights out to make sure that the admission valves do not open, then turn it one revolution with the weights in to note the point of admission to the point of cutoff and to see that no negative lap occurs from overtravel, which would happen

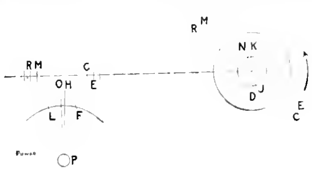

FIG. 4.

if the valve in Fig. 3 were turned further in the direction of the arrow. By decreasing the governor travel the negative lap may be reduced if it is not over $\frac{1}{16}$ in.; if more, a new valve is usually required. The governor, valve levers and rods can now be marked as described.

To reverse this engine set the exhaust valves by turning the shaft to R, Fig. 4, the point of crank-end release, when the engine is running under. Then turn the eccentric in the running-over direction until the crank-end exhaust valve is line to line with the port. The throw of the eccentric will be at J, the rocker-arm at H and, turned over to C, the throw will be at K, with the valve again closing for compression. The head-end exhaust valve will be line to line at E and C.

The weight-arms of the governor and the springs and links require changing to throw the eccentric the other way. The key has to be taken out and the governor turned in the direction of running "under" until, with the engine on its crank-center and the governor weights "in," the

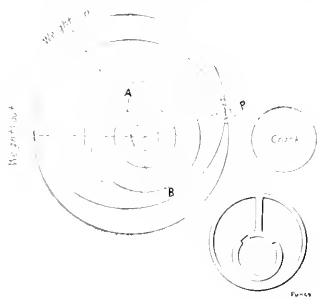

FIG. 5.

crank-end admission valve has $\frac{1}{4}$-in. lead. Fasten the governor and turn the engine under to the head center and the head-end valve will show the same lead. Now throw the weights out and examine the lap; if it is not quite right the governor may have to be moved a little either way. The engine is reversed and the new keyways may be marked.

Fig. 5 shows the position of the eccentric for running under and also the keyways for running the engine in both directions.

Wrong Voltage on Motor

By J. A. Horton

An operator complained that his induction motor was overheating and stated that it was free from grounds; that the trouble was in the motor itself because the one that it had replaced operated normally up to the time of its replacement; and that his service voltage was 550 to 600. He added that one phase took hardly any current, while the two other phases did all of the work.

As the replaced motor had operated normally, the unbalanced symptom suggested a reversed internal connection. Accordingly, a winder was sent to inspect the end connections and to change them if necessary. No changes were needed because the connections were all right. Just after trying the motor and before the oil switch had been opened, the winder approached the connections with the intention of taping some bare ones. The operator hastily opened the oil switch and warned him that the line voltage was 550 volts and that one leg was grounded through a fault. The winder was no general trouble man, but he had looked at the nameplate of the motor and, as he had seen 440 volts marked on it, he failed to see any good reason why a 440-volt motor should be operated on a 550-volt circuit. Wrong voltage was the only trouble.

As far as the unbalancing of the phases was concerned, what had seemed to be an unbalanced condition was due to the fact that the operator, in using a single ammeter on a three-phase circuit, failed to note that the current had changed while changing his meter from one leg of the circuit to the other. The three legs had not been read under like conditions of the load.

A. S. M. E. Boiler Code Approved by Council

Something of an event in the history of the American Society of Mechanical Engineers occurred Saturday, Feb. 13, when the council approved the proposed Boiler Code finally submitted by the committee appointed for that purpose. Probably no one appreciated what an important undertaking this would prove when the suggestion was first made that the society draft standard specifications for the construction, equipment and use of steam boilers with the hope that they might be made the basis of uniform legislation in the several states. Certainly no one anticipated the monumental task it would develop into, nor the keenness of the interest that would be enlisted from so many quarters, many of them unexpected. One member of the council in moving a vote of thanks to the committee characterized the code as the greatest single piece of work that the society has ever done.

In spite of the opposition that was manifested, especially in the early part of the committee's work, by the various industries which feared the code would tend to injure their business and were jealous lest others might obtain advantages over them in one way or another, all of these conflicting interests were finally reconciled; the council approved the code unanimously and even from outside of the society there is practically no objection to the code in its final form.

It is reported that immediately it became possible to secure a copy of the code in its approved form, one was rushed to Indianapolis to be embodied in a bill to be presented, and it is believed that the State of Indiana will adopt the code entirely in the very near future and that eight to a dozen other states are all ready to follow suit before many months have passed by. The council voted not to discharge the committee, but to continue it indefinitely with the idea that it may be made a permanent committee by action of the society, with power to revise the code from time to time whenever that may be warranted due to advances in the arts. This committee was augmented to include not only the original members, but the later advisory committee of eighteen members.

While the existence of the committee dates back to Sept. 15, 1911, when it was appointed during the presidency of the late Col. E. D. Meier, "to formulate standard specifications for the construction of steam boilers and other pressure vessels and for the care of same in service," most of its real activity has been shown during the past year.

The council's instructions were to formulate a model engineers' and firemen's license law, a model boiler-inspection law and a standard code of boiler rules. The necessity of properly constructing, installing and inspecting boilers was naturally to receive consideration and the make-up of the committee was appropriately chosen. The accompanying portraits show the original members.

The chairman, John A. Stevens, at the age of 27 was granted an unlimited engineer's license for ocean steamship—highest class. He resigned as first assistant engineer of U. S. M. S. "St. Paul" in 1893 to take the position of chief engineer of the Merrimac Manufacturing Co. in Lowell, Mass. For eleven years he made all power-plant layouts and estimates for this company. In 1907 he was appointed by the Governor a member of the Massachusetts Board of Boiler Rules and served two terms of three years each, during the first of which the Massachusetts rules were formulated, which have since been the pattern of so many other states. Since 1909 he has practiced consulting engineering.

The other members of the committee included two professors of engineering, two boiler manufacturers, a steel-plate manufacturer and an insurance engineer.

Prof. R. C. Carpenter is professor of experimental engineering at Sibley College, Cornell University, Ithaca, N. Y., a consulting engineer with extensive practice and experience in the boiler field, the author of "Experimental Engineering" and other engineering books, and is frequently called as an expert witness in legal cases concerning boilers.

Prof. Edward F. Miller is professor of steam engineering at the Massachusetts Institute of Technology, Boston, Mass., and similarly qualified by experience. His special services on the committee were in connection with the safety-valve specifications and mathematical formulas.

Col. E. D. Meier, since deceased, was the president and chief engineer of the Heine Safety Boiler Co., St. Louis, Mo., and a builder of water-tube boilers.

Richard Hammond, president of the Lake Erie Engineering Works, Buffalo, N. Y., brought the experience of a maker of marine and tubular boilers to the committee. His advice was especially helpful in relation to rules concerning large-diameter boilers and stayed surfaces.

Dr. Charles L. Huston, vice-president and works manager of the Lukens Iron & Steel Co., and also of the Jacobs-Shupert U. S. Fire Box Co., was particularly valuable to the committee as its special metallurgical expert, for he is one of the foremost investigators into the scientific manufacture of iron and steel plate.

Finally, as the representative of the field of boiler inspection and insurance, William H. Boehm, superintendent of the departments of steam boiler and flywheel insurance of the Fidelity & Casualty Co., New York, rounded out appropriately the committee's personnel.

A first preliminary draft of the rules proposed after consideration had been given to the rules then in force in such states as had any, was prepared and distributed among authorities qualified to criticise it and make suggestions at the St. Paul meeting of the society in May of last year. The interest aroused prompted the arrangement for a public hearing in New York in the fall. This took place in September and another in October, after which the code was revised and a third printing made of the preliminary draft. The fourth printing was called a Progress Report and brought formally before the annual meeting in New York last December. The unusually extended discussion which ensued has already been referred to. Shortly thereafter there was a conference with the boiler manufacturers' association at which it was decided to revise the code at once while the suggestions were fresh in mind and submit the details to representatives of all organizations and interests who would be affected by the proposed code. The result was the appointment of the following advisory committee:

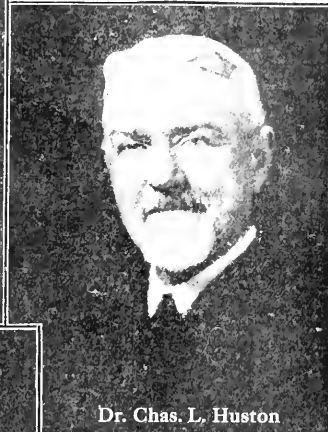
A.S.M.E. Committee on Uniform Boiler Specifications

American industries can now afford a little better boiler for a little more money, and a little more regard for human life.

Wm. H. Boehm

The United States has less legislation regarding boilers than any other civilized country—and more explosions

Prof. R. G. Carpenter



Dr. Chas. L. Huston

John A. Stevens

Col. E. D. Meier

Prof. Edwd. F. Miller

An ignorant or careless attendant can explode the best boiler ever built, and the better the boiler, the more disastrous the explosion.

The report of this committee embodies the collective wisdom of the world's best experts.

D. S. Jacobus, advisory engineer, Babcock & Wilcox Co., New York.
F. H. Clark, general superintendent of motive power, Baltimore & Ohio R.R., Baltimore, Md.
H. H. Vaughan, assistant to vice-president, Canadian Pacific Ry., Montreal, Canada.
A. L. Humphrey, vice-president and general manager, Westinghouse Air Brake Co., Wilmerding, Penn.
Karl Ferrari, Erie City Iron Works, Erie, Penn.
H. G. Stott, superintendent of motive power, Interborough Rapid Transit Co., New York.
I. E. Moultrop, assistant superintendent construction bureau, Edison Electric Illuminating Co. of Boston, Mass.
W. F. MacGregor, superintendent of experimental department, J. I. Case Threshing Machine Co., Racine, Wis.
Richard D. Reed, H. B. Smith & Co., Westfield, Mass.
M. F. Moore, assistant to president, Kewanee Boiler Co., Kewanee, Ill.
S. F. Jeter, supervising inspector, Hartford Steam Boiler Inspection & Insurance Co., Hartford, Conn.
Thomas E. Durban, general manager, Erie City Iron Works, Erie, Penn.
F. W. Dean, consulting engineer, Boston, Mass.
William F. Kiesel, assistant mechanical engineer, Pennsylvania R.R., Altoona, Penn.
Arthur M. Greene, Jr., professor of mechanical engineering, Rensselaer Polytechnic Institute, Troy, N. Y.
Charles E. Gorton, Gorton & Lidgerwood Co., New York.
Elbert C. Fisher, vice-president and general manager, Wickes Boiler Co., Saginaw, Mich.
C. W. Obert, associate editor, American Society Mechanical Engineers, and secretary to the Boiler Code Committee, New York.

The work of revision has continued without interruption, since December 15, except for Sundays and holidays including both day and night sessions. After so tedious a grind it is naturally very gratifying to the hard-worked committee that its efforts have been successful and the report received by the council. For its part the council and all the members of the society, and engineers and others outside of the society too, for that matter, should and do feel their obligation for the earnest work of the men engaged on it. Is it too much to say that humanity generally should honor these men, for their efforts are certain to result in decreased loss of life and property from boiler accidents?

New Blackburn-Smith Twin Filter

A new type of Blackburn-Smith feed-water filter and grease extractor, having twin bodies controlled by a single set of inlet and outlet valves, is built by James Beggs & Co., 38 Warren St., New York City.

A plant carrying a varying load, or one which operates twenty-four hours per day, requires a filter having considerable flexibility as to capacity, and one which would permit of the cleaning of one part while the other was in operation. If such a filter were of such size that either side alone could carry the regular load, then the two sides could be thrown in during the peak load, and so filter the water at all times without interference by the necessary cleanings. This filter, Fig. 1, is designed to meet such conditions.

The turning of both valves to one limit bypasses the corresponding body, and the other body is bypassed by turning both valves to the other limit, thus permitting the alternate operation and cleaning of either side. The combined operation of both sides, as would be desirable during the peak load, is accomplished by turning the valves to mid-position.

The filter is made up of a number of parts, so that breakage or disarrangement of any particular section does not necessitate the discontinuance of all filter service. The valves are of the double-seat type and the disk working between the seats is self-seating, which prevent leakage due to dirt deposited on either disk or seat.

The filter chests are the same as in the single type of filter, each divided into an inlet and an outlet chamber

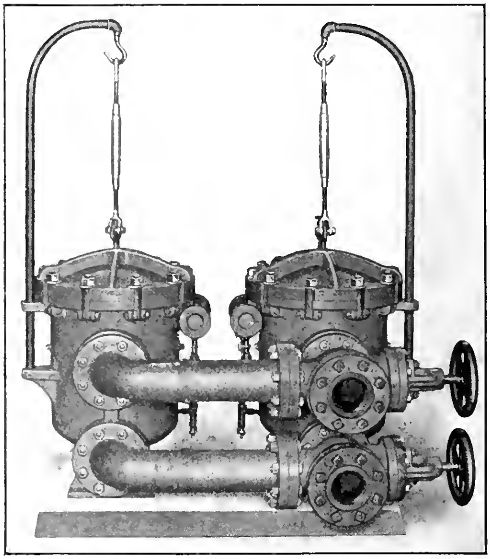


Fig. 1. New Twin Filter

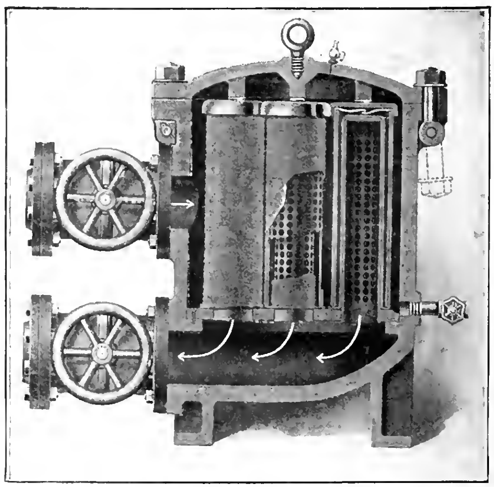

Fig. 2. Section through the Filter

by a partition carrying the filtering cartridges. Fig. 2 is a sectional view. The opening of the filter for cleaning is facilitated by the use of a cover held by swing bolts. A crane with a turnbuckle lifts, swings and holds the cover during cleaning.

Cast Iron—The average weight of cast iron is taken at 450 lb per cubic goot, or 37.5 per sq.ft., one inch thick.

Editorials

The Boiler Code's "Commencement"

College graduation exercises are significantly called "Commencement." To be sure, Commencement marks the completion of the students' college course, but the beginning of their serious or useful life. On page 268 we report the Boiler Code's "Commencement." Its course of preparation is completed and it has obtained the degree of A. S. M. E., which in this case is added before its name instead of after. A great work is done, but another great work is just beginning, without which all the labor of compiling the code would amount to naught, for until the states or municipalities adopt it into their laws and, indeed, until the laws are enforced no real good will be accomplished.

It must be gratifying to those who have given themselves so unselfishly to the task of getting the code in shape, at no inconsiderable expense of time, money and effort, to find many states and cities already eager to avail themselves of this expert assistance in getting proper statutes on their books regulating steam boilers.

This great movement to promote the safety of boiler operation has started auspiciously. As stated in the article referred to, Indiana has already prepared to apply the code and it may even be a part of this state's laws before this issue of Power reaches its readers. Indiana will thereby have the distinction of being the first to adopt the code after its approval by the council of the American Society of Mechanical Engineers. Wisconsin, however, stole the march on all her sister states by adopting it before its completion, in the law which went into effect January 1, 1915, for this law provides that the code, as soon as approved, shall become a part of it. Pennsylvania and Tennessee have departments already established, administered by the police authority, which promise to adopt the code, and Ohio, now operating under an excellent set of laws, has intimated her intention to revise them to conform with the uniform code. Active work is also being taken up in New Jersey and Florida, and the prospects for other states following suit in the near future are excellent.

To speed the good work of bringing the code to the attention of the law makers a legislative committee has been formed, representing three branches of the boiler-making industry. Its members are: Isaac Harter, Jr., of the Babcock & Wilcox Company, representing the American Boiler Manufacturers' Association; Thomas E. Durban, of the Erie City Iron Works, representing the National Tubular Boiler Manufacturers' Association; and H. P. Goodling, of the Farquhar Company, representing the National Association of Thresher Manufacturers. Thus the water-tube, fire-tube and portable boiler interests have united to bring about with all possible dispatch that condition which will be so much to their advantage—uniform requirements in all localities, so that their product built to meet one standard set of specifications may be used in any part of the country without modification.

That Power takes a keen satisfaction in this wave of reformation goes without saying. It will not imitate the daily newspapers which delight in attempting to appropriate the credit to themselves whenever a cause they have championed triumphs. While it is only fair to claim that no single institution has so consistently and persistently and for so long a time urged the need of proper laws to safeguard the handling of steam boilers as has Power, to which its pages for many years back bear witness, it suffices us that the much looked-for end is now in sight, and we are glad to bestow the credit where credit is due. We honor ourselves in saying "well done" to the men who have finally crystallized our cries and those of many others, that there should be laws, into these definite recommendations that these are the laws that should be. With this change of text we shall continue to preach the doctrine and plead for the adoption of the A. S. M. E. code.

License Activity in New York City

The Mayor and his advisers are bending their efforts to centralize the licensing of buildings, electrical work, engineers and firemen, etc., under one head, namely, the present Bureau of Licenses. As far as the Boiler Squad, which now performs the function of licensing engineers and firemen and of inspecting boilers, is concerned, the proposed plan is to allow it to continue inspecting boilers, while men from the Squad would be assigned to the Bureau to examine applicants for engineers' and firemen's licenses.

Engineers of the city have been alarmed because they understood that all of the functions of the Boiler Squad were to be exercised by another department. Because the present work of the Squad is satisfactory, a change was not looked upon with favor. But the change as proposed by the Mayor's committee is really of little significance as far as the engineers and firemen are concerned. One or two bills covering the function of licensing of various men and kinds of work in the city have been introduced in Albany, but it is too soon to tell just what disposition will be made of them. If passed as originally written the Boiler Squad will become defunct.

It must be admitted that the Police Department is not the logical body to administer the work of inspecting boilers and licensing engineers. The real solution of the question is the creation of a state board to conduct such work. This does not necessarily mean that local boards could not exist contemporaneously, as we point out editorially in this issue.

The Boiler Code Committee of the American Society of Mechanical Engineers in its report just completed, has made quite complete recommendations on uniformity of boiler construction. Probably, before very long, a supplementary report embodying recommendations as to the uniformity of boiler inspection and of the licensing of engineers and firemen will be presented. These recommendations will be scientific. They will be based upon all past experience in such work and will embody the best of all that demonstration has proved good. They will be satisfactory to all of the various interests involved.

The Boiler Squad has been guilty of disreputable acts in the past. It is likely to go wrong again at any time, and those interested would again be confronted with the old conditions. If there must be local boards in New York and Buffalo, the two cities that have combated a state law the hardest, let them have them, but they should conform to the regulations of the state board.

It is not too soon for engineers and owners in New York who are interested in their own welfare and in public safety, to create sentiment favoring a state law embodying the recommendations of the American Society of Mechanical Engineers as to uniformity in construction, inspection and licensing.

State and Local Inspection Departments

In states where some of the principal cities are already provided with departments for inspecting boilers and examining and licensing engineers, efforts to pass a state law are hampered by the opposition of local politicians and officials, who fear the loss of the patronage and positions which go with the municipal ordinance. There is also to be dealt with the Home Rule sentiment, and the natural reluctance to give up a successful local administration for one administered from the capitol, which would have less direct contact with local men and conditions.

But the state-wide law need not involve the abandonment of the local systems. Most of the state laws either exempt from inspection boilers which are under the care of boiler-insurance companies authorized to do business in the state, or, better, accept the findings of inspectors of such companies after such inspectors have been approved by the state department having charge of boiler inspections, thus becoming pseudo state officials, although in the pay of their respective companies. In this way the state department has a record of all boilers and is as well assured of their satisfactory condition as though they were inspected by men paid by the department itself.

The same principle may well be, and in Wisconsin is, extended to municipal departments. The local board goes on making its own inspections and examinations, granting its own certificates, keeping its own records, and collecting its own fees, but in addition reports to the state department, which is thus able, in connection with its own work in those parts of the state which have no local system, to keep a complete record of all the boilers and engineers in the state and to exercise some supervision over the whole. The state board may, for example, adopt a code of boiler rules, such as that recently completed by a committee of the American Society of Mechanical Engineers, the requirements of which would be enforced by the local and insurance, as well as by their own inspectors. This would result in uniformity of practice, not only as between different parts of the same state, but, it is hoped, as between the states themselves, for state boards would probably avail themselves of the expert work which has been expended upon the production of this code, and all adopt practically the same requirements. An association of the heads of state departments could be a clearing house for information deduced by the investigations and experience of each, and by recommending revisions of the code as the advisability of such revisions develop, maintain substantial uniformity throughout the nation. And the local inspectors would be a part of the system and in line for advancement to the positions of larger responsibility and emolument which it offers.

The Exposition Opens

February 20 the greatest world's fair to date opened its gates. Our leading article this week is an extensive account of the Exposition, covering somewhat its general features, but more particularly such as will especially interest the engineering field. This is the first of a number of articles which we expect to present, dealing more in detail with the exhibits with which our readers will be concerned, and in the fall an account will be given of the International Engineering Congress, which likewise will be the most notable that has occurred.

The Exposition stands as a commemoration of the greatest piece of engineering in history—the connecting of the Atlantic and Pacific by a canal across the Isthmus of Panama, the benefits of which to mankind will continue down the centuries. The Exposition can hardly have so far-reaching an effect, but if it repeats the experience of like undertakings of the past it will mean much in furthering the progress of all lines of human endeavor by showing what has thus far been accomplished, and thereby indicating the directions in which continued improvement is to be desired.

A fair of this kind is, naturally, of most direct advantage to those who can visit it, and no one who has the opportunity to get to San Francisco should neglect it. It is a liberal education in itself. Next best is to read the descriptions of it which will appear in the periodicals of all kinds. This, too, is an opportunity not to be overlooked. Present-day achievements in the illustrating and printing arts bring within the means of all the ability to gain much of the good that would come from an actual trip to the Fair. But seeing the Fair and reading about it both require a disposition on the part of the individual to avail oneself of the opportunity to broaden one's knowledge.

More indirect, but of certain advantage to the most indifferent, is the influence which such an exposition has on the world at large by stimulating a striving for better things in all lines—art, business, profession or calling of any kind—in consequence of the examples set by the exhibits and in other ways. No one can visit such an impressive collection of the world's best without coming away with new ideas to apply, and these in turn inspire those who do not go.

Innumerable endless chains of uplift are started with every such demonstration of modern achievement. The greater the undertaking, the greater the effect. If argument were needed it could be continued *ad infinitum* to justify all the stupendous labor and expenditure involved in the Panama-Pacific Exposition. Thanks be for the inspiration that conceived the idea and the energy which carried it to fruition!

Correspondence

Cost of Steam

H. L. Strong's article on page 133 in the issue of Jan. 26, under the above heading, strikes an important note. Every engineer is interested and anxious to know how much it costs to make steam in the other fellow's plant, but the mere statement that A's steam costs 25c. per thousand pounds does not tell it all. However, it may be used as a basis for comparison and a standard method of arriving at this cost should be used. The statement should contain the following items: Coal, ——— lb. at ———; Water, ——— gal. at ———; Power for Electric-Driven Auxiliaries; Labor; Miscellaneous Expense; Maintenance; Fixed Charges. The first three items are self-explanatory.

Under "Labor" should be charged supervision, foreman, fireman, ash- and coal-conveyor operators, boiler cleaners, ashmen and shovelers, helpers and laborers, and all other labor, aside from maintenance, incident to operating the station.

"Miscellaneous Expense" takes care of oil, waste, etc.

"Maintenance" should include labor and materials required to maintain in proper condition buildings, stokers, conveyors (ash and coal), boiler-room auxiliaries, pipes and fittings, feed pumps, electrical apparatus, and all other tools or apparatus used in the boiler room in connection with making steam.

Under "Fixed Charges" should be charged depreciation of buildings and equipment, insurance (boiler and fire) and taxes.

The sum of these items gives us the total cost of producing steam. This sum divided by the net amount of steam generated, from and at 212 deg. F., and multiplied by 1000, gives the cost per thousand pounds of steam, from and at 212 deg. F. "Net" steam is the steam produced by the boilers which is available for power, etc. It is the total feed water less steam lost by blow-down and that used by boiler-room auxiliaries, or the amount registered by flow meters on the outlet from each boiler, less the steam used by auxiliaries. From records of steam pressure and feed temperature it is a simple matter to reduce to pounds, from and at 212 deg. F.

After following the above form or an equivalent and arriving at the cost of steam per thousand pounds, there are three important items to be considered before the costs in different plants are comparable. These are (1) cost of fuel, (2) load factor, and (3) equipment.

(1) *Cost of Fuel*—If the cost of the coal used in two plants is known and the charges against cost of steam are kept in accordance with the foregoing form, it is a simple matter to adjust the charges and determine what the total costs would be if the fuel costs were the same. For instance: A burns 2000 tons of coal per month, at $4 per ton and his steam costs 28c. per thousand pounds. If his coal cost him $3.50 per ton the total charges for the month would be $1000 less and, consequently, the cost per thousand pounds of steam would be correspondingly lower.

(2) *Load Factor*—The character of the load on a boiler plant has considerable to do with the cost of output. A plant whose load is steady, with small fluctuations, such as a central lighting and power plant, can produce steam cheaper than, say a plant supplying an industry where steam is used for driving engines or turbines, for drying ovens, for miscellaneous manufacturing purposes and for testing manufactured apparatus, under which conditions it may be necessary to carry banked fires under one thousand horsepower or more of boilers. In order to keep costs comparable, the coal used for banking should be kept account of separately from that used for loaded boilers. Only the coal used for actually producing steam should be charged to the cost of steam. This banking, or stand-by, coal should be charged to the departments responsible, and should not be charged to one boiler plant when making cost comparisons with others.

(3) *Equipment*—There is no way of bringing a variety of equipment to a standard basis. However, if the other two factors are made equitable, then, if there is much difference in the cost of producing steam in two plants, it is fair to claim that it is due to equipment and management, and the plant which shows the cheaper production should be given the credit for having the more efficient equipment and organization.

C. W. Howard.

Erie, Penn.

Purchasing Coal

Under the above caption, in your editorial in the issue of Jan. 26, you say all coal mined must or should be used as fuel. Your argument is good as far as *all coal* is concerned, but if the substance delivered at the plant contains 15 per cent. or more of slate, then the only apparent remedy for this condition is for the consumer to protect himself by the B.t.u. clause in his contract. In the plant of which I have charge we buy all our coal on the B.t.u. basis, and since we adopted this method (three years ago) we show a saving of from 10 to 30 per cent. As to cost of analysis, it is small compared with the saving effected.

Our contract reads $2.20 per ton (2000 lb.) (nut and slack), coal to test 13,400 B.t.u. per pound (100 either up or down not to be taken into consideration), moisture not to exceed 2 per cent., ash not to exceed 10 per cent., samples to be taken with a 2-in. pipe from each load as delivered; part of each sample to be put in a can and sent to a chemist satisfactory to both parties, on the thirteenth and twenty-seventh of each month; consumer to pay for the analysis, which is $3.30 for each sample, or $6.60 per month. There are coal companies that refuse to consider any contract that has this clause included in it, which goes to show that it is a good thing for the consumer.

In January of last year there was a shortage of coal in this city, and dealers took advantage of that condition and boosted the price 50c. per ton, and delivered anything that looked like coal. Of course we got the same grade of coal that the other plants did, but we were protected by our B.t.u. clause and instead of paying $2.70 and sometimes higher, we paid $1.745. The plant consumed 264 tons that month, which if it had stood up to the guarantee of 13,400 B.t.u. would have cost us $2.20 × 264 = $580.80, but on account of low B.t.u. the price went down to $1.745 × 264 = $460.68, or $111.12 rebate.

Now, suppose we had been like the other fellow and were paying $2.70 per ton, we would have paid $2.70 × 264 = $712.80 for that same coal that cost us $1.745 per ton, or $252.12 more than we actually paid. You must admit that this is a good proposition for the consumer, your employer. If the coal runs above the guarantee of 13,400 B.t.u. you can well afford to pay the premium. To sum the whole matter up, it places the consumer in a position where he can get just what he pays for and pays for just what he gets.

In times gone by the coal game has been in the hands of the dealer, but a B.t.u. contract evens up the game and gives the plant owner an equal show.

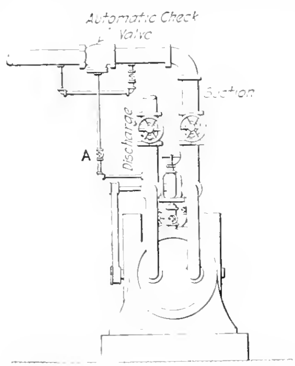
Compressor Trouble Due to Throttled Suction Line

Several changes had been made in the equipment of a small refrigerating plant, including the addition of a compressor the size of the old one. The new machine did not produce the expected gain in refrigerating capacity; in fact, when run alone on the load it failed to do the same work as the old compressor. It was decided that the suction line was too small to serve the two machines, so a duplicate line was put in. This improved matters but little.



Compressor Connections

The suction gage on the new machine registered 8 lb. lower than the one on the old compressor when running and would increase 3 to 4 lb. after the machine was shut down. There was no gage tester available, so the increase was ascribed to inaccuracy of the gage. This compressor ran much warmer than the old machine.

An automatic check valve was provided in the suction line, as shown. One day when the machine was started the engineer was surprised to hear a hissing sound in the valve similar to that made by steam passing through a throttled valve. He found the bypass open and closed it as it should be in normal operation. This stopped the noise, but did not satisfy the engineer, for he correctly reasoned that if there had not been a considerable difference in pressure on the two sides of the check valve there would have been no hissing sound. He noticed by this time that the suction gage indicated 10 lb. lower on this machine than on the old one, which was 2 lb. greater than it had ever been before; the machine was also hotter than usual.

The valve *A* had been closed when he took charge, and he had been told by several who were supposed to know that it was to be kept closed. He opened it a few turns, and immediately the machine began to pound heavily. He closed the valves, and after a few revolutions the machine ran normal.

The engineer reasoned that there must have been an accumulation of liquid in the suction line back of the check valve, and when he opened the valve *A* this opened the check valve wide, and the accumulated liquid was swept into the machine. He decided to try again, but first he shut off the liquid line to the expansion coils and pumped down until the machines were running hot so as to be sure to prevent slugs of liquid remaining in the suction line. Now he opened the valve *A* gradually. The suction gage jumped from 10 lb. lower than the other gage to 5 lb. above, the machine cooled to the same temperature as the other, and the clattering of the valves that had always been present was silenced.

The trouble was in the check valve. This valve is intended to shut off the suction pressure in case of accident or blowout on the machine or discharge line. It depends on the head, or discharge pressure, to keep it open. The valve *A* being shut, there was little pressure in the pipe leading from it to the check valve, and consequently the check valve was nearly closed, which throttled the flow of gas to the machine. There was a welcome increase in capacity, and the new machine now does as much as the other.

Cement as Furnace Lining*

Part of our boiler plant consists of four 90-in. return-tubular boilers rated at 400 hp. each and frequently developing as high as 700 hp. as indicated by the flow meters. Induced draft is used, and the coal burned per square foot of grate averaged, until recently, about 20 lb. One of these boilers has a concrete setting, which in other respects is the same as for the other three boilers, which are brick set. The furnace was lined with firebrick and the bridge-wall was of the same material, but the combustion-chamber walls were bare concrete. These walls were approximately 2 ft. thick and had a 2-in. air space. I have no information as to the mixture, but apparently it was about 1:3:5 cement, sand and crushed stone.

The boiler has been in service twenty-four hours per day for about three-fourths of the time, for about ten years. The furnace lining has been renewed repeatedly, but nothing was done to the setting until a few months ago, when it was found that the combustion-chamber walls had wasted away nearly to the air space; in fact, we cut into the air space in cleaning away the burned

*See "Power," Dec. 15, 1914, p. 840; Jan. 12, 1915, p. 62; Jan. 26, p. 131, and Feb. 2, p. 169.

material. The only practicable repair was a brick lining, which was accordingly put in. A new concrete lining could have been put in if there had been sufficient time to allow the concrete to set or harden before using it. In other respects the setting is sound except for two or three old cracks. These boilers have not all been in the same length of time, but the two nearest the age of the concrete-set one have had all or part of the combustion-chamber linings renewed. The worst fault with concrete seems to be the difficulty of repairing, when that becomes necessary and this example seems to indicate that for boilers operated moderately a concrete setting with a fire-brick-lined furnace will last as long as the boiler.

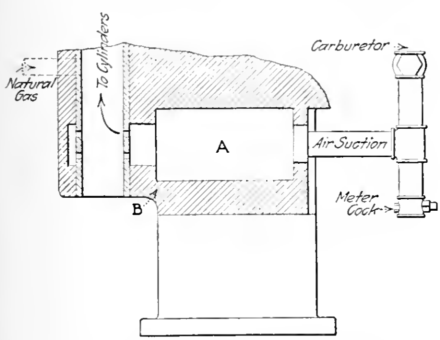
Carburetion Trouble

In connecting up, for emergency use on gasoline, a small gas engine that had been operating on natural gas, considerable trouble was experienced at first in getting satisfactory operation. The engine was still to be operated normally on natural gas and was piped so that it could be switched from one fuel to the other by changing valves. The gasoline carburetor was connected to the air suction pipe as shown in the sketch, the other branch of the air pipe having a meter cock in it. By closing the meter cock and the natural-gas valve and



Section through Mixing Chamber

opening the gasoline supply to the carburetor the engine could be run on gasoline; and by shutting off the gasoline supply and opening the meter cock and gas valve it could be run on natural gas.

In running on gasoline it was found necessary at first to give the carburetor needle valve one full-turn opening and after about a half-hour's run the engine would begin to cough, backfire, and slow down. Then if the supply were shut off for a minute it would pick up again and run along all right for about another twenty-minute period, when the backfiring and slowing down would recur. The trouble lay in the fact that the gasoline, having to travel quite a distance from the carburetor through the air pipe and the chamber *A* to the cylinders, would not all stay in the gaseous form, but would partly liquefy and form a little pool in *A*. The engine would draw from this pool as well as from the carburetor, and would get too rich a mixture and start to backfire and slow down.

A small hole was drilled at *B* with the idea that the air suction through it would help to volatilize the gasoline which collected at the bottom of *A*. This helped matters somewhat, but still the operation was not uniform.

The trouble was finally remedied by connecting one end of a flexible metal tube to the air intake of the carburetor, the other end being attached to a "stove" around the engine exhaust pipe at its hottest point. This gave the carburetor hot air, and the gasoline remained in a volatile condition throughout its passage to the cylinders. The operation was then uniform and satisfactory, and the best running point of the carburetor needle valve was found to be one-half turn instead of one turn, as previously.

Emery around a Dynamo

Commenting upon the letter of Mr. Weaver in the Dec. 15 issue on "Emery around a Dynamo," I believe that if his rules and advice were generally followed it would lead to trouble and give repair men plenty of business. The use of emery on either commutators or brushes should be condemned, as even with the utmost care particles of emery are likely to become embedded in the mica, brushes or commutator bars and cause no end of trouble by cutting and scoring the bars or brushes.

The use of oil on a commutator is another bad practice that is far too common. If it is necessary to provide a lubricant for the commutator a brush with a small percentage of graphite should be used. Oil is bound to get into the mica and in time will help carbonize it, causing short-circuits between the bars; which, in turn, will cause the brushes to spark and the commutator to pit and wear.

If a commutator is badly worn or out of true it should be turned off, and if properly done, there will be no need to use a file. After turning, the final finish is obtained by the use of fine sandpaper and any burrs of copper left from the turning can be picked or cut out with the point of a knife or tool. Should the commutator not be in bad enough condition to need turning, it can be trued by "stoning." Sand-stones for this purpose can be obtained in any desired grade and in various shapes; a handy size being 2x2x4 in. in a medium-coarse sand.

In stoning generator commutators the brushes should be lifted and the stone applied with a fair pressure. In the case of motors in operation it can be accomplished the same as sandpapering. After stoning, a finish is obtained by the use of fine sandpaper, and then all dust should be blown off with a bellows or hose and the commutator wiped with a dry rag.

After turning or stoning a commutator it is advisable to fit the brushes. This is done by placing them on the commutator under pressure and running a piece of fairly coarse sandpaper back and forth under the brush with the sand side toward the brush. This will grind the brush down to a surface that conforms to the curvature of the commutator.

There are many different grades of brushes for use for different services. It sometimes occurs that the bars of a commutator are soft and wear faster than the mica, resulting in high mica. An abrasive brush on a commutator of this sort will cut the mica and the bars at an even rate, or in a case of this kind it is good practice to undercut the mica slightly. Proper undercutting will not cause excessive brush wear. Undercutting is usually advocated on high-speed machines and is rarely resorted to on low- or moderate-speed machines, unless, as has been said, the mica tends to remain high between the bars.

After the commutator of a machine is in good condition it will only be necessary to wipe it off occasionally with a dry rag. The brushes also should be wiped off occasionally, but in the majority of cases should not be removed to do so, as there are few holders in use that will permit of the removal of a brush and its exact replacement relative to the commutator surface. Lifting the brush slightly off the commutator allows wiping it off.

Results of Changes in Boiler Furnace

The furnace changes and results obtained, as described in the article of this title by Morgan B. Smith, appearing in POWER, Jan. 19, p. 92, are similar to what was done by Westinghouse Church Kerr & Co. under the writer's supervision at the plant of the Detroit Edison Co., at Delray, Mich., in 1909, 1910 and 1911, which work was referred to in the discussion of Dr. D. S. Jacobus' paper on "Tests of Large Boilers," in the 1911 Proceedings of the American Society of Mechanical Engineers.

In the furnaces at Delray the stoker arches were cut back and the division walls between the stokers were at first constructed so as to come no higher than the fuel bed. Later, we went a step further, eliminating the division walls between the stokers, moving them together so as to present a continuous grate surface across the furnace, and substituting a short flat suspended arch for the customary construction. By these changes all brickwork other than the inclosing walls was removed from the furnaces, the troubles with the arches were eliminated and better combustion conditions were obtained.

It is interesting to note that the results obtained by us some years ago in the furnaces at the Delray plant are confirmed by those reported by Mr. Smith at this later time from the use of a similar construction.

H. O. POND,
Westinghouse Church Kerr & Co.

New York City.

Decreases the Oil Bill

The work of the power engineer is now primarily concerned with the diminution and prevention of losses more or less secondary in character. One of the best examples of this kind that have come to the writer's attention is that of the lubricating oil for one of the largest New York City office buildings. When this plant was originally installed a high-grade cylinder oil costing about fifty cents a gallon was used, and the oil caught by the separators allowed to run into the sewer.

The first economy was the connecting of all oily drips to a common receiving tank, from which it is pumped to two centrifugal oil separators. These separate the oil and water, the oil being returned to the filters and then to the oiling system. The water is returned to the feed-water heater and from there to the boilers.

The next step was the purchase of graphite lubricators to be used with the cylinder lubricators on the engines, pumps, etc. The graphite lubricators are filled with a paste made of graphite and cylinder oil and connected in between the cylinder lubricator and the steam pipe. The oil from the cylinder lubricator in passing over the graphite picks up enough to form a mixture of graphite and oil, which lubricates the cylinder. As the lubrication is done by the graphite, it is possible to use a much lower grade of oil, because the latter acts principally as a carrying agent for the former. In the case under discussion it was possible to use a 25c. oil, which, with the cost of the graphite, reduced the cost from 50c. to under 30c. per gal.

The separators in handling the oily drips discharge the water and oil as formerly, and also catch and retain the graphite on the plates. These are cleaned every week and the graphite is used in the boilers in place of compound. This system has been in operation for some seven or eight years, and the oil is used over and over without showing any reduction in lubricating qualities. The make-up oil required costs less than $250 a year, and it is calculated that the savings effected pay for the cost of the equipment about once every 11 months. The cost of the separators was about $500 each and the graphite lubricators $15 each. The equipment for this change cost less than $2000 and returns a profit of fully 100 per cent.

Brooklyn, N. Y.

Changed Gear Ratio

Changing the gear ratio of a motor drive is not a wise procedure unless the person making the change knows the probable result. A change that will slow the armature may increase its load beyond safe limits, and a change that will make the armature run faster may increase its speed beyond the tensile limit of its band-wires. The folly of random gear changes on direct-current traction vehicles of various kinds can be testified to by some crane and car operators. Induction motors, while similarly subject to overloads incident to decreased gear ratios, offer the assurance that they will never exceed synchronous speed very much, even when driven by the gravitation of their connected load, and will never reach synchronous speed when driven by the current alone. Above synchronous speed, alternating-current motors have a tendency to load themselves by generation.

There are times when changes in gear ratio may be productive of improved operation. An operator of a large locomotive turntable had a gasoline engine installed on one end of the table. The engine did well until traffic increase demanded faster motive power. He then supplemented it with a three-phase induction motor, installed on the opposite end of the table. The motor handled the work twice as fast as the engine had, but for several reasons, including variable voltage, variable frequency and abusive handling, it began to give trouble by heating. Ammeters showed that the motor was never overloaded except at starting, but that it was starting a large proportion of the time. To ease the starting, the gear ratio was increased 20 per cent. This stopped all trouble without materially affecting the speed of operation, because the armature ran faster.

J. A. HORTON.

Schenectady, N. Y.

Inquiries of General Interest

Highest Temperature of Feed Water with Open Heater—Why cannot the temperature of water in an open feed-water heater be raised higher than 212 deg. F.?

H. R.

Because the water is under atmospheric pressure, and 212 deg. F. is the temperature at which water is converted into steam at that pressure.

Relative Transmission by Rubber and Leather Belting—What thicknesses of rubber belting are equal for transmission of power to single and double leather belts?

R. C.

When made of cotton duck weighing two pounds per yard coated with best India rubber, 3- and 4-ply rubber belting is usually taken as equal to single leather belting and 5- and 6-ply as equal to double leather belting.

Total Heat of Steam—What would be the total heat of a pound of steam at gage pressure of 100 lb. per sq.in., with a barometric pressure of the atmosphere of 28.5 in. and temperature of 62 deg. F.?

S. G.

One inch of barometric pressure at 62 deg. F. is equal to 0.491 lb. per sq.in., and therefore the absolute pressure of the boiler steam would be

$$100 + (0.491 \times 28.5) = 113.99$$

or practically 114 lb. absolute, and according to Marks and Davis' steam tables, a pound of steam at the latter pressure would contain 1188.7 B.t.u. above 32 deg. F.

Wetter Steam Requires More Feed Water—When our boiler is pushed to its highest capacity, why is it that the water level gradually goes down, but as soon as the damper is partly closed and with the feed pump operating at the same speed, the boiler-water level comes up again?

C. J. P.

It is quite likely that when the boiler is forced wetter steam is generated, and although doing the same amount of work, greater weight of steam of the lower quality is discharged from the boiler, thereby requiring replenishment of feed water in excess of the rate required for maintaining the proper water level with the damper partly closed.

Regulation of Oil Burners—In the use of oil burners how can the best regulation of the oil, steam and air supply be determined?

A. C. S.

The best regulation of oil burners is obtained by observation of the top of the smoke-stack and the color of the fire. When the burner valves and the air supply are correctly adjusted, the flame is a bright white and there is no smoke. When the supply of steam is too great, steam will appear around the burning spray and will be discharged from the smoke-stack. If too little steam is being used, atomization will be incomplete, and if the air supply is insufficient the color of the flame will be red, and incomplete combustion will be indicated by the discharge of smoke from the stack.

Advantages of Extended Front Boiler Setting—What are the advantages and disadvantages of an extended front setting as compared with a flush front setting for a horizontal return-tubular boiler?

W. C.

The principal advantages of the extended front are the employment of a shorter brick setting and obviation of passage of the furnace gases direct to the front smoke connection, as is likely to occur with a flush front setting, from settling of the fire-door arch or other causes of leakage of the joint between the fire-door arch and the under side of the boiler. The disadvantages are that with a low setting the front extension may be in the way of the fireman, and also that the extended front does not present as good an appearance as the flush front.

Depth of Front and Back Connections for Return-Tubular Boilers—What should be the depth of front and of back smoke connections for horizontal return-tubular boiler settings?

G. R.

The depth of back connections for any size of boiler should be not less than 24 in., so as to allow sufficient space for examination and expansion of tube ends in the back tube sheet, and for boilers larger than 66 in. in diameter the depth of back connections should be not less than 28 in. Greater depth is advantageous for equalizing the distribution of the heated gases to all tubes of the boiler. Front connections should be of such form and depth as to permit of an easy sweep of the gases to the uptake. The minimum depths should be 12 in. for boilers up to 54 in. diameter, 16 in. for boilers 60 and 66 in. diameter, and 18 in. for boilers 72 and 78 in. diameter

---

Operation of Centrifugal and of Inertia Governors—What is the difference between the operation of centrifugal and of inertia governors?

J. E. B.

In centrifugal governors a change in position of the governor parts is effected solely by a change of centrifugal force resulting from a change of speed. In inertia governors, revolving weights are so arranged that when the engine wheel is accelerated, as by removal of load, the inertia of the weights causes them to lag behind and assist centrifugal force in adjustment of the valve gear for admission of less steam, thus checking the speed, while if the speed of the wheel is retarded, as by an increase of load, the momentum of the weights causes them to surge ahead and assist the spring action of the governor to attain a position of parts that will increase the speed. Therefore, inertia governors are prompter than centrifugal governors, and also may be more powerful and closer in regulation.

Air Required for Burning a Ton of Coal—What volume of air should be supplied for burning a ton of coal?

B. S.

Most fuels require between 11 and 12 lb of air per pound of fuel, according to their analyses, and it is usual to consider that 12 lb. of air will be required to burn each pound of coal. But to make sure that each atom of carbon will meet with an abundance of oxygen, it is necessary to admit an excess of air to the furnace, the amount depending on the force of the draft. With natural draft at least twice as much and with forced draft at least $1\frac{1}{2}$ times as much air will be required. As one pound of air at 62 deg. F. has a volume of 13.14 cu.ft., then for burning a ton (2000 lb.) of coal the air supply should be not less than

$$12 \times 2 \times 13.14 \times 2000 = 630,720 \text{ cu.ft.}$$

of air with natural draft, nor less than

$$12 \times 1\frac{1}{2} \times 13.14 \times 2000 = 473,040 \text{ cu.ft.}$$

of air with forced draft.

Loss of Water Level in Gravity-Return Boiler—What may be the cause and remedy for occasional loss of proper water level in the sectional boiler of a low-pressure gravity-return steam-heating apparatus?

H. B. L.

The proper water level will not be maintained by automatic return of the water of condensation to the boiler when the temperature of steam in the pipes or radiators is so much reduced by radiation of hea hat the pressure, plus the static pressure of the return connection, is less than the sum of the pressures required for overcoming pipe friction, and opening the return check valve added to that in the boiler. Under these conditions the water level may also become reduced by the water of the boiler backing up into the system through leakage of the return check valve. The remedy is to obtain higher relative pressure in the return water by increasing the sizes of steam supply pipes or increasing the static pressure of the return water by raising the level of pipes and radiators or lowering the boiler.

The Elasticity and Endurance of Steam Pipes*

By C. E. Stromeyer

In the present paper it is proposed to inquire into the causes of steam-pipe failures by dealing with about a hundred reported explosions which have been attributed to fatigue and to want of elasticity, though it may have to be admitted that bad material and workmanship, including injudicious or unnecessary annealing, have occasionally either accelerated the failures or have been their chief causes.

In dealing with this subject it will first be necessary to fix on a standard of comparison for the fatigue stresses which may have caused the failures, but in order not to complicate this subject, and also because definite information is not available, it will for the present be assumed that Guest's law for steel also applies to copper, which means that the circumferential stresses in pipes, due to internal steam pressures, do not affect the bending stresses which in the cases under consideration have caused the fractures. Then, also, nothing is as yet known about the influence of temperature on the power of copper to resist fatigue stresses, though it is probable that it has a weakening effect; but temperature also increases the elasticity of copper, so that as regards deformations due to fatigue stresses no serious error will be committed by leaving these two temperature influences out of account.

According to experiments the relationship between the fatigue stresses ($\pm S$) and the number (N) of the stress cycles (revolutions) which cause fracture is expressed by the formula

$$\pm S = Fl + C\,(10^6 \div N)^{1/4}$$

Here C is a constant depending on the nature of the material and Fl is the fatigue limit of the material. Both Fl and C have been obtained by breaking a number of samples by fatigue stresses and marking off the test results on diagrams in which the ordinates were spaced to represent $(10^6 \div N)^{1/4}$. The test results were then found to lie on straight lines which, when prolonged, cut the zero ordinate at the heights Fl, which were then adopted as being the fatigue limits. These tests could naturally not have been continued to an infinite number of revolutions, and there was therefore no absolute certainty that this exterpolated fatigue limit was a reality until by improved methods of testing this point was firmly established. In other words, more recent experiments have demonstrated the fact that this formula applies not only within the range of previous experiments, say from two thousand to twenty million alternations of stress, but also to an infinite number. Wöhler's experiments, and in fact all past experiments which have been examined, confirm the above-mentioned formula.

Wöhler's experiments confined themselves to steels, except one series of tests on wrought iron, but they have been extended by the author to embrace, at least as regards torsion-fatigue tests, about fifty different qualities of steel and steel alloys, cast and wrought iron, nickel, copper, aluminum, phosphor bronze, magnalium, and other alloys, and in all cases the test results harmonized with the formula, which may therefore be accepted as correct. A matter of even greater importance than the general form of the formula is that the fatigue limit can now be expeditiously determined with greater accuracy even than the static tenacity. In one case its extreme values among eight test pieces cut from one crankshaft differed by less than ±0.4 per cent. of the mean value.

Unfortunately no bending fatigue tests have been made on copper, but this omission will be made good in the near future, and the determination of the fatigue stresses which caused fractures in copper pipes will therefore have to be based on deductions drawn from a few torsion-fatigue tests on copper bars which are summarized in the following formula, in which $\pm S_t$ is the alternating shearing stress due to torsion strains which cause failure at the nth revolution:

Copper bar as rolled...	$\pm S_t = 5.4 + 0.37\,(10^6 \div N)$
Copper bar as rolled	$\pm S_t = 5.6 + 0.51\,(10^6 \div N)^{1/4}$
Mean of above.....	$\pm S_t = 5.5 + 0.44\,(10^6 \div N)^{1/4}$
Copper bar annealed in vacuo. . .	$\pm S_t = 2.55 + 0.87\,(10^6 \div N)^{1/4}$
Copper bar annealed and chilled in water	$\pm S_t = 2.69 + 0.97\,(10^6 \div N)^{1/4}$

It having been found that on an average the bending fatigue limit for steel is about 60 per cent. higher than for torsion, the last of the above torsion-fatigue limits may reasonably be increased from 2.69 to 4.30 tons per square inch for the bending-fatigue limit for copper, and as the same comparative tests on steels show that the value of C for bending is three and a half times as great as that for torsion, the value of C = 0.97 may be increased to 3.4 tons per square inch and the formula for the bending-fatigue stresses of copper is probably

$$\pm S_b = 4.3 + 3.4\,(10^6 \div N)^{1/4}$$

As wrought-iron and mild-steel pipes are now largely used on steamers, formulas for their bending-fatigue stresses are of interest. Among the writer's own tests he finds the following results for basic steel, which is the quality of which many welded-steel pipes seem to be made:

TABLE I

	Fatigue Limit, Tons per Sq In.	Values of C, Tons per Sq.In.
British ordinary...	9.69	4.53
British dead soft.	11.26	3.92
German ordinary.....	11.34	4.10
German dead soft.	8.94	4.79
Mean for mild basic steel. .	10.31	4.33

It will be noticed that the fatigue limit for the softer qualities of basic steel, which contain about 10 per cent. carbon, are not necessarily lower than those for ordinary mild qualities, which have about 40 per cent. carbon. This is due to the presence of varying percentages of nitrogen, which element has a tenfold greater influence than carbon on the fatigue limit. The fatigue limit for cast steel is only a little higher than the above, viz., about twelve to thirteen tons per square inch.

The formula for the bending-fatigue stresses of mild steel may therefore be written

$$\pm S_b = 10.30 + 4.33\,(10^6 \div N)^{1/4}$$

Only one set of bending-fatigue tests has been made on wrought iron (by Wöhler). The results can be expressed by the formula.

$$\pm S_b = 6.73 + 4.43\,(10^6 \div N)^{1/4}$$

Among the Board of Trade reports on steam-pipe failures there are none which may be attributed to fatigue of mild steel, but there are a fairly large number of failures of copper pipes, of which a few are capable of being analyzed with the help of the above formula. The following are the report numbers of the failures in question—failures said to be due to vibrations:

Straight pipes—Nos. 948, 1113.

L-bends, like Fig. 6—Nos. 453, 854, 945, 958, 1024, 1049, 1057, 1095, 1111, 1164, 1181, 1187, 1207, 1291, 1296, 1491, 1516, 1611, 1651, 1795, 1852, 1895, 1931.

U-bends, like Fig. 9, without central branch—Nos. 480, 1011, 1021, 1069, 1172, 1185, 1313, 1426, 1435, 1501, 1922, 2105.

U-bends, with central main pipe at right angles to bend, similar to Fig. 9—Nos. 970,992, 1015, 1036, 1696.

S-bends and two L-bends placed at right angles to each other—Nos. 657, 718, 749, 772, 775, 915, 1290, 1527, 1654, 1709, 1926, 1993.

Expansion bends with straight lengths—Nos. 767, 943, 1616, 1795, 1852, 1895, 1931.

The following failures are probably due to looseness of the engine or the boilers:

Engine seating loose—Nos. 742, 833, 1013, 1160, 1355, 1443, 1666, 1922, 1964, 2021, 2088. (In these cases it is presumable that the movements were appreciably great and as numerous as the revolutions of the engines, which on an average may be assumed to be 60 per minute for six months a year.)

Boilers loose—Nos. 543, 728, 1210, 1467. (In these cases it is probable that the movements were large but few, and the empirical rule for the fatigue stresses does not apply.)

Relative movement between boilers or engines and the ship's structure—Nos. 1268, 1543, 1291, 2176.

Shaft brake and engine raced violently—No. 1216. (This pipe had many bends, otherwise the stresses might have been estimated.)

Most of the aforementioned cases cannot profitably be analyzed on account of complexity of form and absence of details. However, Nos. 958, 1049, 1181 and 1954 of the first group and Nos. 1355, 1543 and 2021 of the second group are suitable for this purpose. The estimated fatigue stresses which fractured the aforementioned ten pipes are contained in Table II.

No allowances have been made for the internal steam pressures and their temperatures, though with the exception of

*Paper read before the Institution of Naval Architects and abstracted from "Engineering," London.

2021, for which the steam pressure was 200 lb., the pressures in all the cases were 160 lb.

Case No. 1954 deserves special attention, for the estimated fatigue stresses are approximately equal to the static tenacity of copper. The fact that this pipe withstood these alternative stresses for four hours suggests either that the adopted value of C = 3.4 tons per sq.in. per 1,000,000 revolutions is too high or that the copper was of a harder quality than usual. Among the 200 cases of steam-pipe explosions reported on by the Board of Trade, only three have been found in which measurements of movements which may have caused the failures are given.

TABLE II. ESTIMATED FATIGUE STRESSES UNDER WHICH CERTAIN COPPER PIPES FAILED AFTER N REPETITIONS

Report Number	Age at Time of Fracture	Assumed Number of Revolutions	$(10^6 \div N)^{\frac{1}{4}}$	Estimated Fatigue Stresses, Tons per Sq.In.	Remarks
Failures due to Vibrations of the Engines					
958 (1)	12 months	15,000,000	0 505	6.02	Starboard pipe
958 (2)	25 months	31,000,000	0.423	5 74	Port pipe
1049 (1)	2½ years	40,000,000	0.397	5 65	First failure
1049 (2)	1 year	15,000,000	0.505	6 02	Second failure
1181 (1)	10 years	150,000,000	0 285	5.27	First failure
1181 (2)	24 hours	86,000	1 846	10.57	Heavy weather
1954 (1)	8½ years	120,000,000	0 302	5 33	First failure
1954 (2)	4 hours	14,000	2 900	13 85	Engines racing
Failures due to Loose Engine Seatings					
1355	35 months	44,000,000	0 388	5 62	Long bend
1543	4 years	60,000,000	0 359	5.52	U-bend secured to deck beam
2021	3 years	45,000,000	0.386	5 61	Long bend

Report No. 1467 mentions that the boiler rolled ½ in. Report No. 1296 mentions that when getting up steam the length between the two valves (no dimensions given) shortened by 0.47 in., and the difference of level between the two valves altered by 0.44 in., the boiler top having risen $\frac{5}{16}$ in. as compared with the ship's structure and the engine stop-valve, which had risen ⅛ in. The history of this pipe is interesting It was made of solid-drawn copper and put in service in July, 1899; it cracked near its flange Jan. 17, 1900 (five and one-half months' interval). The cracked end was cut off and replaced by a sleeve, which cracked nine hours after lighting the fires. A new sleeve of thicker copper (1¼ in.) was now fitted, which ran, say, from the end of February to July 30, 1900 (about five months), and then cracked. A new pipe with a larger bend was fitted (August, 1900), but this pipe cracked (no date given). The crack was repaired and the gland made workable. These several failures seem to have been due, not to frequent movements associated with the revolutions of the engine, but to steady stresses caused by the difference of expansion of the boiler and engine, intensified by the vibrations of the engine. No experimental data as to the endurance of copper under these conditions are yet available.

No. 1318 reports that the boiler top rose up $\frac{5}{16}$ in. and the engine ¼ in. due to the raising of the steam pressure, the two boilers separated by ¼ in., and the distance between the engine and one boiler stop-valve was reduced by $\frac{5}{16}$ in. In this case the explosion was due to imperfect brazing of one of the flanges.

To understand the stresses which arise when pipes are strained, the several possible deformations of straight and curved pipes, as represented in Figs. 1 to 5, have been expressed mathematically in Table III.

TABLE III (Figs. 1 to 5).

	Estimated Inclinations a	Estimated Displacements δx	δy
Fig. 1	$+ M \times L \div E \times I$		$+ \frac{1}{2} M \times L^2 \div E \times I$
Fig. 2.	$+ \frac{1}{2} Y \times L^2 \div E \times I$		$+ \frac{1}{3} Y \times L^3 \div E \times I$
Fig. 3	$+ \frac{1}{2} \pi M \times R \div E \times I$	$- 0.571 M \times R^2 \div E \times I$	$+ M \times R^2 \div E \times I$
Fig. 4	$- 0.571 X \times R^2 \div E \times I$	$+ 0.356 X \times R^3 \div E \times I$	$- \frac{1}{2} X \times R^3 \div E \times I$
Fig. 5	$+ Y \times R^2 \div E \times I$	$- \frac{1}{2} Y R^3 \div E \times I$	$+ \frac{1}{4} \pi Y \times R^3 \div E \times I$

M is the external bending moment shown in Figs. 1 and 3; X is the external horizontal pull shown in Fig. 4; Y is the external vertical pull shown in Fig. 5; E is the modulus of elasticity, say 13,000 tons per sq.in. for wrought iron and steel, 8300 for copper, and 4500 to 8000, or say 6000, for cast iron; I is the moment of inertia of the section of the pipe and is equal to $(D^4 - d^4)\ \pi \div 64$, where D is the external and d the internal diameter of the pipe; a, δx, and δy are the acquired inclination and the displacement of the ends of the pipe (see Figs. 1 to 5); S_b, the maximum bending stress for any moment M, is ½ M × D ÷ I, which expression can be introduced in the formulas when the movements produced by X and Y are known.

One application of these formulas can be illustrated with the help of Fig. 6, which represents half a U-bend. Assume, as was the case in Prof. Bautlin's experiments, which will shortly be dealt with, that the flange A, which is the middle of the bend, is a fixture and that a pull X is acting horizontally on the flange C. Then the bending of BC is the same as that in the curved pipe in Fig. 4, X being applied as in that figure. The bending of AB is represented by the two cases, Figs. 3 and 5, M being equal to XR and Y equal to X. Then the acquired inclination of a of the flange B is according to the third and fifth lines of Table III:

$$a = (\tfrac{1}{2}\pi\ R \times X \times R \div XR^2) \div E \times I = 2.571\ X \times R^2 \div E \times I.$$

The displacement Δ of the flange C is the sum of the displacement δy of Figs. 3 and 5, of δx of Fig. 4, and of the product of the inclination a into the radius R of the bend BC

$$\Delta = (X \times R^3 + 0.785\ X \times R^3 + 0.356\ X \times R^3 + 2.571\ X \times R^3) \div E \times I = 4.713\ X \times R^3 \div E \times I.$$

The bending moment at A is of course 2X × R, and this is equal to S × I ÷ ½D, where D is the external diameter of the pipe. On replacing I by X2R × D ÷ 2S, the stress S at the flange A can be expressed in terms of the displacement Δ:

$$S = \Delta \times D \times E \div 4.712\ R^2$$

For copper, the value of E is about 8300 tons per sq.in., so that for pipes of this material S = 1750 Δ × D ÷ R², and assuming 4.3 tons per sq.in. as being the fatigue limit for copper, the maximum permissible movement of half a copper U-bend (Fig. 6) should not exceed

$$\Delta_c = R^2 \div 405\ D$$

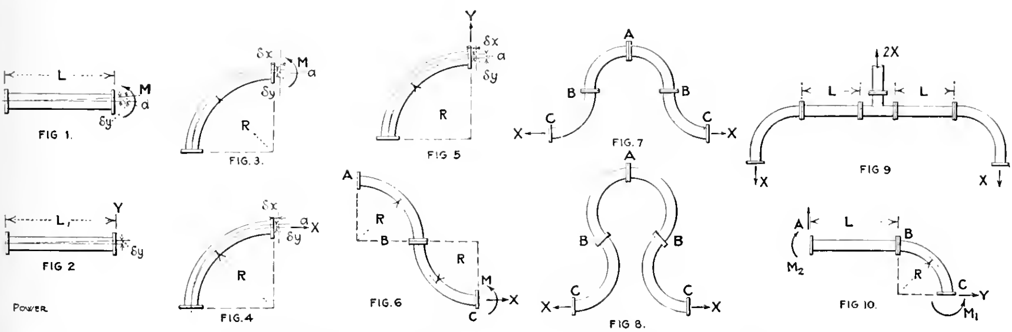
For steel and wrought iron E = 13,000, and therefore S = 2750 Δ × D ÷ R², and assuming the fatigue limit for wrought iron to be 6.75 tons per sq.in., we have

$$\Delta_i = R^2 \div 410\ D \text{ for wrought iron}$$

Assuming a fatigue limit of 10.3 tons per sq.in. for mild steel, we have

$$\Delta_s = R^2 \div 265\ D$$

Thus a U-bend (Fig. 7) of 8 in. diameter and 8 ft. high which forms part of a long length of pipe will take up the following expansion movements without injury to itself: 1.40 in. if of copper, 1.40 in. if of wrought iron, and 2.20 in. if



THE LETTERS CORRESPOND TO THOSE IN THE ALGEBRAIC EXPRESSIONS IN THE TEXT of mild steel. **This last result agrees with experiment A in Tables IV and V.**

TABLE IV. PROFESSOR BAUTLIN'S EXPERIMENTS ON THE ELASTICITY OF BENDS

Details of Bends	Height, In	Outside Diameters and Thicknesses, In	Moment of Inertia I	M I. Millions
A, mild steel pipe .	94 7	8 7 × 8 2 × 0 26	27 0	810
B, mild steel pipe.	88 8	5 3 × 5 1 × 0 175	2 65	80
C, cast-iron pipe	94 7	8 5 × 8 4 × 0 78	139 0	275
D, mild steel rod .	54 6	3 14 square	8 0	240
E, mild steel rod.	62 5	3 14 square	8 0	240

Prof. Bautlin carried out some experiments on U-bends shaped as shown in Fig. 8*. As the bends were not square other but similar formula to the above had to be constructed for estimating the displacement of the flange C. These are recorded in the columns marked "Est." in Table V. The observed displacements are to be found in the columns marked "Obs." The modulus of elasticity of the cast-iron pipe was 7870 tons per sq.in.

The formula for these bends is

$$\Delta = 17.27\ X \times R^3 \div E \times I \text{ and } S = \Delta \cdot D \times E \div 17.27\ R^2$$

It must not be overlooked that whereas in the previous case (Fig. 7) the height of the bend is 2R, in the present case (Fig. 8) it is 3.414 R. The agreement for the mild-steel rods between the estimated and observed displacements is satisfactory, but pipes seem to be rather more elastic than was expected. The discrepancies between the estimated and the observed displacement for the mild-steel pipe A have been explained as being due to slight puckers on the insides of the bends of the pipes. In part they are also due to the thinning during the bending operation. Generally speaking, Professor Bautlin's important experiments confirm the mathematical estimates of the deformations of bent pipes, and these may therefore be applied to the few exploded steam-pipes for which the probable alternating stresses have already been calculated. It is unfortunate for the present investigations that the Board of Trade reports contain so little information about those parts which, in the opinion of the reporting surveyors, are not the direct causes of the explosions. Among about one hundred reports on steam-pipe explosions, which it is believed were brought about by want of elasticity, the diameters of the pipes and the thicknesses at the points of fracture are given, but rarely is any mention made of the lengths or the elasticities of these pipes, although these are the determining factors.

For the purpose of this paper, these lengths, as well as the radii of curvature, had to be approximately ascertained by scaling them with the help of the diameters as sketched. It is therefore possible that the dimensions which have been adopted in the following calculations are not always correct.

U-bends (Fig. 9) with central branch do not seem to have failed, and this form need not be discussed.

L-bends and simple U-bends (see Fig. 10). The following formula for the displacement δy in the case of L-bends and $2\,\delta y$ for U-bends can be determined in terms of the horizontal pull Y and the bending moment M by combining the formula in Table III for the cases represented by Figs. 1, 2 and 5. As there is no pull X, and as the sums of the deflections of the length L and the bend is zero, Y can be eliminated and M expressed in terms of S_b, the maximum bending stress.

$$\delta y = 0.712\ S_b \times R^2\ (L + 0.65\ R) \div E \times D\ (L + R)$$

For copper E = 8300 tons per sq.in., so that

$$\delta y = S_b\ R\ (L + 0.65\ R) \div 11{,}600 \times D \times (L + R)$$

This formula has been used in calculating the displacements δy for the following L-bends and $2\,\delta y$ for U-bends, S_b being the fatigue stresses which have been previously determined for the separate cases.

Report No. 958 deals with the two separate L-bends made of electro-deposited copper of 5 in. external diameter hooped with iron bands. The shorter length, in which, according to the sketch, L and R seem to be respectively about 11 in. and 57 in., failed after 12 months' service. Assuming the correctness of the previously found alternating stresses of ± 6.2 tons per sq.in., the relative movements of the two ends of the pipe should by the formula be ± 0.38 in. In the longer branch, L and R seem to be respectively 75 in. and 68 in. Assuming the correctness of the previously found stresses of ± 5.74 tons per sq.in., the relative movements of the pipe ends should be ± 0.25 in.

Report No. 1049 deals with another L-bend of solid-drawn copper of 5¾ in. external diameter. According to the sketch, L and R seem to be respectively 80 in. and 25 in. Assuming the correctness of the previously found alternating stresses of ± 5.65 tons per sq.in. for the first failure after 2½ years' running, the relative movements of the two ends of the pipe should be 0.049 in., and for the second failure after 12 months' running the alternate stresses would be ± 6.02 tons and the relative movements should be 0.051 in. The comparative smallness of these relative movements is due to the rigidity of the small bend, which was only five times as large as the diameter of the pipe. In fact, the pipe probably acted as a stay between the engine and the boiler and restricted their movements while being fatigued. Had the relative movements been larger and the stresses more intense, the failures would have occurred sooner, as happened in the following two cases:

Report No. 1181 deals with an L-bend of solid-drawn copper 6⅞ in. external diameter. According to the sketch, L and R seem to be respectively 42 in. and 50 in. Assuming the correctness of the previously found alternating stresses of ± 10.57 tons per sq.in. for the failure, which occurred after 24 hours' heavy service immediately after previous annealing, the relative movements of the ends of the pipe should be 0.27 in. Seeing that the estimated alternating stresses during the previous ten years' running were only ± 5.27 tons per sq.in., the relative movements of the pipe ends during this longer period do not seem to have exceeded ± 0.14 in.

Report No. 1954 deals with an L-bend of sheet-copper 4.92 in. external diameter. According to the sketch, L and R seem to be respectively 93 in. and 32 in. Assuming the correctness of the previously found alternating stresses of ± 13.85 tons per sq.in. for the new pipe, which failed during a run of four hours in heavy weather, the relative movements of the ends of the pipe should be ± 0.23 in. For the old pipe, which failed after eight years' running under stresses of ± 5.33 tons per sq.in., the relative movements should be ± 0.09 in.

The elastic limit was reached with pipe A with a thrust of 1809 lb

Report No. 1355 deals with an L-bend of solid-drawn copper 5.19 in. external diameter. According to the sketch, L and R seem to be respectively 70 in. and 100 in. long. Assuming the correctness of the previously found alternating stresses of ± 5.62 tons per sq.in., the relative movements of the ends of the pipe should be ± 0.39 in.

Report No. 1543 deals with a U-bend of solid-drawn copper 4.94 in. external diameter. Judging by the sketch, L and R seem to be respectively 16 in. and 46 in. long. Assuming the correctness of the previously found alternating stresses of ± 5.52 tons per sq.in., the relative movement of the ends of the pipe should be ± 0.26 in.

Report No. 2021 deals with an L-bend of solid-drawn copper 5.5 in. external diameter and 0.25 in. thick. According to the sketch, L and R seem to be respectively 68 in. and 42 in. Assuming the correctness of the previously found stresses of ± 5.1 tons per sq.in., the relative movements of the ends of the pipe should be ± 0.17 in.

TABLE VI. ESTIMATED INTENSITIES OF FATIGUE STRESSES AND THE RELATIVE MOVEMENTS OF THE ENDS OF THE FRACTURED PIPES

Report Number	Assumed Number of Vibrations	Estimated Fatigue Stresses, Tons per Sq.In.	Estimated Fatigue Movements, In.
Failures Due to Vibrations of the Engines			
958 (1)	15,000,000	± 6 02	± 0.38
958 (2)	31,000,000	± 5 74	± 0.25
1049 (1)	40,000,000	± 5.65	± 0 049
1049 (2)	15,000,000	± 6.02	± 0.051
1181 (1)	150,000,000	± 5.27	± 0.14
1181 (2)	86,000	± 10 57	± 0.27
1954 (1)	120,000,000	± 5.33	± 0.09
1954 (2)	14,000	± 13.85	± 0.23
Failures Due to Loose Engine Seatings			
1355	44,000,000	± 5.62	± 0.39
1543	60,000,000	± 5.52	± 0.26
2021	45,000,000	± 5 61	± 0 17

*Zeitschrift des Vereins Deutscher Ingenieure, 1910, Vol. 54, page 43. Also Mitteilungen über Forschungsarbeiten des Vereins Deutscher Ingenieure, Vol. 96.

These and the previous estimates are summarized in Table VI. They are all based on the empirical formula which correlates the fatigue stresses for copper and the number of their repetitions up to the point of failure. The experiments on which it is based are comparatively few, and more comprehensive ones will shortly be carried out on a new fatigue-testing machine which is nearing completion; but seeing that the results of fatigue tests with mild steel are consistent, the intended further experiments on copper will probably merely confirm those already obtained.

Assuming the correctness of the empirical formula, then, judging by the estimates contained in Table VI, relative movements between engines and boilers of ±0.38 in. (see No. 958) or more should be allowed for. These were associated with fatigue stresses of ± 6.02 tons per sq.in., which exceed the fatigue limit of ± 4.3 by 1.7 tons per sq.in. If these relative movements of ± 0.38 in. had not exceeded ± 0.27 in., the pipe would not have failed. Had the pipe been made of steel it would also not have failed, for although its modulus of elasticity is 13,000, as against 8300 tons per sq.in. for copper, the respective fatigue limits are 10.3 and 4.3 tons per sq.in., and the maximum relative movement to which such a steel pipe would have submitted without injury would have been ± 0.43 in. Conversely, if a steel pipe of the above dimensions were replaced by a copper one and the relative movements of its ends were maintained at ± 0.43 in., then the fatigue stresses in the copper pipe would be ± 6.77 tons per sq.in., or ± 2.47 tons above the fatigue limit of ± 4.3 tons, and the copper pipe would fail after 3,600,000 repetitions. This means that if any copper pipe were to fail after experiencing 3,600,000 stress cycles, which corresponds to 42 days' continuous running of the engines at 60 revolutions per minute, and if it were to be replaced by a steel pipe, this would last forever, and as most of the pipes dealt with in the Board of Trade reports did last longer than 42 days, the number of explosions would have been correspondingly reduced if steel pipes had been used instead of copper.

But—and this is the point which should not be overlooked—it is highly probable that the cast-iron valves to which these steel pipes would have to be attached would have fractured at an early date, because the resisting moments of steel pipes are 1.56 times greater than those of copper pipes of the same dimensions, and even copper pipes are occasionally strong enough to fracture the cast-iron valves to which they are attached, as is evident from the following Board of Trade reports:

No. 389. A copper pipe with fairly large bends broke the neck of the valve-chest to which it was attached.

No. 556. The thrust on an expansion-gland acting at the end of a copper pipe as a lever broke the neck of the valve-chest to which it was attached.

No. 971. A copper pipe attached to the end of a combined expansion gland, stop valve and throttle-valve casing broke the latter.

No. 1072. A copper pipe broke the cast-iron neck of a steam chest to which it was attached. The other end of the pipe formed part of an expansion gland which was attached to the engine whose lateral motion was the cause of the fracture.

No. 1177. A copper U-bend between the boiler and its engine acting on the end of a throttle-valve casing broke it.

No. 1572. The thrust of an expansion gland acting at the end of a copper bend broke the valve-casing to which it was attached.

In the following cases the pipes were of wrought iron:

No. 1230. A straight wrought-iron pipe between an expansion gland on the engine and a short cast-iron bend on the boiler stop-valve broke the neck of the latter.

No. 1404. A straight iron pipe which ended in an expansion joint broke the neck of the valve-casing to which it was attached.

The following rather unusual failures may be due to bad material, but seeing that they occurred both with sheet-copper, solid-drawn and electro-deposited pipes it is not unlikely that they were due to fatigue stresses. However, as all these cracks are along the neutral line of the copper bends where there are no bending stresses, but where the shearing-fatigue stresses are maximum, it is not unlikely that these alternating shearing stresses were relatively more intense than the bending stresses near the flanges. It should also be remembered that the fatigue limit for shearing stresses is only ± 2.5 tons per sq.in.

No. 1231 deals with a sharp bend of sheet copper 3.55 in. external diameter which cracked near the brazing line, which is also the neutral line of the bend. The bend was eight years old when it failed.

No. 1262 deals with a bend of sheet copper 10.2 in. external diameter which cracked near the brazing line like the above-mentioned bend. This pipe failed after sixteen months' work.

No. 1662 deals with a bend of solid-drawn copper 6½ in. external diameter which failed along the neutral line after three years' work, when it was repaired and annealed, but it failed again after seven years.

No. 1839 deals with an expansion bend of solid-drawn copper 5.42 in. external diameter which failed along the neutral line after nine years' work. Locally the tenacity was reduced to 5.6 tons with no elongation.

No. 1882 deals with a bend of solid-drawn copper 5.2 in. external diameter which failed along the neutral line after three years' work. It had probably been damaged locally while being repaired. Locally the tenacity was reduced to 7 tons with 1.5 per cent. elongation.

No. 2110 deals with an expansion bend of solid-drawn copper 5.4 in. diameter which failed along the neutral line after four and one-half years' work.

No. 2140 deals with an expansion bend of solid-drawn copper 6½ in. external diameter which failed along the neutral line after six years' work.

No. 986 deals with a bend of electro-deposited copper 3⅞ in. external diameter which failed along the neutral line after three years' work.

No. 1383 deals with a bend of electro-deposited copper 4.8 in. in external diameter which failed along the neutral line after seven years' work, close to a repair sleeve which had been brazed on three months before the explosion.

No. 1736 deals with a bend of electro-deposited copper 3.8 in. in diameter which failed after one year's work. The tenacity was locally reduced to 12.5 tons with 5 and 8 per cent. elongation.

No. 1770 deals with a bend of electro-deposited copper 5.4 in. in external diameter which failed after two years' work. The tenacity was reduced from about 13.5 tons with 45 per cent. elongation to between 9 and 10 tons with 5 to 7 per cent. elongation.

No. 2163 deals with an expansion bend of electro-deposited copper 6 in. external diameter which failed along the neutral line after six years' work.

If, as seems probable, the above 12 failures (about 8 per cent. of the total) were due to sheer fatigue stresses, which are severest along the neutral lines of beams, they would indicate that the bends had been subjected to more complicated forces than have been assumed when dealing with the other failures, but in the absence of any details about the relative movements of the engines and boilers it is fruitless to venture on any estimates, except to say that the formula for torsion fatigue stresses should be applied to these cases and that the stresses which are due to the internal steam pressures should not under any circumstances be overlooked.

While studying those Board of Trade reports which seemed to have a bearing on the present question it was noticed that many copper pipes had failed shortly after being annealed, although until then they had worked satisfactorily for years. This experience would suggest either that annealing does not remove the effect of fatigue stresses or that, if carried out injudiciously, it changes tough copper into a brittle material. In the following list of reported cases the numbers in parentheses denote the periods in months which elapsed between the dates of annealing and of failure:

Pipes of Brazed Sheet Copper.—Nos. 1922 (4), 1210 (5), 1021 (6), 2105 (17), 1011 (19), 1443 (23).

Solid-Drawn Copper Pipes—Nos. 1839 (½), 1926 (2), 1709 (5), 1327 (6), 1327 (8), 1993 (9), 1187 (10), 2003 (21), 2110 (36), 1898 (48).

Electro-Deposited Copper Pipes—Nos. 1164 (3), 1501 (12), 970 (12), 1610 (19).

The average life of a copper pipe after being annealed seems to be about one year for each one of the above three groups, but as already suggested these cases do not prove that annealing is or is not a remedy for fatigued copper. This experience as regards copper does not apply to steel pipes.

As a safeguard against fatigue stresses in steam-pipes expansion glands are sometimes fitted, but they are not always applied where wanted; they sometimes stick fast, and if badly designed the pipes blow out of their sockets.

This latter class of accidents is illustrated in reports Nos. 779, 1702, 2246.

Pipes which stuck fast in their sockets and did not take up the movements are to be found in reports Nos. 283, 1296, 1404, 1666, the last being a doubtful case.

In the following cases the thrusts of the pipes in the glands acting on long bends fractured these near the roots or the glands had stuck fast and the fractures were due to fatigue: Nos. 556, 1113, 1187, 1207, 1230, 1343, 1489, 1572, 1583, 1605, 1609, 1852, 1916, 1978. These are mostly marine cases.

In the following cases the expansion glands neither prevented the pipes from fracturing nor did they cause the fractures: Nos. 169, 584, 971, 1011, 1035, 1056, 1072, 1109, 1172, 1185, 1214, 1264, 1398, 1461, 1515, 1537, 1556, 1747, 1771, 1899, 2006. About half of these cases occurred on steamers.

The New York Central Wins the Harriman Medal

At the annual meeting of the American Museum of Safety held in the United Engineering Societies Building, 29 West Thirty-ninth St., New York City, Feb. 10, 1915, the E. H. Harriman memorial gold medal for the American steam railway making the best record in accident prevention and industrial hygiene affecting the public and its own personnel during the year ending June 30, 1914, was awarded to the New York Central R.R. The award was made to this road for its record on the New York Central & Hudson River R.R. prior to its consolidation with the Lake Shore. The medal was offered by Mrs. E. H. Harriman to be awarded through the American Museum of Safety. The committee of award consisted of: Arthur Williams, president American Museum of Safety; Samuel O. Dunn, editor "Railway Age Gazette"; Prof. Alexander C. Humphreys, president Stevens Institute; Hon. Chas. P. Neill, former U. S. Commissioner of Labor; and Hon. Edgar E. Clarke, member Interstate Commerce Commission. The medal was received on behalf of the railroad by Alfred H. Smith, president. The silver medal was awarded to the operating department, and the bronze medal to Dennis Joseph Cassin, who had been an engineer on the Central since 1867. He had never had an accident.

The Overloading of Safety Valves

The formal Board of Trade inquiry in connection with the terrible boiler explosion that occurred at the Thornhill Iron & Steel Works, Dewsbury, on Aug. 10 last, causing the death of eight men, and more or less serious injury to 17 others, provides a lesson which it is to be hoped will be taken to heart by every boiler attendant in the country, as to the criminal folly of interfering with the action of safety valves. The facts of the case were very simple. The boiler, which was one of eight at the works, all coupled together, was of the Rastrick type, heated by the flames from iron furnaces, and was normally worked at 55 lb. per sq.in.

The works were closed from July 31 to Aug. 10, and when the boilers were started the engineer noticed steam blowing off at the safety valves on No. 4 boiler, and without examining the stop valve or the pressure gage he assumed that the escape of steam was due to some defect of the safety valves—of which there were two loaded by levers and weights—and tried to correct it, first by sliding the weights to the end of the lever, and this proving insufficient, by adding a weight of 50 lb., which, being still inadequate to prevent the escape of steam, was supplemented with another 63 lb. As a matter of fact, which was proved after the explosion, the stop valve was shut and the boiler thus isolated from the others to which it was supposed to be connected, and the escape of steam was due to the steady rise of pressure in the boiler, in which steam was being generated without any outlet, and was being bottled up by the extra load on the valves. There could, of course, be only one end to this incredible madness, and that was reached about two or three hours after the fire was started, when the bursting pressure, which would probably be getting near 200 lb., was reached and instantly converted the whole works into a heap of ruins, killing or injuring nearly everybody in the place.

How anyone with a knowledge of boilers could be guilty of such recklessness as to overload safety valves in this deliberate way, without seeing what the pressure was or making sure that any steam generated had at least access to the safety valves of the other boilers, surpasses belief, and we can well understand the Board of Trade Commissioner, when he heard the frank admissions of negligence at the inquiry, "wondering whether or not he was in a lunatic asylum." There were, of course, no technical questions involved in the explosion, for whatever type of boiler had been used the explosion would inevitably have occurred. The inquiry resolved itself into one of fixing responsibility for the disaster, and in view of the engineer's admissions as to the personal part he played there could be no doubt where it lay. The only excuse he could offer was that he thought the stop valve was open, as it was left open when the boilers were laid off on July 31, but he took no steps to verify this assumption or even to look at the pressure gage before he proceeded to hang on weights practically equivalent to a man sitting on the end of the levers. Who shut the stop valve it was impossible to find out, and as regards responsibility little matters, for the most ordinary precaution should have suggested to the engineer that freedom for escape of the steam generated in the boiler should be provided in some way before such "an act of madness" as the overloading of the safety valves was resorted to.

The question remains, how can the consequences of similar crass ignorance be guarded against in the future? The ordinary lever type of safety valve does, it must be admitted, permit of being easily tampered with and overloaded. Of course, whatever type of safety valve is used there is little to protect it from interference, from reckless ignorance or malignant ingenuity, though a locked-up valve which no one could touch would protect such a fitting to some extent from the former risk, and as the Commissioners, in their judgment, which saddled the responsibility for the explosion entirely on the engineer and the boiler attendant who assisted him, emphasize the necessity of valves which can be protected from any interference being adopted, it is possible we may before long see some Board of Trade regulation of this kind imposed on all steam users.—"The Mechanical Engineer," Manchester, Eng.

Elimination of Smelter Smoke

With the idea of bringing about a better understanding between the metallurgical industry and agriculture as to the troublesome smoke problem at smelting and ore-roasting plants, the United States Bureau of Mines has just issued "Bulletin 84."* Copies may be obtained by addressing the Director, at Washington, D. C. Owners of smelting plants are making every effort to devise ways and means to do away with possible damage and annoyance from great volumes of smelter smoke, comparatively rich in sulphur dioxide and other injurious constituents.

It has been customary to discharge the smelter smoke by very tall chimneys, on the assumption that if the noxious gases are discharged at considerable height they will have opportunity to diffuse more thoroughly and thus become so diluted as to be comparatively harmless, but the efficiency of this method is now being questioned. There is reason to believe that the use of high stacks increases the area to damage, whereas low stacks may intensify the damage but concentrate it within a small area. Probably high chimneys do not serve their purpose as well as was anticipated, and the better method may be to dilute the smelter smoke and discharge it from a number of low stacks.

Massachusetts Electric Rates Discussed

A battle royal on the subject of electric rates was started on Feb. 5 before the Committee on Public Lighting of the Massachusetts Legislature, which is considering House Bill No. 346, relative to the prices to be charged for electrical energy by central stations. The bill was brought before the committee on petition of the New England Power League, an organization formed about three years ago by manufacturers, business houses, engineers of isolated plants and others interested in the economical use of power. Ernest Stevens, chief engineer of Riverbank Court Hotel, Cambridge, Mass., led the advocates of the bill, which provides that no public-service corporation shall be allowed to sell electricity at less than 5 per cent. above the cost of production and distribution, that the maximum price charged for electricity shall not exceed 25 per cent. over and above the cost of production and distribution, and that the Board of Gas and Electric Light Commissioners shall have power to determine such costs after a thorough examination of all books and properties belonging to such companies.

The principal evidence on behalf of the bill was offered by Thos. W. Byrne, consulting engineer, of Boston, who contended that 90 per cent. of the users of electricity purchase energy at the maximum price and that these small users are charged at least five times as much per kilowatt-hour as the large consumers of power, who easily buy electricity at two cents or less per kilowatt-hour. The speaker urged that the central-station policy is to "charge what the traffic will bear," and said that the National Electric Light Association at its Philadelphia convention in 1914 had gone on record in support of the principle that the value of central-station service was in a large measure determined by the ability of the consumer to install a private plant.

Mr. Byrne contended that the basis of rates should be a fair return on the investment and advocated a valuation of all existing electric-lighting properties in the state by the Gas and Electric Light Commission, for the purpose of checking up the reasonableness of the rates now in force. He pointed out that in the decision of the board in the Worcester street-lighting rate case, the commission had called attention to the power of the company to dictate prices to the small consumer. Members of the Power League feel that present

*The suggestions contained in this bulletin may also be applicable to the power-plant smoke problem.—EDITOR.

central-station rates in various cities of the state are discriminatory, and favor requiring the commission to set forth its views upon the price differences, if any, which should be allowed between lighting and power rates, and between residential and other users, as related to the quantity of energy purchased and as affected by long and short periods of use.

Available Water Power in United States

According to recently compiled figures made by the U. S. Geological Survey, the total available water power in the United States amounts to about 200,000,000 hp., of which only 6,000,000 is developed. The total available is estimated on the basis of practicable maximum storage of waters possible by the construction of dams and reservoirs. Without storage, the available water power is placed at only 61,678,000 hp., of which the present development is about one-tenth. The water powers as listed by the Geological Survey are distributed in the several states and sections of the country as follows:

North Atlantic States:	
Maine	971,000
New Hampshire	295,000
Vermont	206,000
Massachusetts	273,000
Rhode Island	16,000
Connecticut	164,000
New York	2,037,000
New Jersey	127,000
Pennsylvania	821,000
	4,910,000
South Atlantic States:	
Delaware	13,000
Maryland	146,000
Dist. of Columbia	13,000
Virginia	1,044,000
West Virginia	1,261,000
North Carolina	1,050,000
South Carolina	812,000
Georgia	752,000
Florida	16,000
	5,107,000
North Central States:	
Ohio	213,000
Indiana	141,000
Illinois	414,000
Michigan	352,000
Wisconsin	804,000
Minnesota	593,000
Iowa	458,000
Missouri	195,000
North Dakota	248,000
South Dakota	90,000
Nebraska	439,000
Kansas	323,000
	4,270,000
South Central States:	
Kentucky	236,000
Tennessee	913,000
Alabama	1,132,000
Mississippi	75,000
Louisiana	2,000
Arkansas	73,000
Oklahoma	250,000
Texas	661,000
	3,342,000
Western States:	
Montana	5.197,000
Idaho	3,080,000
Wyoming	1,566,000
Colorado	2,036,000
New Mexico	527,000
Arizona	2,038,000
Utah	1,581,000
Nevada	331,000
Washington	10,376,000
Oregon	7,935,000
California	9,382,000
	44,049,000
Summary of States:	
North Atlantic	4,910,000
South Atlantic	5,107,000
North Central	4,270,000
South Central	3,342,000
Western	44,049,000
Grand total	61,678,000

Fatal Sawmill-Boiler Explosion

On Jan. 20 at about 10 a.m. the boiler of a portable sawmill near Beverly, Mo., exploded, killing two and seriously injuring another. A father and his four sons were operating the sawmill on the lowlands of the Missouri River. The engine had been stopped to make some adjustment to the saw. Two of the boys had just left for home near-by, and the other two, aged 7 and 18 years, respectively, were in front of the boiler.

The explosion killed the two boys instantly, disfiguring them almost beyond recognition. The father was found in the underbrush near-by, severely scalded and unconscious. It is believed that he will recover. The boiler was blown through a shed and across a boggy creek for a distance of about 300 ft. from its foundation, striking the ground twice before it finally stopped.

The boiler was of the locomotive type 11½ ft. long with firebox 30x48 in. The front part of the crown and sides of firebox were forced down nearly to the bottom of the furnace. This was the only part that gave way, the tubes, shell and outer firebox sheets remaining intact. The firesheets and stay-bolt ends were badly pitted and eaten away by corrosion, so that the stay-bolts had very little hold. At some parts of the blowoff opening the plate was less than one-sixteenth of an inch thick.

The safety valve and steam gage had not been found up to the time of writing this, as the ground was covered with several inches of snow that had fallen the following night. The inside of the boiler seemed clean. The water column and connections were clear so that it showed the true water level. The injured man claims that there was plenty of water in the boiler just before it exploded.

The owner bought the second-hand boiler about a year ago, when he was told not to carry over 80-lb. pressure. From the appearance of the boiler it ought not to have been used and should have been in the scrap pile.

This is the third explosion of old boilers that has occurred in this vicinity in the last three years, which goes to show the great need of state boiler inspection and engineers' license laws.

Recent Court Decisions

Digested by A. L. H. STREET

Assumption of Risk by Employee—An employee of a power company who was directed to make repairs on a dam while water and ice were running over it assumed the risk of being swept from the dam by the force of the stream, according to a late decision of the Maine Supreme Judicial Court, announced in the case of Monk vs. Bangor Power Co., 92 "Atlantic Reporter," 617.

Negligent Operation of Boilers—When negligence of an engineer leads another employee of a common employer to believe that an explosion has occurred or is imminent, and such other employee is injured in attempting to avoid the danger apprehended, the employer may be held responsible in damages, unless the "fellow-servant rule" happens to be applicable. This statement is warranted by a late decision of the Indiana Supreme Court, in the case of Stringer vs. Vandalia R.R. Co. (106 "Northeastern Reporter," 865), wherein defendant was held liable for injuries sustained by a brakeman leaping from a locomotive after the engineer had permitted the crown-sheet of the boiler to run dry and then suddenly turned water on it, causing the crown-sheet to fall, under circumstances which naturally tended to make the brakeman suppose that an explosion had either occurred or was imminent.

PERSONALS

Edward P. Burch, E. E., has opened an office as consulting engineer, in the Dime Bank Building at Detroit. General practice is contemplated, with specialization in mechanical and railway work and in property valuations.

Dr. Robert Grimshaw, one of the early editors of "Power" and the only living charter member of James Watt Association No. 7, N. A. S. E., of New York, attended the Feb. 13 meeting of that association. Dr. Grimshaw is on a brief visit to the United States, having lived for many years in Germany.

Guy E. Marion, secretary-treasurer of the Special Libraries Association, has severed his connection with Arthur D. Little, Inc., the well known chemists, engineers and managers, of Boston, where he has been located for the last five years in charge of their information department. He has offices in the Tremont Building, Boston, with W. H. Manning, landscape designer.

William W. Cole, of 43 Exchange Place, and Arthur S. Ives and Rolland A. Davidson, composing the firm of Ives & Davidson, of 84 William St., announce the formation of a partnership for the general practice of engineering, under the firm name of Cole, Ives & Davidson, with offices at 61 Broadway, New York. Especial attention will be given to investigations and reports for financial interests, inventories and valuations of public utility or industrial properties and design, installation or management of power plants of all descriptions.

Walter N. Cargill has been appointed superintendent of power and lines of the Rhode Island Co., with headquarters at Providence, and will take up his new work on Apr. 1. For eight years he was in charge of engineering, construction and operation in the one substation and 10 power stations of the lines north of Boston now comprising the northern portion of the Bay State Street Ry. He resigned in 1911 to join the engineering staff of the Stone & Webster Engineering Corporation, where he has since been occupied with investigations, appraisals and problems of a mechanical character in connection with the generating plants designed, examined or operated by the organization.

Lyndon F. Wilson, vice-president of the Railway List Co., Chicago, has resigned to become vice-president of the Bird-Archer Co., New York, manufacturers of boiler compounds, effective Apr. 1, 1915. He was born at Rush Lake, Wis., Nov. 4, 1883. He was educated at Ripon College, Lawrence University and the University of Wisconsin, and after some general machine-shop and power-plant experience, became an engineer in the service of the United States Government (Department of the Interior), passing examinations in steam, electricity, and heating and ventilating. After one year in this service, he joined the engineering department of the Western Electric Co. and was so engaged until the fall of 1908, when he became mechanical department editor of the "Railway Review," Chicago. In the spring of 1909 he became editor of the "Railway Master Mechanic" and was subsequently given editorial charge of "Railway Engineering," both being published by the Railway List Co. He was promoted to the vice-presidency of this company in the summer of 1913. After Apr. 1, Mr. Wilson will be located in the Chicago office of the Bird-Archer Co.

NEW PUBLICATIONS

COAL SAMPLING AND ANALYSIS—Technical Paper 76, of the Bureau of Mines, Department of the Interior, is a collection of notes on the sampling and analysis of coal, by A. C. Fieldner. Copies may be had free by applying to the Director of the Bureau of Mines, Washington, D. C.

GEORGE WESTINGHOUSE—To those who did not know him personally, a reading of the Tribute, by Arthur Warren, will give an idea of the elements of his greatness and success, and of the fullness of the life which he lived. Mr. Warren's association with the master was intimate and of long duration, and his Tribute is an evident labor of love.

PENNSYLVANIA RAILROAD has issued a booklet, for distribution at the Panama-Pacific Exposition, describing its activities and exhibit at the Fair and containing a map of the entire system, which, it is claimed, serves 52 per cent. of the population of the United States. It also contains illustrations of the proposed Union Station in Chicago, the main span of the East River bridge, and a model of New York City. A photograph of the last is also reproduced in colors on the cover page. This model shows the city just as if one were looking at it from an aëroplane. It reproduces faithfully not only the main physical features of Manhattan Island and the surrounding country and water courses, but the prominent buildings, the streets, the bridges spanning East River, the parks, and the squares.

CENTRIFUGAL PUMPS—What is probably the most complete commercial publication devoted solely to centrifugal pumps is being distributed by the De Laval Steam Turbine Co., of Trenton, N. J. This book of 298 pages contains over 300 illustrations, including centrifugal pumps for all capacities and heads and for motor and steam-turbine drives, diagrams showing the "characteristics" of such pumps and explaining the relations between impeller-blade angles and characteristics, interior views and views of parts showing the construction, views showing the method of manufacture by the use of limit gages and methods of testing, installations of pumps for various services, also numerous illustrations of the DeLaval reducing gear employed to allow electric motors, water turbines, steam engines and steam turbines to operate at the most economical speed when driving a centrifugal pump. The text matter is divided into chapters under such headings as, "The Introduction of the Centrifugal Pump and the Work for Which It is Adapted"; "Features to be Considered in Selecting Centrifugal Pumping Equipment"; "The Use of the Characteristic Curve"; "Methods of Testing Centrifugal Pumps"; "System of Manufacture for the Production of Interchangeable Parts"; "Details of Design and Construction of Single-stage and Multi-stage Pumps"; "The Speed Question, Particularly Relating to Steam Turbine-Driven Centrifugal Pumps"; "Helical Speed-Reducing Gears"; "Motor and Belt Drives"; "High-Duty Steam Turbine-Driven Pumps as Compared with Reciprocating Pumping Engines for Water-Works Service"; "The Adaptation of Pumps for Circulating Condenser Water, Feeding Boilers and other Steam Power-Plant Service"; "Drainage and Irrigation Pumps"; "Hydraulic Pressure and Elevator Pumps"; "Pumps for Marine Uses, Mining Service, Fire Service and Hot Water and Brine Circulation", etc. Tables and charts are given for determining the resistance of pipes and the relation between heads and spouting velocities. The investigation of the pumping problem, together with drawing up of specifications for centrifugal pumps, are also treated at some length. The chapters on "Pump Characteristics" will prove more valuable to the pump user than many of the more technical treatises. The chapter on "Water Works Pumps," showing that under many conditions the centrifugal pump can handle water at a cost 20 to 40 per cent. lower than it can be handled by reciprocating pumps, because of the lower fixed charges, it is thought will be a revelation to many who have not recently given this matter consideration.

THE LONGER WAY IS SAFER

Fairview Sewage-Pumping Station

By Thomas Wilson

SYNOPSIS—An attractive plant equipped with angle-compound-centrifugal pumping units. Its capacity is 150,000,000 gal. in twenty-four hours. The efficiency of the pumps is 70 per cent. The equipment cost $118,000.

One of Detroit's show plants, put in commission in October, 1912, is the Fairview sewage-pumping station. The machinery is neatly arranged and kept in excellent condition. The boilers wear a "dress suit" of white enamel brick, which with metal trimmings at the corners and across the front add to the general attractiveness of the boiler room.

The building itself is of the classic style of architecture to harmonize with the surroundings, as eventually the plant will be in a residence district. Buff Roman brick walls trimmed with terra cotta are reinforced by a steel frame. Concrete slabs covered by red tile form the roof. Within, a wainscoting of white glazed tile, walls of gray face-brick, a floor paved with red tile, steel doors, electroplated railings and Fenestra steel sash lend an attractive appearance.

The plant is located at the foot of Parkview Ave., near Waterworks Park, and 234 ft. back from the harbor line. It was designed to raise domestic sewage and storm water from a 9-ft. sewer draining 3500 acres of residence property and discharge it into the Detroit River. The sewage enters a screen chamber, shown to the left of the main building in Fig. 2, and passes on to a water gallery formed between the building foundation and a division wall in the basement. This well is 137 ft. long, 40 ft. deep and 9 ft. wide. As shown in Fig. 1, the sewage flows by gravity into the suction of the pumps and through cast-iron pipes is raised 36 ft. to brick outlets discharging into the river. Hydraulically operated gate valves are placed in the discharge lines.

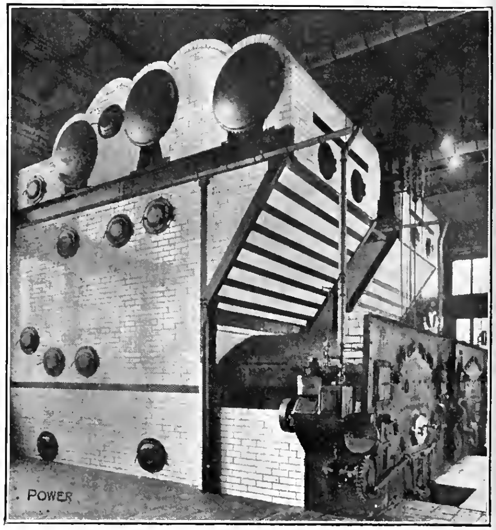

Fig. 3. Boilers in Their Dress Suits of White Tile

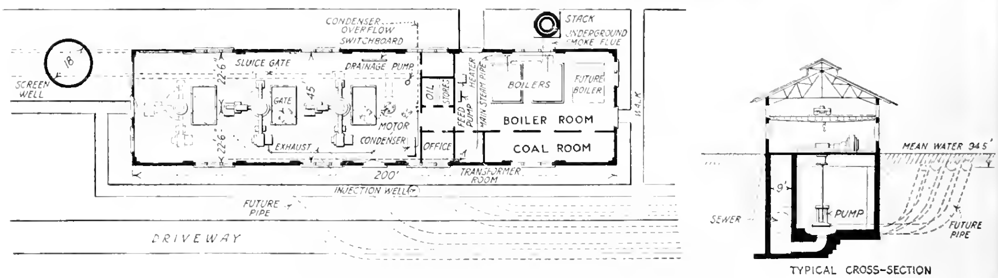

Fig. 1. Plan and Vertical Section through Station

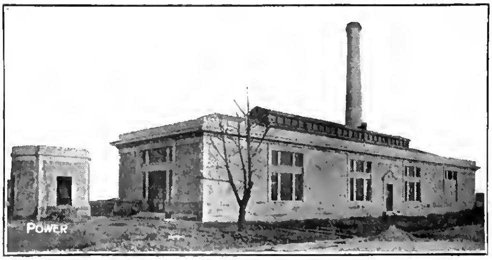

Fig. 2. Fairview Sewage-Pumping Station

The pumping equipment consists of two steam-driven units, each having a capacity of 100 cu.ft. per sec., and a motor-driven pump capable of delivering 30 cu.ft. per sec. Provision has been made in the design of the plant for the future installation of a third steam unit. The pumps are of centrifugal type set horizontally with vertical shafts and half imbedded in the concrete of the basement floor. Two are 42-in. units and the third is a 24-in. pump, the suction connections to the water gallery being 54 and 36 in. diameter, respectively. The large pumps are driven by variable-speed angle-compound engines, 18 and 36 by 36 in., which, at 150 lb. gage pressure, 18 lb. receiver pressure, a vacuum of 25 in. and a speed of 100 r.p.m., indicate 500 hp. The steam supply pipe is 6 in. diameter, the high-pressure exhaust 10 in. and the low-pressure exhaust 12 in. All piping except the loop to the throttle is underneath the floor. Connection between engine and pump is effected by a 9½-in. vertical shaft 40 ft. long. Near the center of its length a bronze and cast-iron thrust bearing carries the weight of the shaft. The bearing runs in oil and is provided with a water jacket which may be used if needed on long continuous runs. Ordinarily, the oil keeps the bearing cool.

PRINCIPAL EQUIPMENT OF FAIRVIEW SEWAGE PUMPING STATION

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
2	Engines	Angle, compound	18 and 36 by 36-in.	Drive cent. pumps	Steam press. 150 lb., vacuum 25 in., 100 r.p.m.	Wisconsin Engine Co.
2	Pumps	Centrifugal	42-in.	Main units	Capacity 100 sec.-ft. against 36 ft. head	Camden Iron Works
1	Pump	Centrifugal	24-in.	Main unit	Driven by 150 hp. Westinghouse motor, 360 r.p.m.	Camden Iron Works
1	Condenser	Barometric	16-in.	Serving engines	River injection water, vacuum, 25-in.	Camden Iron Works
1	Pump	Centrifugal	6-in. discharge	Water to condenser	Driven at 350 r.p.m. by 8x10-in. Shepherd double engine	Camden Iron Works
1	Pump	Centrifugal	2-in. discharge	Sump pump	Driven by 5-hp. Westinghouse motor, 1120 r.p.m.	Camden Iron Works
1	Crane	Traveling, hand operated	11 tons	Serves main pump room		Northern Engineering Co.
2	Boilers	Vertical water-tube	300 hp	Generate steam	150 lb. press., sat. steam, stokers	Babcock & Wilcox Co.
2	Stokers	Top feed	Projected area 18 sq.ft.	Serving boilers		Detroit Stoker Co.
1	Pump	Duplex	8x5x10-in.	Boiler feed pump		Canton-Hughes Pump Co.
1	Injector	....	2½-in.	Boiler feed		Penberthy Injector Co.
1	Heater	Open	600 hp.	Heat feed water	Use exhaust steam from pumps	Warren Webster & Co.

A barometric condenser maintains a vacuum of 25 in. on the engines. Cooling water is obtained from the river and is forced to the condenser head by a centrifugal pump driven by a double 8x10-in. vertical engine at a speed of 350 r.p.m.

The 24-in. pump is directly connected to a 150-hp., 550-volt, three-phase motor, having a speed of 360 r.p.m. Current at 6500 volts, supplied from the public lighting plant, is stepped down to the proper voltages for the motors and lamps in the station. The ordinary dry-weather flow is handled by this unit, which, due to the

Fig. 4. Angle-Compound Pumping Engines

large capacity of the water chamber, may be shut down during peak loads at the source of electric supply. The plant is operated on three shifts per day and ordinarily an hour and a half of pumping on each shift will dispose of the sewage. It is necessary, however, to keep the boilers banked and the steam units ready for service, as a heavy storm would soon supply enough surface water to tax the capacity of the station.

In the steam-generating part of the plant, two 300-hp. water-tube boilers are installed, with space for a third unit. Top-feed stokers with a projected grate area of 18 sq.ft. serve the boilers. City water is used as boiler feed, as the river water supplied to the condenser is muddy and unsuited for the purpose. Either a duplex pump or an injector handles the supply, which is raised to a temperature of 200 deg. in an open heater, taking exhaust steam from the feed and condenser pumps.

Meadowbrook run-of-mine coal is burned. It is stored in a 200-ton bunker in front of the boilers and delivered by hand to the stokers. Over the top of the bunker a ¼-ton electric hoist is suspended from an 8-in. I-beam. The track extends out of the south end of the building where coal is delivered by wagon. Eventually a dock will be built and coal will be delivered by water.

Due to the intermittent operation, satisfactory operating data are not available. In the guarantee the pumps were to have an efficiency of 70 per cent. and the engines to develop an indicated horsepower-hour on 14 lb. of saturated steam. The three units have a total capacity of 150,000,000 gal. in 24 hr. The building cost $144,000, the site $20,000 and the equipment $118,000. Per million gallons of daily capacity, the total equipment of the station cost $786.66. Smith, Hinchman & Grylls, of Detroit, were the architects and engineers for the station and Charles Meny is chief engineer of the plant.

The Rate of Radiation from bare steam pipes is approximately 3 B.t.u. per hr. for each square foot of surface exposed to a temperature difference of one degree between the steam inside the pipe and the air surrounding it. Therefore, the square feet of surface multiplied by the temperature difference (inside and outside of the pipe) multiplied by the constant 3 gives the total loss in B.t.u. per hour from a given pipe.

Interesting Accounts are to hand from Sweden regarding the results of trials lately conducted by a leading Swedish company on two sister steamers, one, the "Mjölner," being fitted with turbo-electrical engines and the other, the "Mimer," with ordinary triple-expansion engines. Each is of 2225 tons displacement and designed for a speed of 11 knots, a stipulation being that in each case the engines were to develop 900 i. hp. The most important factor, however, was with regard to the consumption of coal, which was guaranteed to be 30 per cent. less in the turbo-electrical vessel than in that fitted with the triple-expansion engines. For the trial trip, which lasted seven hours, the screws of the "Mimer" were fitted to the "Mjölner," so as to avoid possible difference arising from any difference in construction. During the trip the turbo-electrical engine developed 975 i. hp., or 75 more than the guaranteed maximum, while the average speed was 11.8 knots, as against 11 guaranteed. Good as these results are, the small consumption of coal exceeded the most sanguine expectations, amounting to 0.4 kg. per indicated horsepower, which works out at 35 per cent. less than the consumption on the sister ship, the "Mimer." Both steamers are to be employed in the coast trade and their hulls have been especially constructed for navigation on the ice.—"The Engineer."

Interesting Steam-Pipe Installation

By Hubert E. Collins

SYNOPSIS—Two old boiler plants are piped to give a common steam supply and to equalize the load on each. Details of the pipe-line construction are given.

The United Piece Dye Works, Lodi, N. J., were confronted with the problem of maintaining operation with an insufficient boiler capacity in one of the mills during the past winter and space did not permit of putting in more boilers. A larger plant, however, had some capacity to spare which would be of assistance to the other if properly connected. The two boiler plants were not far from 1500 ft. apart, and it was decided to connect the headers of the two boiler rooms with two 6-in. steam lines. The combined capacity of these two boiler rooms is around 3000 hp. Mill A has about 2000 boiler-horsepower capacity.

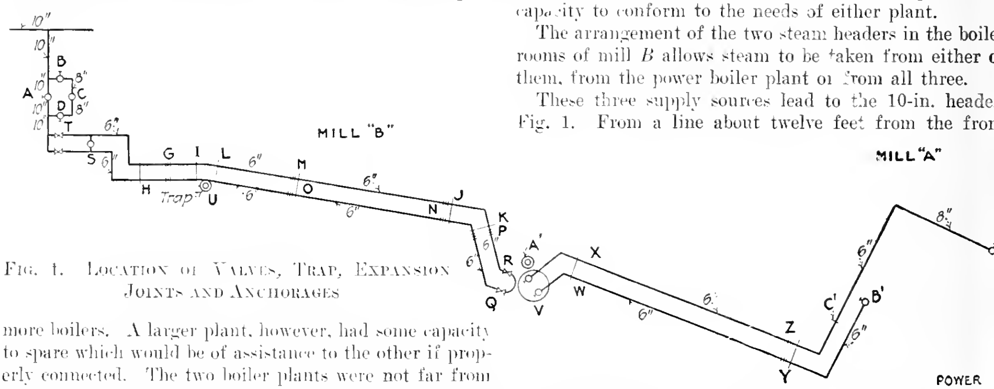

Fig. 1. Location of Valves, Trap, Expansion Joints and Anchorages

The boilers in mill B are connected to two headers, one over the front and the other over the rear of the settings. The power plant in mill B is connected to a single header, which is connected to the mill boiler headers with a 6-in. bleeder. These three headers are the sources of steam supply, connected as shown in Fig. 1.

The 6-in. header from the power plant runs into the one over the front of the boilers in the mill plant and the two headers there are connected with a 10-in. header. As this combined boiler plant carries 120 lb. pressure and the boilers at mill A 75 lb., a reducing valve is situated at the mill B end of the pipe line.

Equalizing Steam Lines

The lines connecting these two boiler plants are called equalizing steam lines, as the purpose is to equalize the capacity to conform to the needs of either plant.

The arrangement of the two steam headers in the boiler rooms of mill B allows steam to be taken from either of them, from the power boiler plant or from all three.

These three supply sources lead to the 10-in. header, Fig. 1. From a line about twelve feet from the front header, the 10-in. line branches to the outside wall of the building next to the river. This line has a 10-in. stop valve A, which is bypassed through an 8-in. reducing and regulating valve C, with stop valves B and D on each side of it. At the point where the 10-in. line comes outside the wall over the smoke breeching, two 6-in. lines are taken through two 6-in. valves. These two lines run parallel to the mill A boiler plant. From the 10-in. header they run at right angles horizontally to the wall of the power boiler plant, turn at a right angle and pass over the smoke flue on to the corner, then another right-

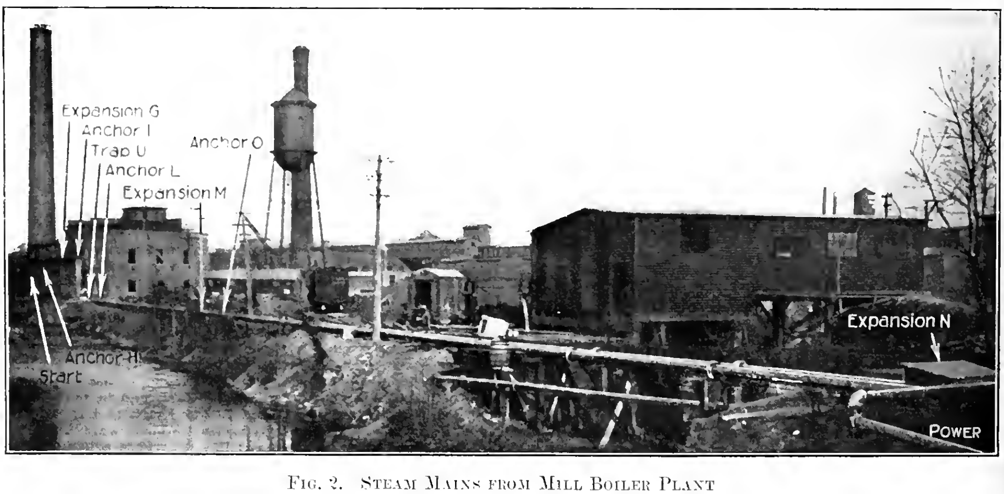

Fig. 2. Steam Mains from Mill Boiler Plant

angle turn and along to a point midway of the engine-room wall, where they drop to the level of the river bank. The lines are supported on brackets made fast to the wall of the building, and are pitched in the direction of flow with a fall of 1 in. in 15 ft.

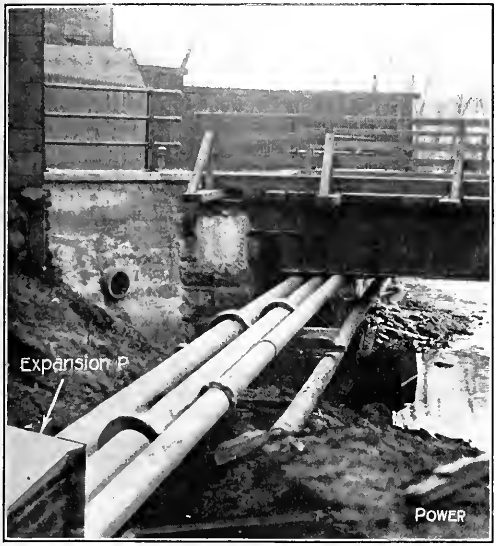

FIG. 3. TWO STEAM LINES RUNNING UNDER A BRIDGE

The pipes are anchored at the first corner of the power boiler-plant building and near the pier support outside the engine room, where they take the first drop. Midway between these anchorages *H* and *I* is placed the first slip expansion joint *G*.

After the first drop the lines run horizontally along the river bank on wood supports. At the bottom of the first fall is placed a tee on each line that acts as a drop-leg, from which the drippage is removed. The lines are pitched down along the river bank in the direction of flow, 8 in. to 15 ft., to a point beyond the railroad trestle (Fig. 2), also at the turn between the anchors *J* and *K* (Fig. 1). At the first support from the power boiler plant and the engine house is the anchor *L*. The distance from these third anchors to the fourth set on the river bank is 256 ft. A set of expansion joints *M* is placed in front of the fourth anchorage. From fourth to the fifth anchorage is 237 ft. and the expansions *N* are placed just in front of the anchorage *J*.

Fig. 2 gives a view of the steam lines as they come from mill *B* boiler plant around and along the wall of the power boiler plant to the point where they drop to the ground surface and along the river bank to the expansion *N*, at which point they turn to run under the bridge to reach the yard of mill *A*. At the extreme left of Fig. 2 can be seen the smoke flue, over which these steam lines pass. The pipes are supported on the walls above the ground by brackets. At the extreme right is the housing for the expansion joints *N*.

Ten feet beyond this the lines drop 21 in., then turn to go under a bridge. At the first support after turning from the railroad track is the anchorage *J*. Just beyond is the expansion set *P*. The lines run under the bridge with a fall of about 1 in. in 15 ft. and next to the retaining wall of the mill *A* side the drop is 21 in. At this point the lines turn at another angle and pass through this wall underground to the receiver room, where just inside the wall in the pipe tunnel are placed the valves *Q* and *R* on the horizontal runs. From these, the lines are joined in a Y and empty into a receiver, which catches all drippage from the valves *S* and *T*. It also takes care of the drippage from the vertical lines over the receiver, and which is dropped by the trap *U*, placed in the receiver pit. From the receiver the lines are taken from a Y on the top. Two 6-in. valves *V* and *W* are placed on the top of this Y and from these valves the lines extend through the roof of the receiver house and are carried over the roof of the adjacent buildings.

Fig. 3 shows the two steam lines near the point where they turn toward the bridge, looking toward the trolley bridge and mill *A* yard from the mill *B*. The first pipe is for water; the two steam lines are just back of it.

Fig. 4 shows the steam pipes passing from under the bridge through the concrete abutment in front of the receiver house. The steam lines in this view are the ones on a line with the lower side of the bridge girders. The steam pipes are also shown as they leave the receiver house to the level of the roof of the adjacent building and rest on the roof supports.

At the second roof support is placed the anchor *X* (Fig. 1). The pipes have a fall of 1 in. in 15 ft. over the roofs of the buildings and are pitched down from the point over the receiver house. Fig. 5 shows the lines on the roofs from the point over the receiver house almost to

FIG. 4. VIEW FROM THE OTHER SIDE OF THE BRIDGE

the first turn, shown in Fig. 6 at the extreme left. On the second support beyond this turn (not shown) is placed anchor *Y*, Fig. 1, and in front of it is the expansion *Z*.

On the edge of the roof at the alleyway the lines break at right angles horizontally and run over the alleyway roof. One line feeds the finishing-room side of mill *A*, going through the roof of the alleyway to the finishing-room steam main, which runs horizontally and at right angles to the equalizing lines just under the roof. Just in front of this break in the line is a drop-leg, to which is attached a trap, and next to this drop-leg is the valve

B'. The 6-in. drop-leg ends in a blank flange, from which the drip line is taken to the trap in the basement almost underneath the drop-leg. The other equalizing line supplies the dye house and runs across the roadway in front of the alley, turns at right angles horizontally for a few inches and then drops to the 8-in. dye-house main. At the second support over the alley is placed the anchor *C''* on the dye-house main only. Expansion in the finishing-room main is taken care of by the drop

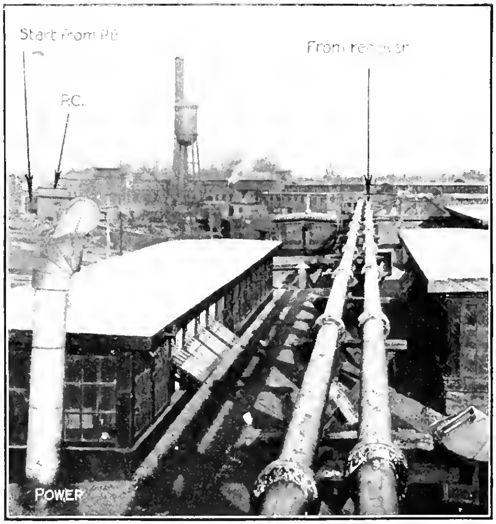

FIG. 5. PIPE LINES ON ROOF

of Fig. 1 and the other illustrations will show as few turns and bends as circumstances would allow. The exposure to the weather required care as to the drainage and the amount of pitch given seems to have been adequate.

The supports were required to carry an average of 530 lb. each when spaced 15 ft. apart. Figs. 7 and 8 show the type of the ground and roof supports, respectively.

The ground supports have a plank 10 in. by 5 ft. on the bottom to take the weight. They are bedded on stone or brick. The two side braces are buried in the earth and thus take up any lateral thrust in the direction of the pipe lines.

The roof supports are braced to take this thrust. In order to distribute the weight on the roof as much as possible, a continuous line of plank was placed under the legs of the supports.

Fig. 9 represents the type of support used on the side walls of the buildings that the lines skirted. A channel was placed at the back of the wall to distribute the load.

Fig. 10 shows how the anchorage of the pipe is made at the different points. It consists of a distance piece made of ⅝x3-in. iron, to hold the pipe in line above the wood support, and a strap of the same size of iron to hold the pipe down.

Fig. 11 shows the method of anchoring along the river bank. In addition to the clamp on the support, there is a clamp on the pipe with a rod leading from it to a plank buried some feet in front of the support.

The pipes were covered with 85 per cent. magnesia molded nonconducting material, wired on and covered with magnesia cement on the flanges and fittings. Over the covering was placed rubberoid paper wired on and over this was sewed tarred canvas.

Settling of the supports on the river bank was looked

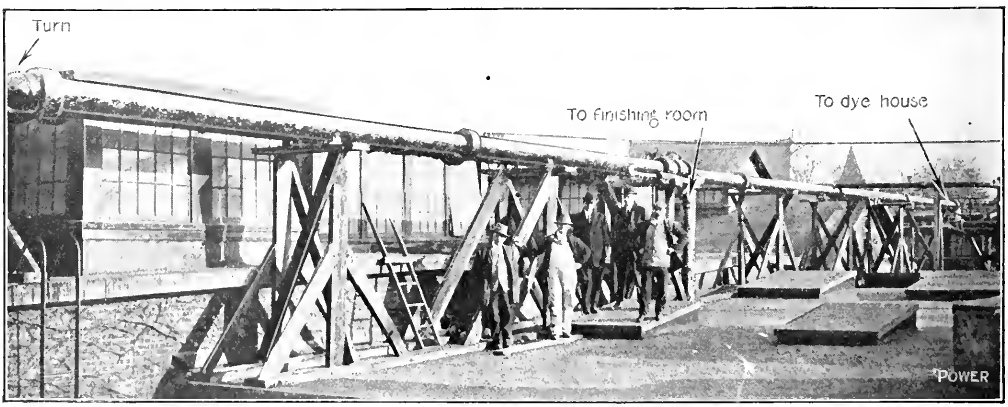

FIG. 6. NEAR VIEW OF PIPE LINES ON ROOF AND METHOD OF SUPPORTING THEM

through the roof of the alleyway. The expansion in the dye-house main beyond the anchor *C''* is taken care of at the drop to the 8-in. main, which forms a swing joint.

DETAILS OF CONSTRUCTION

The details of construction of the line and its accessories are of interest, because some of the conditions met were outside the average experience.

The installation of these lines offered many difficulties, as much of them were exposed to the weather. A study

for and taken care of by placing the loose lengths of pipe on the supports for about ten days before the roller bases were lined up. There was considerable rain during that time and therefore there was but little settling after the line was in position.

SOME PERFORMANCES

When the steam lines were put under steam pressure, there were less than ten leaks on all this piping and only three defective flanges.

While the pipes were still bare and the temperature of the atmosphere was 30 deg. F., the lines were heated and put in commission within 25 min. without water-hammer from condensation.

After the lines were covered and in commission, the losses by condensation were checked. The two dumping traps on the line were observed to take, on an average, 8 sec. for an operation. As the amount of water discharged by each operation was known, a close estimate of the amount of condensation was secured. The trap at the receiver discharges at each operation 65 lb. of water and number A' 20 lb. During a given period in December the traps were watched and it was observed that the trap U was operated five times per hour during the 24, and trap A' three times. The amount of steam flowing through the pipes was recorded by steam-flow meters.

The average amount of steam per hour for the six days of the observation was 18,990 lb.

Amount of condensation equaled:

$$65 \times 5 \times 24 = 7800$$

$$20 \times 3 \times 24 = 1440 \text{ for finishing-room side.}$$

$$1440 \text{ for dye-house side.}$$

$$\text{Total for 24 hr., } 10,680 \text{ lb.}$$

$$\frac{10,680}{24} = 445 \textit{ lb. per hr.}$$

$$\frac{445}{18,990} = 2.3 \textit{ per cent. loss by condensation}$$

The chart (Fig. 12) gives some idea of the performance of the two lines. The heavy line gives the steam pressure at the source of supply at the pressure-regulating valve in mill B. The dotted lines give the pressures on each of the two lines at a distance close to 1300 ft. from the source of supply. One point gained by these equalizing lines was that there was a more uniform pressure in mill A, as shown by this chart, whereas prior to this the daily steam variation amounted to as high as 45 lb. pressure. The drop in pressure in the 1300 ft. of pipe can also be observed. At the point of maximum drop, the amount is 15 lb., while the two 6-in. pipes are supplying steam at the rate of 30,000 lb. per hr.

When the lines were first installed a trap was placed on the drop-legs at the first drop outside the wall of the engine room. It was later observed that after the lines were warmed up there was not enough condensation collected at that point to operate the trap more than once or twice per day. The trap at this point was therefore disconnected and only the drip valve left to use when first warming up.

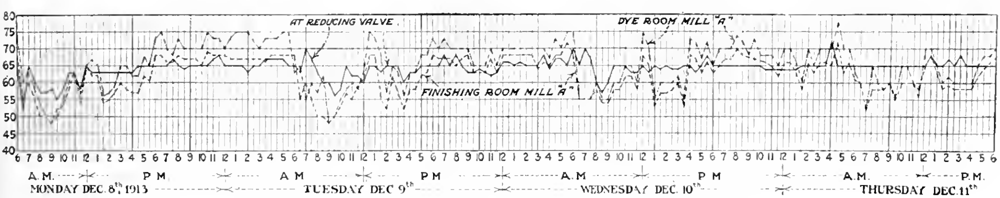

FIG. 12. CHARTS OF STEAM PRESSURE ON STEAM LINES

The Effect of Vanadium in plain carbon-steel castings is to increase the elastic limit about 30 per cent., giving a much higher proportion of available strength for the same ultimate strength.

An Effective Treatment by which the porosity of cement used in constructional work can be stopped and the free lime neutralized is said to be the painting of the surface with a solution of 8¾ lb. of zinc sulphate in a gallon of water. A reaction between the zinc sulphate and the free lime occurs as deeply as the solution penetrates, and by it the insoluble neutral salts, calcium sulphate and zinc hydroxide are precipitated into the pores. This priming coat should be given some 96 hr. to dry, the surface then being brushed and painted with two coats of a good cement paint.

Keeping Track of Plant Operation

By A. D. Williams

SYNOPSIS—Recording instruments and system of plant records employed at the Cleveland Municipal plant.

Economic conditions make it necessary to keep an accurate check upon each process of power-plant operation. The new municipal plant in Cleveland is provided with facilities for determining the heat value of coal and the analysis of coal, ashes and flue gases; instruments and meters are installed which either indicate or record changes in the operating conditions; and a few simple forms provide a complete report of operation.

The bunkers at the plant have a storage capacity of 3400 tons, and the coal cars are spotted on two tracks above it, the coal being dumped through steel-bar gratings which are shown in Fig. 1. Telpher weighing larries having a capacity of two tons each are used to transport the coal from the bunker spouts to the stoker hoppers. Each telpher operator turns in a report giving the weight of coal delivered to each boiler and the time of delivery. These weights are totalized for each watch and entered on the daily plant report.

This daily plant report is arranged to give a complete insight into station operation, there being twenty items to be filled in for each watch. Sixteen of these are obtained from the readings of meters or recording instruments, three are computed from other items and one is obtained by reference to a steam table. The equipment of meters and gages in this plant is interesting. Fig. 2 shows the engineer's office where eight different recording instruments are installed. The readings of the CO_2 recorder are checked every few days by an Orsat apparatus. One electric meter is found in the engineer's office; this is a graphic megowatt meter which totalizes the entire electrical output of the three main generating units.

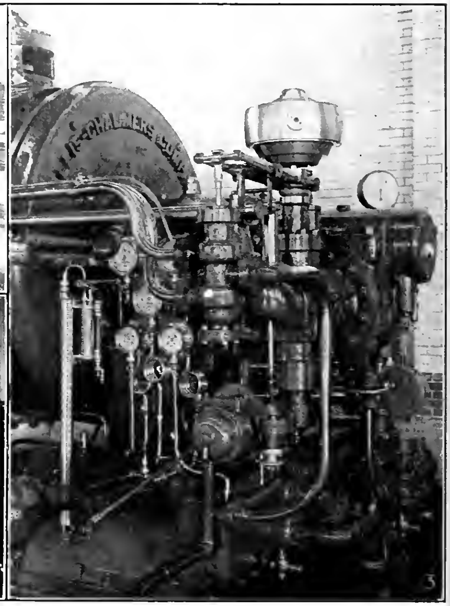

Fig. 1. Grating over Coal Bunker. Fig. 2. Office. Fig. 3. Turbine Governor and Gages

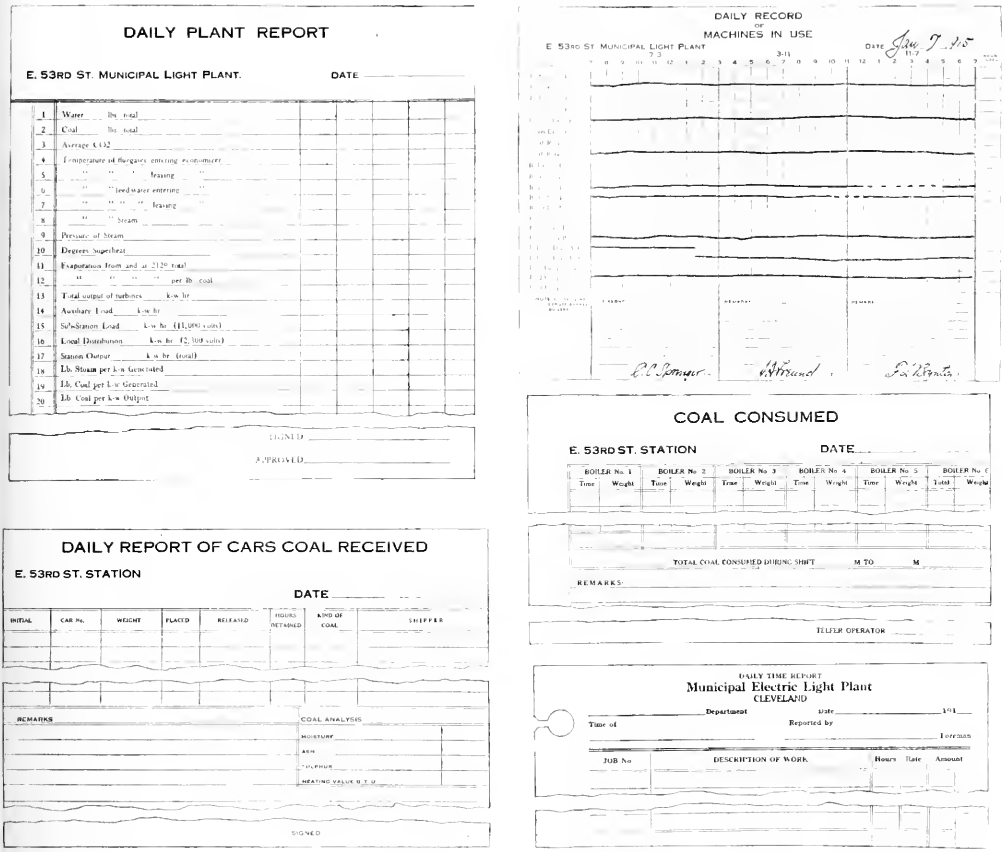
Slack coal is delivered at the plant in dump cars run on a switch over the coal bunker, and four samples for analysis are taken from each car. All the samples for each shipment are mixed and crushed, and two laboratory samples are taken—one for analysis in the laboratory, the other to be held as a check sample in case any question arises. The chemist determines the moisture, ash and sulphur content of the coal and its heat value, the last determination being made by a Parr oxygen bomb calorimeter. The price paid for the coal is based upon a specified standard of 13,000 to 13,099 B.t.u. with less than 15 per cent. ash and less than 3 per cent. sulphur. Lower heat value and higher ash and sulphur are penalized, while a premium is paid for a higher heat value. A blank form is provided upon which all shipments of coal received are reported by the chemist, together with its analysis.

The feed water for the boilers is metered or weighed by a V-notch meter having a capacity of 275,000 lb. per hour, and its temperature is recorded before it enters and after it leaves the economizers. The temperature of the flue gases is also recorded at both ends of the economizers, and the temperature of the ingoing gases is a continual check upon the combustion results obtained



FORMS FOR OPERATING RECORDS

in the boiler furnace. A further check upon boiler operation is obtained from the indicating flow meter showing the steam output and by draft gages which show the draft pressure in the combustion chamber and in the boiler blast main, while the steam temperature and pressure in the header actuate recorders installed in the engineer's office. An indicating draft gage in the induced-draft fan room shows the draft at this point in the flue.

The test of the boilers and stokers developed an interesting draft feature. In these boilers, a cross-section of which was shown in POWER of Jan. 19, the combustion chamber is extremely high, resembling the well known Delray setting. The following draft readings were obtained:

Test No	1	2	3	4	5
Per cent. of rated load	156.87	106.53	149.51	197.86	273.83
Draft, inches of water					
Furnace	—0.09	—0.06	—0.05	—0.09	—0.08
Top of first pass	+0.19	+0.16	+0.22	+0.16	+0.15
Bottom of last pass	+0.02	+0.06	+0.04	—0.07	—0.15
Upper damper	—0.10	+0.07	—0.03	—0.43	—0.05

Each auxiliary turbine for power and exciter service has a gage and tachometer similar to those for the main units
The switchboard equipment comprises the usual integrating and indicating meters

These readings show positive pressure at the top of the first pass, which is rather remarkable. At the same time the CO_2 in all the tests was over 15 per cent, and in only two did the oxygen run over 3 per cent.

Priming a Centrifugal Pump

By J. F. Jones

Centrifugal pumps, unless submerged, must be primed before they will operate. The experience of the writer with priming while in charge of an irrigation plant in the Gulf Coast regions of Texas may be interesting.

This plant lifts water from the San Jacinto River to a 300-ft. wooden flume, which discharges into a canal system watering several thousand acres of rice. The four centrifugal pumps used have rather long discharge pipes, Fig. 1. The pump shown is a 30-in. single-suction, 25,000-gal. per min. capacity pump and is rope-driven by a Greenwald compound condensing engine.

The discharge pipe is 67 ft. long, the upper end being closed by a flap-valve. For priming, a steam ejector was connected to a 2-in. hole on top of the pump casing. The ejector produced enough vacuum in the suction-pipe, pump and discharge pipe to fill the suction pipe and pump with water; then the engine would be started and brought up to speed.

This is the usual method of starting recommended by the pump builders. The length of the suction and discharge pipes caused many small air leaks, which condition was further aggravated by the difficulty of making the flap-valve seat air-tight. One night when shutting

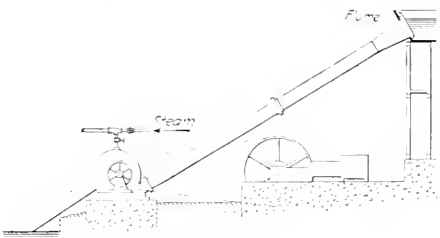

Fig. 1. Relative Locations of Pump, Engine and Flume

down there was a loud report and a stream of water came pouring down from the end of the flume. It was found that the upper end of the discharge pipe had collapsed for a distance of several feet and that the heavy cast-iron flange on its end was broken and torn loose from the flume.

The cause of the accident was plain. When the flap-valve on the end of the discharge pipe closed, the water ran down through the pump, forming a vacuum in the pipe, and the atmospheric pressure collapsed it. Just why a pipe calculated to resist an internal pressure of 150 lb. should fail under an external pressure of less than 15 lb. may not be apparent at a glance, but there was no disputing the fact. It was clearly time to make a change in the method of starting this pump.

First, the flap-valve was removed and a swinging gate was put in the flume several feet from the end of the discharge pipe which, being open to the air, could not be subject to a vacuum. Second, the ejector was taken off the top of the pump casing and connected to a 1¼-in. pipe-threaded hole drilled in the highest part of the suction elbow, Fig. 2. With this arrangement, the pump is started as follows:

First, it is necessary to have the lower end of the

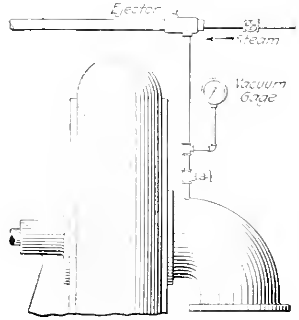

Fig. 2. How the Present Priming Ejector Is Connected

discharge pipe contain enough water to seal the discharge outlet of the pump casing. The leakage from the gate in the flume was usually ample for this purpose. Except when the water in the flume was low, it would be necessary to open the gate by hand to allow enough water to flow back into the discharge pipe.

Second, the throttle would be opened and the engine brought up to speed, as shown by the cutoff hooks beginning to trip by the action of the governor. When the ejector was started, and as the sealing water would be held in place by the revolving impeller, a vacuum was created in the suction pipe and in the pump sufficient to cause them to fill with water. When the pump "got the load," as shown by a slight decrease of speed, the throttle was opened.

As the ejector no longer had to exhaust the air from the 67 ft. of discharge pipe, the time required to start the pump was shortened, usually taking only four or five minutes for priming. A vacuum gage on the suction side of the ejector was found desirable.

Simplified Formulas—Two rules or formulas for finding the capacity of tanks in U. S. gallons and for finding the heating surfaces of boiler tubes are given below, which are easily worked out by simple multiplication, no division being necessary:

Rule—To find the capacity of a cylindrical tank in U. S. gallons, square the diameter in inches, multiply by the length or height in inches and multiply the product by the constant 0.0034.

Formula, $D^2 \times H \times 0.0034 = \text{capacity}$

Proof, $0.7854 \div 231 = 0.0034$ the constant

Rule—To find the heating surface of boiler tubes, multiply the diameter of the tubes in inches by their length in feet and that product by the constant 0.2618.

Formula, $D \times L \times 0.2618 = \text{heating surface}$

Proof, 3.1416 cir $\div$ 12 in. $=$ 0.2618

The Eighth Annual Report of the District Police of the State of Massachusetts, for the year ending Oct. 31, 1914, regarding the examination and licensing of stationary engineers, contains the following: The number of applicants examined for licenses as engineers or firemen was 6490, of which 2955 were granted licenses and 3535 were rejected; for operators of hoisting machinery 147 were examined, 125 passed and 22 were rejected; grand total of applications, 6637; number licenses, 3080; rejected, 3557

Just for Fun

[More "original ideas" sent in by readers in response to our request in the Jan. 19 issue for stories of amusing stupidity.—EDITOR.]

In a certain power plant which the writer visits occasionally, there is a recording boiler feed-water meter. Some six months ago the nozzle became so stopped up with the sediment in the feed water that the records were worthless. Nevertheless, the engineer religiously changes the charts every day and reads the integrating dial, in spite of the fact that he knows the nozzle is plugged up.—*Loren L. Hebberd, Milwaukee, Wis.*

The following piece of rank stupidity is reported "just for fun." We purchased a forced-draft system for a boiler, which was a miserable failure. When the writer told the representative of the company the facts of the case he hauled out his data sheet and started to take down the data which were given him. He finally asked what kind of coal we burned, and when told it was pea coal he immediately said: "That's the reason it would not work. This blower is so delicately adjusted and carefully designed for buckwheat coal that it could not be expected to work on pea coal."—*T. Newbury, Monroe, N. Y.*

A 10-kw. dynamo was used to light the mill, and short-circuits were common. One night a short came on that nearly threw the belt. I looked the main mill over, but failed to find it. In a short time it came on again, and I finally asked some of the men if they had done anything to the wiring. One of them said he had put an extension on a certain light, but had insulated it so that he knew it was all right.

He had found a couple of pieces of bare No. 12 wire, also a long piece of rubber tube. He twisted the wires together, put them in the rubber tube, attached the socket to one end, and hooked the other ends on the circuit wires. He said he didn't see how there could be trouble, when they were covered with the rubber tube.—*V. C. Wood, Copenhagen, N. Y.*

"Last week," said a friend of mine, "I was called to inspect an engine installation that our firm had sold. Complaint had been made that neither the pump nor the injector that came with the outfit would work. We had sold engines and boilers equipped with pumps and injectors of this particular kind for many years and never received any complaints about them. I was rather curious and somewhat perplexed as to what the trouble could be.

"When I arrived at the plant and the steam pressure was brought up to normal, I attached one end of a hose to the suction side of the feed pump and put the other into a pail of water. The first stroke of the pump emptied the pail. Then, with a barrel of water I tested out the pump and injector and both worked perfectly. There was only one conclusion to arrive at, and to the accompaniment of a few choice remarks the cover over the well used as a source of water-supply was removed and revealed the trouble—the well was dry.

"The manager was told that the cost of the lesson that neither pump nor injector could create water would be an even $50."—*C. E. Anderson, Chicago, Ill.*

Mixed-Pressure Turbine and Condenser Outfit

The Columbia Plate Glass Co., Blairsville, Penn., has recognized that the utilization of exhaust steam for the generation of power would effect a desirable saving in coal costs and help the production by giving better fa-

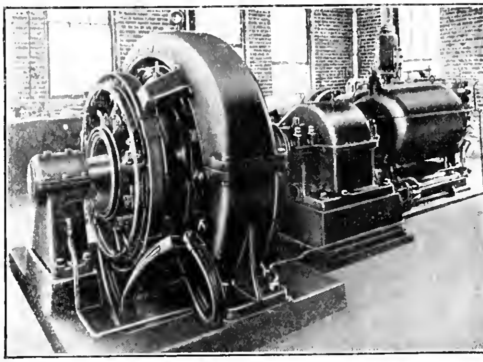

FIG. 1. THE MIXED-PRESSURE TURBINE UNIT

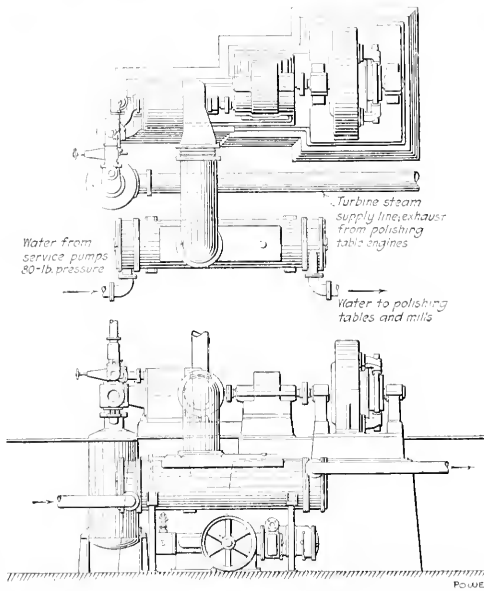

FIG. 2. ARRANGEMENT OF THE TURBINE AND CONDENSER

cilities for output. Accordingly, a 300-kw. mixed-pressure Kerr steam turbine was purchased, Fig. 1. It is a 450-hp. capacity, seven-stage, impulse-type unit connected through reduction gears to a 600-r.p.m., direct-current generator. The exhaust steam from several Corliss engines is piped to the turbine and ordinarily enough steam is obtained from this source, at a pressure of about one pound above atmosphere, to generate all of the electricity required in the plant. Whenever the Corliss engines are shut down, live steam is admitted automatically through expanding nozzles.

The turbine exhausts into a surface condenser of the water-works type—that is, it is installed in the water-supply line to the mills, Fig. 2, and this water produces the cooling effect necessary for a vacuum of 28 in. on its way to the grinding tables. This feature of the installation eliminates any pumping of water for the condenser and makes use of the water which is being pumped. The condenser is designed for a water pressure of 80 lb., the pressure carried in the mill lines.

The turbine is placed beside two engine-driven generator sets which have operated continuously on high-pressure steam for years. It is estimated that these machines used about $20 worth of coal per day, so that the saving effected by the exhaust turbine is about $6000 per year, or enough to cover the cost of the machine in a period of two years. The turbine operates continuously twenty-four hours a day, six days a week.

Oil under 6 lb. pressure is pumped to the bearing, and then flows by gravity to an oil reservoir in the bedplate; there it is strained and cooled. A small steam turbine-driven centrifugal pump is bolted on this bedplate and used for starting the oiling system before the turbine is started.

Strength of Diagonal Joints

By J. E. Terman

Nearly all authorities on boiler construction have advocated the use of diagonal seams for boiler patches of small size. Hence, the common use of the horseshoe and diamond shapes, where bags or similar defects in the vicinity of girth seams have made the removal of a part of the shell plate necessary. The writer has long been an advocate of such a method of repair and does not now wish to be understood as having changed.

However, analyzing diagonal boiler joints in the light of what is known of the strength of riveted joints, it appears possible that there may be an error in assuming that such angular joints, unless occupying a position of angularity of 45 deg. or more with a line parallel to the axis of the boiler, are superior in strength to joints of the same design placed on lines parallel to the axis of the boiler.

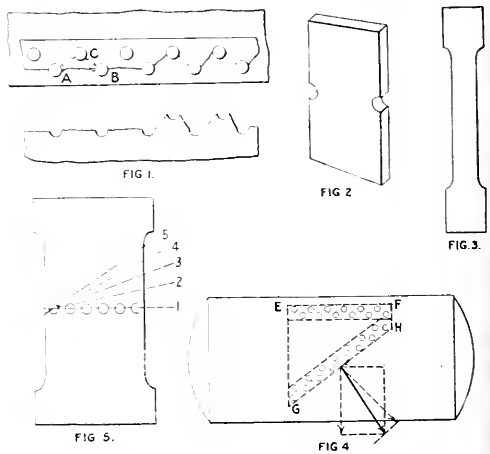
It was determined by experiments on riveted joints made many years ago, that in order to insure the breaking of the net section of a double-riveted joint as illustrated in Fig. 1, the combined net section of the metal from *A* to *C* and *C* to *B* would have to be about 30 to 35 per cent. greater than from *A* to *B*. With less metal on the diagonals than indicated, the break would be liable to occur, as illustrated on the right-hand side of Fig. 1, at the last space between rivets.

There are probably two reasons for the diminution of strength in the angular section, the first being that the material is not subjected to true tensile stress, but is partly in shear and is weaker to resist a stress of this character; the second reason is, the material can draw down more readily in the inclined sections than in the longitudinal. The latter reason is based on the effect noted in testing materials, where, if a sample of plate is tested in the shape which was formerly used by the U. S. Government and illustrated in Fig. 2, the tested tensile strength would be about 10,000 lb. higher than if tested in the form shown in Fig. 3, which is the standard, because the area of metal at the time of failure is greater than would be the case with the same-sized test specimen arranged in the form illustrated in Fig. 3.

This increase of area is due to the reinforcing effect of the additional metal (Fig. 2) close to the ruptured section, the radii of the semicircles on the side of the test specimen being only one-half inch.

Rivet holes in a plate produce the same effect on the apparent strength of the net section of metal between the holes as is produced by the semicircles in Fig. 2, and this effect is maximum when the line of holes is at right angles to the direction of applied stress and diminishes as the angle between the line of holes and the direction of applied stress decreases.

It is, of course, true, as can be demonstrated by calculation, that the stresses in a cylinder due to internal pressure and at right angles to the direction of an angular joint such as *GH*, Fig. 4, is less per unit length of joint than if the joint occupied a position parallel with the axis of the cylinder, as *EF*. However, the girth-wise stress is the same in all parts of a cylinder, and unless the angle between *EF* and *GH* is such that the net sec-



Proposed Tests for Diagonal Seams

tion of metal from *G* to *H* is 30 per cent. or more in excess of the net section of metal from *E* to *F*, then failure along *GH* may be expected, if the test results for the strength of angular net sections in riveted joints hold good in such a case.

It appears that no tests have been made to determine the effect on its strength of varying the angle of a joint with respect to the direction of the applied stress. However, it may be inferred from the behavior of the angular sections between rivet holes in tests made on riveted joints located at right angles to the applied stress, that if a series of test specimens were prepared as illustrated in Fig. 5, the rivet holes being drilled the same distance apart for each specimen, but the line of holes occupying a different angle on each specimen, as No. 1, No. 2, No. 3, etc., indicated in Fig. 5, the breaking strength of the different specimens would probably not vary greatly. If such tests were conducted using a sufficiently wide range of angles, they would demonstrate in a measure if the angularity of a joint as commonly used in making repairs is a real factor in determining its strength. It might be argued that in such a test the actual conditions with respect to the stresses applied to a joint on a cylinder subjected to internal pressure would not be reproduced, because in the latter case there would be longitudinal stresses produced by the pressure acting on the heads of the cylinder. However, by including such longitudinal stresses the joint could hardly be expected to show greater strength than when considered without taking them into account. Also, in the horizontal-tubular type of boiler, it is possible that the longitudinal stresses in the shell along the bottom of the boiler are a negligible quantity. After all is said and done in the matter of estimating the strength of short boiler seams as used for patches, we cannot hope to have come very close to the true facts in the case, because the distribution of the stresses in the shell or patch, due to difference in the fitting of the patch and fit of rivets in the holes, would be likely to materially change the results in every case.

The intent of this article, as stated at the beginning, is not to discourage the use of diagonal boiler joints for patches, but to show that by the usual methods of calculating the strength of such joints there is a possibility that some of the most important factors entering the problem have been neglected. It is also probable that considerable changes in the angularity of such joints may produce relatively slight changes in their strength.

The determination of the facts, as regards the effect on the strength of a test specimen when pierced by rows of rivet holes equally spaced, but occupying various angles with respect to the line of direction of stress, as illustrated in Fig. 5, would be an experiment easily performed by anyone having the facilities to make tensile tests on large specimens, and the results would be of great interest to all engaged in boiler design and construction.

Firebrick for Boiler Furnaces

By A. D. Williams

Modern large combustion chambers with high boiler settings result in much higher furnace temperatures than are reached in those settings where the cold tubes are close to the coal bed. These high temperatures mean that the materials for furnace construction must have a higher refractory resistance to meet the demands of the service. The grades of firebrick which proved everything to be desired with the old-style setting may not be at all satisfactory with furnaces of large volume. The chemical composition of a brick and its fusion temperature are not reliable indications of its refractoriness in service, for structural differences have an effect upon wearing qualities.

Gilbert Rigg* gave the following properties to be possessed by a product which is to be used as a refractory:

1. Absolute infusibility at the highest working temperatures.

2. Complete absence of deformation and shrinking under working conditions.

3. Mechanical strength.

4. Complete resistance to the penetration of vapors, slags, etc.

5. A chemical composition fitted to withstand as completely as possible the corrosive action of the substances to which the bricks are exposed.

6. Equality and fixity of form and dimensions.

*See "Metallurgical and Chemical Engineer" for May, 1910.

The writer would add two more properties as being desirable, although some might, perhaps, consider them covered by the properties specified by Mr. Rigg. They are:

7. Resistance to erosion.

8. The ability to withstand sudden temperature changes without frittering or spalling off.

Technological paper No. 10 of the Bureau of Standards gives the melting points of various bricks as follows:

Kind of Brick	Melting Point, Degrees C	Melting Point, Degrees F	Chemical Nature
Fireclay	1555-1725	2863-3169	Neutral or acid
Bauxite	1565-1785	2881-3277	Basic or neutral
Silica	1700-1705	3092-3101	Acid
Chromite	2050	3754	Neutral
Magnesia	2165	3993	Basic

Iron, silica, alumina, lime and sulphur are the clinker-forming elements of coal. The degree of fusibility of the clinker varies directly as the percentages of sulphur, iron and lime and inversely as the percentages of silica and alumina.* The tendency of the iron to combine with silica in the coal and ash and form a slag is well known, and a cinder of this kind will have a strong affinity for the silica in the brickwork. This is one of the reasons that silica and fireclay brick have a strong tendency to disintegrate at high temperatures along the side of the furnace. Cinder in cooler furnaces sticks to the brickwork, which is often damaged in the attempts made to bar the clinker loose. With certain kinds of cinder it is possible to feed a small quantity of limestone and melt a pasty slag free from the side walls. Fluorspar has a similar effect upon some cinder. Both of these remedies should be used with discretion and care to avoid fluxing the cinder to such an extent that it will flow down on the grate bars and chill there, in which case it will be more troublesome than in its original consistency.

There is no reason why silica brick should not be used above the cinder line, for the upper parts of the walls and for coking arches, where they are exposed to the action of the flame only. Silica brick are used in this manner in basic openhearth furnaces and have proved durable.

Bauxite brick have been tried to some extent for the side walls of the firebox. These brick cost from two to three times as much as silica or high-grade fireclay brick. They are very hard and tough, the cinder does not stick to them and they last considerably longer than silica brick where exposed to the action of the slag. They have one serious disadvantage—a tendency to spall or fritter off if suddenly chilled. In a firebox this is often troublesome. The barring doors for the fires are generally located close to the side walls, and whenever these doors are opened a blast of cold air will be drawn in along the walls unless the draft can be so well balanced that the furnace is slightly above or at the same pressure as the atmosphere. When the furnace is below the atmospheric pressure this chilling draft results in rapid spalling close to the door and it may be necessary to shut the boiler down to patch this portion of the lining long before the rest of the fire requires repairs. Bauxite brick, even with this disadvantage, have proven quite durable, lasting from three to eight times as long as the cheaper brick. Although bauxite is extremely refractory, it must be almost completely calcined, otherwise it will shrink excessively at furnace temperatures. These brick must be burned in an oxidizing atmosphere, otherwise the iron compounds in the

*That sulphur causes clinkering is not generally agreed. The belief that it has no appreciable influence on clinkering is on the increase.—EDITOR.

bauxite will be reduced and the brick will have a low heat resistance. Bauxite brick are frequently considered as basic, though in many ways they partake of a neutral character. Bauxite is mined extensively as an ore of aluminum. The average composition of that from Georgia is:

Silica (SiO_2)	3.00 per cent.
Iron peroxide (Fe_2O_3)	1.50 per cent.
Alumina (Al_2O_3)	58.67 per cent.
Water (H_2O)	32.33 per cent.
Titanium (TiO_2)	4.50 per cent.

Another material used in making refractories which may possess some possibilities of assisting in building durable fireboxes is chrome iron ore or chromite. These brick cost more than twice as much as bauxite brick, but are neutral in character. This material is infusible and it is difficult to sinter it thoroughly, and unless thoroughly sintered it does not stand erosion.

TYPICAL ANALYSIS OF CHROMITE

Sesquioxide of chromium (Cr_2O_3)	35-50 per cent.
Alumina (Al_2O_3)	16-28 per cent.
Iron peroxide (Fe_2O_3)	17 per cent.
Silica (SiO_2)	4- 8 per cent.
Magnesia (MgO)	10-17 per cent.
Lime (CaO)	1- 2 per cent.

Chrome brick are well adapted to resist extremely high temperatures, though chrome iron ore is variable in composition.

Changing the Service of Direct-Current Machines

By Gordon Fox

SYNOPSIS—Directions for changing over a motor into a generator, and vice versa; also a discussion of the relative characteristics when operated under these conditions.

Occasions often arise making it desirable to utilize a direct-current motor as a generator, or *vice versa*. Most direct-current motors and generators are very much alike; the armatures and commutators are identical, the brushes are the same except as to setting, and the fields are similar. That the machines are interchangeable is shown by the fact that if two direct-current generators, *A* and *B*, are operated in parallel (driven from separate sources) and the engine driving *A* be shut down, its generator will run as a motor and draw current from generator *B*.

A motor is, in reality, a "counter electromotive-force generator." The armature rotating within the field poles generates a voltage less than the impressed voltage by an amount sufficient to allow the load current to flow. As the load increases the motor speed decreases, the counter electromotive force decreases and the current increases. A 230-volt compound-wound motor may have a counter electromotive force of perhaps 225 volts at no load and 215 volts at full load, the decrease being due partly to the drop in speed. Consider that the no-load speed of this motor is 900 r.p.m. and its full-load speed 850 r.p.m. If, instead of driving a mechanical load, the machine were driven at a speed of about 950 r.p.m. it would act as a generator, tending to generate more than 230 volts and pumping current out into the line. The armature IR drop must be subtracted from the line voltage to obtain the counter electromotive force of a motor but must be added to the line voltage to determine the generated electromotive force of a generator. Therefore, as a generator a machine must run faster than as a motor to operate at the same line voltage.

As a generator it is further desirable to have a little leeway for the use of the field rheostat. This necessitates a greater increase in speed to compensate for the slightly weakened field. Moreover, generator voltages are usually higher than motor voltages upon the same system because of the line drop. In general it may be stated that a motor must be driven about 10 per cent. above its speed rating in order to deliver rated voltage as a generator. Conversely, a generator used as a motor upon rated voltage will rotate about 10 per cent. below the speed indicated on its name-plate. These figures are at best only approximate, due to the wide range of characteristics of different designs.

In connecting a compound-wound motor for use as a generator the only change ordinarily required is the reversal of the series field connections. If this is not done the series field will buck the shunt field and the voltage regulation will be very poor. If the direction of rotation as a motor be unchanged, the machine will build up as a generator. If the rotation as a generator be opposite to that as a motor, then it becomes necessary to reverse the armature terminals in order to enable the generator to build up. If this is not done, the voltage generated in the armature through the action of the residual magnetism will cause the field coils to buck the residual effect rather than to aid it.

The external connections of a generator differ from those of a motor, in that the generator requires no starting resistance in series with the armature, but is provided with a rheostat in the shunt field circuit.

If a shunt motor be used as a generator it will not deliver a very satisfactory voltage. The purpose of the compound winding of a generator is to maintain the voltage or to cause it to increase under load. A shunt machine will drop in voltage from 5 to 15 per cent., under load, depending upon the design. The voltage can, of course, be regulated by manual control of the field rheostat. A compound-wound motor should be selected if possible where automatic voltage regulation is desirable. Standard motors are built for 20 per cent. to 40 per cent. compounding effect; that is, the series ampere-turns at full load are 20 to 40 per cent. of the shunt ampere-turns at rated voltage. The majority of over-compounded generators are designed for a voltage increase of about 10 per cent. under full load. This requires perhaps 20 per cent. series ampere-turns at full load, since generators are ordinarily operated above the knee of the saturation curve where the series ampere-turns are proportionately less effective. Therefore, a motor having 20 per cent. compounding is usually well adapted to run as a motor.

Since it is desirable to have some rheostat leeway for controlling the voltage, the shunt field will usually be worked at a lower density as a generator than as a motor, the deficiency in magnetic strength being compensated by increased speed. A low density at no load means that the compounding ampere-turns have greater effect. It will usually be found that a compound-wound motor adapted for generator service has an excess of compounding. This is a good fault inasmuch as it is an easy matter to shunt the series winding with german silver resistance and thus adjust its value as desired.

The full-load neutral, or best running, brush position for a motor is at a point shifted from the no-load neutral in a direction against that of rotation. In a generator the neutral shifts with the direction of rotation as the load is imposed. Consequently, if a machine be operated first as a motor and then as a generator, the rotation being unchanged, it is necessary to shift the brushes a considerable distance in a direction with the rotation. On the other hand, if the rotation be reversed, the original motor shift against the direction of rotation now becomes a generator shift with the rotation, and further change will likely be unnecessary. However, if, due to increased speed, the machine operates as a generator upon a weaker field than it had been running as a motor, the armature reactions will have an increased effect and a greater shift may be required.

An interpole motor is well adapted for use as a generator. If a compound motor is not available the interpole motor is its best substitute, since the action of the interpoles can be utilized to some extent in securing the voltage regulation desired. The interpoles of a motor have the same polarity as the main poles preceding them in a direction against the rotation. The interpoles of a generator have the opposite relation, being of the same polarity as the main poles following, in a direction with the rotation. When an interpole motor is changed over into a generator the relative polarity of the armature and the interpole must be reversed. One armature terminal is usually connected permanently to one interpole terminal. In making the change it is necessary to reverse this connection, using the other interpole terminal and the same armature terminal.

One cause of the dropping off in voltage of a shunt generator under load lies in the armature reaction. Since the interpole neutralizes armature reaction, it tends to thus better the voltage regulation. The regulation of an interpole generator can be further improved by giving the brushes a slight shift off neutral in a direction against the rotation. This procedure is in a way similar to shifting the series winding of the interpole over to the following main pole. The magnetizing effect of the interpole assists the main poles, increases their magnetism under load and, therefore, tends to maintain the load voltage and to improve the regulation.

It is obvious that the procedure for changing a generator into a motor is the exact reverse of that for changing a motor into a generator.

When the Gas Engine Will Not Start

By E. N. Percy

SYNOPSIS—Directions for systematically following up the trouble when an engine refuses to start; and, after having located the trouble, suggestions for remedying it.

When a gas engine refuses to start, there is usually one of two things wrong—the mixture or the ignition. It is best to test out the ignition first because it is easy to determine definitely if the trouble is from this source. First, test the battery by short-circuiting it with a piece of wire and note if a fat spark is obtained when the wire is snapped across the terminals. All engines with electric ignition have a timing commutator, regardless of the system used. Therefore, turn over the engine to a firing point, and if high-tension ignition is used the buzzer on the coil should sound. If it does not, it is probably out of adjustment or the spark-plug points need going over with a fine file or piece of emery paper. The adjusting screw should then be turned carefully back and forth until the buzzer begins to sound.

After the buzzer is working, place a screw-driver on the cylinder head and tip it until within about $\frac{1}{16}$ in. of the spark plug. If no spark jumps across from the top of the plug to the screw-driver, the indications are that either the plug is foul and the points short-circuited, the connection is broken, or the high-tension cables are leaking sparks onto the frame somewhere. The farther the spark jumps the stronger the battery.

One of the most baffling troubles is a weak battery. This may comply with the usual tests without giving indications of troubles, yet the spark will not be hot enough to ignite the mixture in a cold engine, although it may have been working well when the engine was shut down. For this reason, it is wise to use batteries only for starting, after which a generator or a magneto should be switched on.

Engines having make-and-break ignition should be tested in the same way, so far as the timer is concerned, but there is no buzzer. Instead, a screw-driver or piece of wire is snapped across the wire connection on the make-and-break plug, the other end of the wire being in contact with the engine cylinder. If a fat spark is had in this way, the igniter may be removed and snapped by hand, to see if it sparks. The wire should then be connected, and the ground side of the igniter should touch the iron of the cylinder. Care should be taken that the mixture in the cylinder is not ignited, or the operator may get burned. The make-and-break plug may now be returned to the cylinder and the adjustment examined. In this connection it should be remembered that the spark is made when the electrodes separate—not when they come together—and the quicker they separate, the better will be the spark. For this reason, slow-speed engines must have a snap-off mechanism for a make-and-break spark, while a high-speed engine can get a good spark from an igniter connected directly to a cam rod, without a snap-off mechanism.

Having determined that the trouble is not with the ignition, or having fixed such trouble as may exist, and still not being able to start the engine, it becomes necessary to investigate the mixture. If the engine is operating on gas of any kind, there is an excellent method of getting the right mixture into the cylinder. Let the air and gas be set as nearly correct as possible under the circumstances; then draw in a charge by turning over the engine by hand, and compress it slightly. Open a cylinder pet-cock slightly and apply a match. If the flame is smoky, there is too much gas in the mixture; if it is hard to light, there is not enough gas, particularly if the flame is colorless. If the flame is a clear blue or silver, the mixture is about right and should ignite. In fact, it may ignite by striking back into the cylinder through the pet-cock, but no harm will be done, except to move the piston slightly. If there is much compression the mixture may blow out of the pet-cock so hard that it will be difficult to light it.

With carbureting engines, this same plan is successful, but is attended with risk of fire, because of the tendency of liquid fuels to collect around the engine, their vapors greatly increasing the risk. In this type of engine trouble may be expected in starting in cold weather. To make certain of starting easily, fill the jackets with boiling water, if possible, and prime each cylinder with one squirt of gasoline, and fill the inlet pipes with air saturated with gasoline. If the engine still refuses to start, take out the spark plugs and drop a lighted match into the cylinder, first making sure that there is nothing in the vicinity to take fire. The cold gasoline in the cylinder will explode and rush out of the spark-plug hole with a roar, and the operator must be careful not to get too close. This is practically the only remedy for a flooded cylinder, except to laboriously turn over the engine until it is dried out.

Many of the cheaper engines have no carburetors, but merely a valve which lets the fuel into the inlet pipe, and some rough device for controlling the air. They frequently give trouble in starting, no matter how familiar the operator becomes with them. The best way to start such an engine is to have the fuel shut off, prime the cylinder, and squirt fuel over the inside of the inlet pipe. The engine will then start, and run for several revolutions, during which the fuel valve may be opened until the operation is regular. The reason for this is that this type of fuel valve usually floods the engine when starting, and a flooded cylinder is decidedly troublesome.

Unless an engine is badly flooded, it will start on most any kind of a mixture, but will not run long, nor will it develop much power unless the mixture is just right. Find out first where the adjustments are, then start the engine by priming, and after it is going, feed it with the squirt can with one hand and adjust the carburetor with the other, until it is fairly under way. Then, when under load, make the adjustments that seem to do the work best. If black smoke is given off, the mixture is too rich. This should not be confused with blue smoke which comes only from an excess of lubricating oil. There is usually a small excess of oil in the crank case when the engine is first started, and for this reason the supply of lubricant should not be cut down unless the smoke continues for some time. When the engine misses, and "coughs" back into the carburetor or inlet pipes, the mixture is too lean, and more fuel is required. The greatest economy is secured by using the thinnest mixture that will carry the load reliably. Mixtures rich enough to smoke are weak, not strong. The strongest mixture has been found to be that which contains a little more air than necessary to properly burn the fuel.

There are some two-stroke-cycle engines, mostly small, that are perfect mules of obstinacy when being started. The reason is that after the fuel is carbureted it does not go into the cylinder at high velocity, as in a four-stroke-cycle type, but is first detained in a cold crank case, where the fuel condenses, and air or a very lean mixture goes to the cylinder. Also, many of these engines have gauze in the inlet port to prevent backfiring into the crank case. This gauze, when cold, condenses much of the fuel, and it becomes necessary to prime the cylinders in starting, but it is equally important to refrain from flooding them. A good method is to draw off all the lubricating oil from the crank case and replace it with oil which has been heated until it smokes. This will usually heat the engine enough to start easily, as the cylinder does not have to be particularly hot if the crank case is hot enough to keep it from condensing the fuel.

In starting a cold engine, it pays to take the trouble to heat it up by one of the methods suggested, for after such treatment it starts so easily, provided the ignition is all right, that the uselessness of tugging and straining is apparent. The writer has seen engines of 40 or 50 hp. started by pouring a tea-kettle of hot water into the jacket of one cylinder. Those that give the most trouble are of the cheap factory type, without adequate carburetors or reliable ignition, yet they are used extensively in contracting work, agricultural machinery, and general small power work. The gas or gasoline engine is just as reliable as the steam engine, provided it is made equally well and receives equal attention and study.

There are now many devices and systems for making these engines self-starting. These systems, as a rule, are reliable, but a man must know his engine just the same, and be able to know that it is in condition to start, before he risks using up the power stored by the self-starter for that purpose.

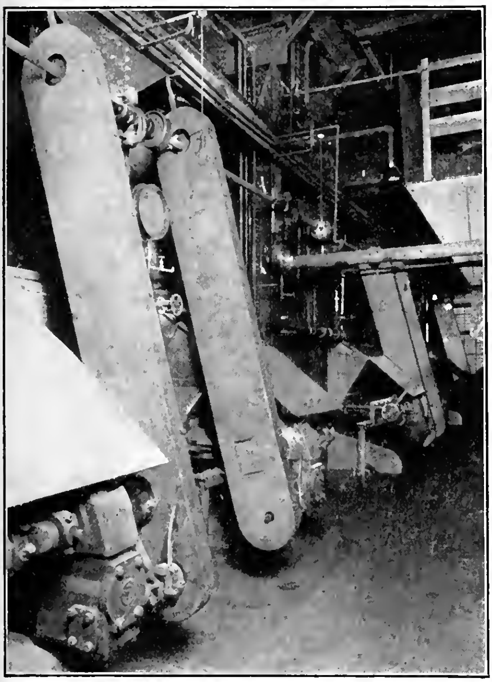
Comparative Tests of Stoker- and Hand-Fired Boilers

By H. S. Knowlton

Through the courtesy of the engineering department of the Norton Co., Worcester, Mass., the following test data are given, showing the comparative efficiency of hand and stoker firing in the boiler plant of this concern at Barbers Crossing. This plant was recently equipped with self-dumping, underfeed stokers, which are comparatively new in the field of power-plant equipment. The figures given are among the first to be published upon their operation. Their most striking features are: In place of stationary dead plates are moving, air-supplying grates, carried by the reciprocating sides of the retorts; moving overfeed grates extending across the entire width of the stoker, and pusher noses with ash-supporting plates for continuously dumping the refuse. This is the only type of underfeed stoker having live grate surfaces and the continuous automatic dumping of refuse.

As shown in the illustration, the Norton installation consists of a set of three-retort units per boiler, the steam-generating equipment of the plant having five 300-hp. vertical fire-tube boilers. The stokers are chain-driven from a fan shaft carried along the boiler fronts, the fan being located in the engine room to enable it to be under the eye of the engineer, besides furnishing a means of exhausting air from the engine room and aiding in the ventilation. The fan is 5 ft. 6 in. diameter, with three-quarter housing, and is driven by a 7x6-in. vertical inclosed engine, the maximum speed being 150 r.p.m. The fan discharge to the stoker air chambers is through a concrete duct in the floor with a maximum cross-sectional area of 1720 sq.in., each stoker being supplied through an 18x18-in. branch duct, while the cross-section of the main duct is diminished accordingly at each boiler. The fan speed is automatically controlled by the boiler pressure.

The boilers are fed with water by a centrifugal pump with a capacity of 90 gal. per minute, the pump being direct-connected to a 20-hp., 440-volt induction motor running 3600 r.p.m. This is about the smallest size of



View of Boiler Room of Norton Co.'s Plant

centrifugal feed pump capable of being operated at good efficiency, in view of the limitations of water passages. It is estimated that the steam consumption of the boiler-feed equipment of the plant has been cut in half by the installation of the motor-driven pump.

A fuel bed about 2 ft. thick is maintained on the grates, and above each set of retorts is a hopper containing 750 lb. of coal.

At a coal cost of about \$4 per ton, the equipment of the five boilers of the plant will pay for itself in about two years.

In analyzing the tests the Norton company points out that they represent an average taken from daily practice. While the hand firing is not all it should have been, the stoker eliminates all chance of carelessness likely to arise in a plant of moderate capacity not equipped with recording instruments maintaining a constant check on the fireman. The company has had but one stoker in operation continuously for about a year, and in that time has had no expense for repairs. The design of the working parts seems well balanced, as no weakness has so far developed. The capacity of the stokers has not as yet had to be tested, but the company is of the opinion that, if necessary,

TEST DATA

Boiler No.	1	3
Type of firing	Stoker	Hand
Date	May 14, 1914	June 16, 1914
Time	7 a.m. - 6 p.m.	7 a.m. - 6 p.m.
Duration	10 hr.	10 hr.
Average temperature feed water	179 deg.	157 deg.
Average gage pressure	142 lb.	142 lb.
Coal burned	8690 lb.	8470 lb.
Ash	720 lb.	790 lb.
Per cent. ash by weight	8	9
Water fed	97,200 lb.	80,774 lb.

it could push the boilers much beyond their rating. It is now doing with three boilers what formerly required four. This is due to the ease with which the boilers can be maintained at full rating and better efficiency. When the coal-hopper installation is complete, with facilities for overhead gravity delivery of fuel, it is expected that one fireman will handle five boilers, whereas under the old methods of hand firing two men were required.

The Storage Battery is composed of three fundamental working elements, namely, the positive plate, the negative plate and the electrolyte. There are several processes used in the manufacture of the plates, but the one most generally employed consists in making the positive elements of lead peroxide (PbO_2) and the negative of sponge lead (Pb). The electrolyte consists of sulphuric acid (H_2SO_4) diluted with water (H_2O). The active materials are held in their respective positions by lead grids.

There are various theories in regard to the chemical reactions which take place in a storage cell, but the one most generally accepted is that the passage of the current upon discharge causes the acid to react upon the active materials of the plates, forming in their places lead sulphate ($PbSO_4$), the reaction being accompanied by a reduction of part of the acid and the formation of water in its place. This is the cause of the decrease in the density of the electrolyte observed upon discharge. The chemical formula expressing the reaction at the positive plate upon discharge is

Lead Peroxide + Sulphuric Acid = Lead Sulphate + Water + Oxygen

$$PbO_2 + H_2SO_4 = PbSO_4 + H_2O + O$$

That of the negative plate is

Sponge Lead + Sulphuric Acid = Lead Sulphate + Hydrogen

$$Pb + H_2SO_4 = PbSO_4 + H_2$$

Upon charging, the current is passed through the battery in the direction opposite to that of discharge, with the result that the reactions expressed in the foregoing equations are reversed. The lead sulphate is reduced, the active materials—lead peroxide and sponge lead—are restored to their respective plates and the acid taken from the electrolyte on discharge returns to it, the water previously formed disappearing. This replenishment of the electrolyte causes the rise in density observed upon charging.

Forty Years' Advance in Steam Power Units

SYNOPSIS—Comments on the accompanying graphical comparison of the Centennial Corliss engine with a turbine of the same power, showing its relative size, and a turbine of the same size, giving its relative power.

In the account given of the Panama-Pacific Exposition in last week's issue reference was made to the big Corliss engine which was a feature of the Centennial Exposition at Philadelphia in 1876. This was in connection with an outline of the advance which has been made in steam prime movers since that day. The accompanying page illustration shows this progress of forty years graphically and gives briefly some of the more important data respecting the three units shown. The story is not complete in that it leaves out the chain of steps in the evolution, but it was not the purpose to portray this. Rather was it the intention to contrast and compare the old Centennial engine with the turbine form of prime mover, which is generally adopted today where large power capacities are desired in the space allotted.

Directly beneath the Corliss engine is shown a turbine of equivalent power, reproduced to the same scale in order to compare the relative sizes of the two machines. In other words, they are shown as the two machines would actually appear when viewed at the same distance from the observer. At the bottom of the page is shown, also to the same scale, another turbine, the largest at present in operation. The comparison of spaces required by the three units is unfair to the turbines in that they are complete electric generating units, whereas the Corliss engine shows only the steam end, its output being purely mechanical energy—for direct-connected steam-electric units were unknown at that time.

In the article of last week mention was made of the manner of distributing the power from the Centennial engine through an elaborate system of shafting with both gear and belt drives. This needs no repetition for the present purposes, but more in detail is in order concerning the engine itself, which will include some of the principal facts already given.

The Centennial engine had its cylinders and means of connection with the single flywheel, in duplicate, so that it was strictly a pair of beam engines, although connected as one unit. George H. Corliss, of Providence, R. I., was the inventor and manufacturer. The engines were designed to work expansively, with steam at an initial pressure up to 80 lb. The valves and valve gear were Corliss type with several improvements specially designed for and first applied to these engines. The cylinders were 40 in. diameter and the stroke 10 ft. Each of the beams was 27 ft. long by 9 ft. deep and weighed 11 tons. The flywheel, to the shaft of which the engines were connected at right angles, was a cut-gear wheel 30 ft. in diameter by 2 ft. face width and weighed 56 tons. It made 36 r.p.m., giving a piston speed of 720 ft. per min.

The pinion which the flywheel drove was 10 ft. diameter and weighed $8\frac{1}{2}$ tons. This rotative speed is in marked contrast to that of both the turbines, which is the big factor in accounting for the disparity of sizes between the two types of machine. It is a fundamental law that the power developed increases as the speed so, naturally enough, increasing the speed a hundred times means a greatly reduced size of prime mover.

An interesting comparison, if it could be made, would be that of steam consumption per horsepower-hour, but unfortunately Mr. Corliss would not allow the figures to be given out for his engine, if indeed they were ever determined by test; but doubtless a better economy would have been shown by the Centennial engine in spite of the lower steam pressure used, the absence of superheat in the steam, and the use of live steam in the cylinder jackets. The engine developed 1400 hp. and could be driven up to 2000 hp. when required. The platform on which the engine stood was 55 ft. diameter, or 2376 sq.ft. area, so that it is fair to consider this as the floor space occupied. The total height was 39 ft. and the total weight 700 tons.

Striking by contrast are the figures for the turbine of the same power shown beneath the engine. As before stated, it runs at 100 times the speed, or 3600 r.p.m., but it occupies only $\frac{1}{20}$ the floor space, or 119 sq.ft., and weighs about $\frac{1}{32}$ as much (22 tons). Its height is less than $\frac{1}{5}$ as great (7 ft.), but it uses nearly twice the steam pressure (150 lb.). The turbine shown in this instance is of the Curtis type, as built by the General Electric Co., rated at 1000 kw., which is very nearly the equivalent of 1400 hp. If anything, the turbine is more powerful than the engine, for the brake horsepower developed by the turbine would be more, there being some loss in the transformation to electrical energy through the generator.

The picture at the bottom of the page is that of the 30,000-kw. so called cross-compound Westinghouse-Parsons type turbine built by the Westinghouse Machine Co. and the Westinghouse Electric & Manufacturing Co. for the Interborough Rapid Transit Co.'s Seventy-Fourth St. station in New York City.

In some ways it makes a better type to compare with the engine, for it is also practically two machines and occupies very nearly the same floor space—51 by 40, or 2040 sq.ft. Therefore, whereas in the first case the Centennial engine was compared with a turbine of the same power, here it is compared with one of the same size and, incidentally, nearly the same weight—900 tons. The power, even allowing for no losses between the turbine and its generator, is seen to be nearly 29 times as great (40,200 hp.), the steam pressure $2\frac{1}{2}$ times as much (200 lb.) and the speed of the high-pressure rotor 42 times as much (1500 r.p.m.) and that of the low-pressure rotor 21 times as much (750 r.p.m.).

The use of two speeds is a notable advance in the design of this form of prime mover. To get the most suitable blade speeds for both the high-pressure and the low-pressure steam in elements all on one shaft and avoid severe stresses, involves mechanical difficulties. Using a high speed for the high-pressure element and a slow speed for the low-pressure overcomes these difficulties.

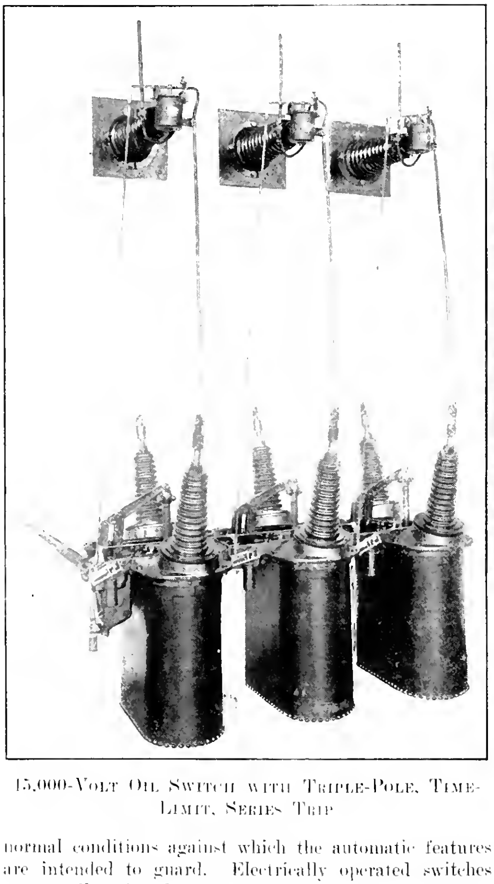
A 40,200-hp. PARSONS-TYPE TURBO-GENERATOR of 1915

In addition to the dissimilarity dimensionally, there is not the slightest resemblance in form between the machines at the bottom and top of the page, yet within a period of forty years both have been designed to perform the same work—to convert the heat energy in steam into work.

Some of the advantages which the later form has over the earlier have been mentioned. Another is its ability to use steam at very low pressures, say 26 to 29 in. vacuum. The reciprocating engine becomes prohibitively unwieldy when it carries the expansion of steam into a very high vacuum, and the excessive condensation offsets the desirability of low exhaust pressures. That is when the turbine as a coworker with the engine comes in, and in the future we shall probably see more and more of the combination units—reciprocating engines exhausting into steam turbines. Thus are the rivals becoming partners.

New Series Trip for High-Voltage Oil Switches

Low-voltage current is usually employed to trip high-voltage automatic oil switches on the occurrence of abnormal conditions against which the automatic features are intended to guard. Electrically operated switches are usually tripped by direct current, and for tripping hand-operated switches alternating current is generally used. In many instances, however, neither low-voltage direct current nor alternating current is conveniently or cheaply available, in which case automatic protection is secured by the use of a high-voltage series trip.



15,000-Volt Oil Switch with Triple-Pole, Time-Limit, Series Trip

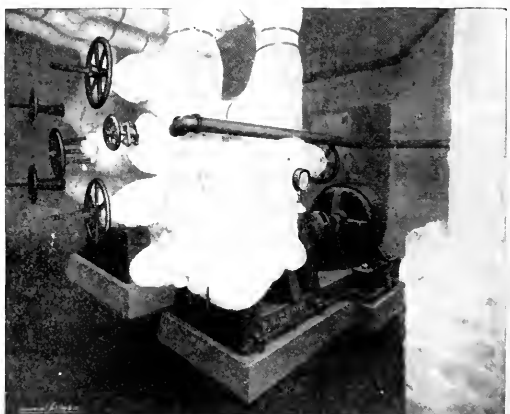
For this service the General Electric Co. has developed an arrangement representing an improvement on types of high-voltage series tripping devices heretofore in use. The new features are accessibility of the working parts for inspection, cleaning or adjustment while in service, without danger; calibration at the oil switch itself and not at the insulator supporting the series tripping solenoid; and the use of a new type of solenoid, consisting of a few simple and rugged parts that need practically no attention after installation.

The solenoid plunger is connected to the tripping mechanism of the oil switch by a wooden rod. Calibration, that is, change in current tripping values, is accomplished by a movable weight located near the operating mechanism of the switch, at a considerable distance from the high-voltage current.

This type of series trip is furnished for instantaneous or inverse time-limit operation. Time delay is obtained by means of a dashpot mounted on the tripping mechanism at the switch.

Good Service from Brine Pump

The illustration shows two brine pumps at the plant of the Independent Packing Co., Chicago. One of these units has been working 24 hr. per day for nearly a year without a stop for repairs. Covered with four to five inches of ice, it has run continuously at about 900 r.p.m. against a head of 20 lb.



The Pump Heavily Frosted

The pump is of the two-stage, all-bronze centrifugal type, made by the American Well Works. It has a capacity of 500 gal. per minute and is driven by a variable-speed direct-current motor. When starting the brine through the system, the pump requires about 27 hp. The speed is boosted to 1300 r.p.m. and the head is about 80 lb. When the brine is in circulation, the speed is lowered and only about 8 hp. is required to drive the pump. The second unit is held as a reserve, as there is danger of freezing the system.

Editorials

The Most Suitable Firebrick

The need of adapting the fuel to the furnace and *vice versa* has long been recognized. Adapting the refractory lining of the furnace to the temperature ranges and character of fuel is, at most, meagerly practiced, if at all in boiler work. It is common to line the furnace with one kind or grade of refractory material, yet the brick in contact with the fuel and ash is subjected to conditions never imposed upon that above the fire line. The latter is exposed chiefly to high temperatures only, while that below, besides being highly heated and carrying the load due to the weight of the brick above, is subjected to the chemical influences of the slag of the fused ash. Clinker tends to stick to the brick. When hit with a bar to loosen it, the brick is usually broken away where the clinker joined.

It would seem worth while, as pointed out on page 297, to use in most plants a highly refractory, tough, nonfrittering though expensive brick for that part of the furnace lining below the fire line, while a cheaper grade could be used above. The coal that will give the greatest number of pounds of water evaporated per unit of cost is best for the plant. Should not the refractory material that will give the longest service per unit of area or volume per unit of cost under the existing furnace temperature ranges be most suitable?

Synthetic Fuel

Fuel is capable of producing energy because it has the capacity of combining chemically with something, the union producing heat. The rise in temperature is simply an increase in the velocity with which the molecules move.

If a weight is in contact with the earth it has no inherent energy with respect to the earth. It cannot fall. Place it at an elevation, and it has potential energy which it can exert in other forms, as does the hammer of a pile driver or the weight of a clock.

The atoms of carbon and hydrogen in fuel attract, and are attracted by, atoms of oxygen, as the earth and the weight attract each other. When this attraction is sufficient, as in the furnace, to overcome the existing arrangement they rush together, gathering velocity and momentum, as does the weight falling to the earth. They do not impact and lose this velocity, as do the weight and the earth in overcoming the resistance of yielding substances or setting up molecular vibration at the point of contact (the heat of impact), but vibrate about each other like miniature planetary systems, with a vastly increased velocity. Their temperature is a function of this velocity and their mass; a measure of their momentum.

When they come in contact with the molecules of the boiler plate they set them into more active vibration, and this vibration is passed on to the molecules of the water, inciting them to such rapidity of motion that they break away from each other and fly off, like stones from a sling-shot, impacting upon the walls of the containing vessel and producing by their bombardment that which we recognize as pressure.

The gases, cooled (having imparted a part of their velocity or momentum to the atoms of the heating surface), pass off to the atmosphere. They are in the condition of the weight and the earth which have come together; the clock which has run down. They cannot get up any more velocity or momentum in themselves by falling any closer. How, then, are they to be separated that they may be again available as media of energy?

When the carbon combines with the oxygen they form carbonic-acid gas, the gas which makes the bubbles at the soda fountain and gives the sparkle to wine. When hydrogen combines with oxygen they form water. To decompose the carbonic-acid gas or the water, that is, to dissociate these molecules into atoms of carbon or hydrogen and oxygen, takes as much energy as is generated by their combustion or coming together.

And here comes in one of the most wonderful, beautiful and mysterious of Nature's processes, described in this way in an old school chemistry, the name of the author of which we do not recall: It is a peculiar property of vegetation that under the influence of sunlight it can overcome the attraction which exists between the atoms of carbon and oxygen, appropriating the carbon to its own use, building it into its structure, and letting the oxygen go free into the atmosphere. To separate these elements in our laboratories, we are obliged to resort to the most powerful chemical agents and to conduct the process in vessels composed of the most refractory material, under all the violent manifestations of light and heat; and we then succeed in liberating the carbon only by shutting up the oxygen in a still stronger prison. But under the quiet influence of the sunbeam, in that most delicate of all structures, a vegetable cell, the chains which unite together the two elements fall off, and while the solid carbon is retained to build up the organic structure, the oxygen is allowed to return to its home in the atmosphere. To separate a pound of carbon from the oxygen with which it unites in burning would require the expenditure of an amount of energy which would raise the weight of a ton to a height of over a mile, and yet, in the economy of Nature, this process is constantly going on, not with the noisy demonstration of prodigious effort, but quietly, in the delicate structure of a green leaf waving in the sunshine.

The most promising direction in which to look for a more direct or rapid process than that of waiting for fuel to be produced by the slow growth of vegetation is through the discovery of the secret of the vegetable cell, and the application of the sun's energy either to the direct production of other forms or to the synthetic production of fuel. At a meeting of the French Society of Civil Engineers some time since, M. Daniel Bertholet said that, working in conjunction with M. Gaudechon, he had succeeded in producing the principal sugars by acting with ultra-violet light on a mixture of gaseous carbon dioxide and water. In a further set of experiments compounds of carbon, oxygen, hydrogen and nitrogen were produced by acting with these ultra-violet rays on a mixture of carbon dioxide and ammonia. In these conditions the carbon dioxide is decomposed just as it is by chlorophyll under the action of sunlight. Activity in this direction would be much more promising than that in the direction of the fuel mixtures, of the rise and decline of which so much has recently appeared in the public prints.

Keeping Track of Plant Operation

Plant revenue is derived from plant output, but for many years the switchboard output was the only thing about the plant that was metered except where the local authorities applied a water meter to the service pipe. Of course, the monthly payroll, repairs and the cost of fuel, oil and supplies were recorded, and in a few cases the weight of the coal fired was noted. Occasional indicator diagrams were taken on the engines, and some plants were tested when new. Records along these lines were at one time considered the last word in refinement, although there were some who strenuously maintained that there was a big gap between the grate bars and the switchboard, where serious plant losses might occur undetected. One of the difficulties to be overcome in isolating these losses was the supposedly fragile nature of the instruments required and their unsuitability to the boiler room.

When the steam turbine came into general use in central stations the steam-engine indicator retired, and then there really was nothing between the grate bars and the switchboard to tell what was happening except the recording steam-pressure gage. The first instrument to become a factor in boiler-room operation after this was the CO_2 meter. This revealed many sources of leakage and expense without adequate return and put a premium upon complete combustion. The Orsat apparatus revealed high oxygen and checked the combustion recorder. Between these two lies the responsibility for a general advance in fire-room practice and the patching up of boiler settings. The disadvantage resulting from porous brickwork brought the marine type of setting to the attention of power-plant engineers, and sheet-steel casings are not uncommon in modern practice.

Extended experience, however, showed that there were still uncovered sources of waste. High CO_2 occasionally failed to be an accurate index of economy, particularly where a number of boilers were employed and premiums paid. Instances occurred where it took more boilers to carry the load than were absolutely necessary, or low steam pressure somewhere was revealed by an unexpected jump in the load curve. The investigation of uptake temperatures and draft pressures furnished a partial cure for the trouble, but the final check was the use of the steam meter and the feed-water meter.

Incidental to the introduction of these instruments came the close study of boiler settings, boiler output and the possible increase in power output, increase in grate area and large boilers. It took years for the metallurgical engineer to learn that the low-roofed furnace designed to force the heat into the bath by close contact with the flame was a mistake. He raised the roofs of his furnaces, gradually learning that the larger combustion chamber and the radiant heat resulted in economy of fuel and reduced roof repairs. Today the same lesson is being brought to the attention of those interested in boiler output along economical lines. The published tests of the Delray boilers and the tests and operating results secured in the new Cleveland municipal plant indicate what the boiler room can do.

License Legislation in Massachusetts

A new engineers' license law (House Bill 1111) is before the Massachusetts legislature and is occasioning a great deal of interest. It appears under the patronage of a voluntary committee, which has headquarters in the Sears Building, a secretary in the person of Richard B. Stanley, and representatives from the paper, pulp, cotton, woolen, metal-working, quarry and lime industries, and the boards of trades. The difference between the present and proposed laws is thus set forth by the propagandists:

PRESENT LAW	PROPOSED LAW
It recognizes no difference in the risk of operation between steam engines and steam boilers.	It recognizes much difference in the risk of operation between steam engines and steam boilers.
It fails to determine the scope of examinations and to require them to be uniform throughout the state.	It determines the scope of examinations and requires them to be uniform throughout the state.
It permits the requirement of knowledge of the principles of design in the examination of applicants for licenses to operate.	It limits to knowledge of operation the examination of applicants for licenses to operate.
It permits the requirement of knowledge of the principles of design of boilers in the examination of applicants for licenses to operate engines.	It limits to knowledge of engine operation the examination of applicants to operate engines.
It permits the examiner to require involved mathematical calculations, thereby denying employment to competent men.	It prevents the examiner from requiring involved mathematical calculations.
Complex and difficult to understand.	Simple and clear.

The bill appears, probably from oversight, to fail to forbid the operation of engines between twenty-five and one hundred and fifty horsepower without a licensed engineer, and is evidently designed to forestall any attempt to restrict the supply of available engineers and firemen by subjecting them to an impassable examination and to the requirement of a licensed man for everything about the power house from superintendent to coal passer.

Another bill (House Bill No. 19) puts into effect, if passed, the recommendations of the Chief of District Police with regard to the examination and certification of inspectors of boiler-insurance companies.

Some Dates to Remember

Dec. 15, 1912, Hall of Records Test begun.

Dec. 15, 1913, Hall of Records Test finished.

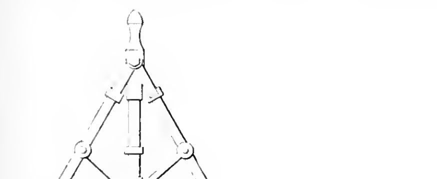
Mar. 2, 1915, Advisory board of engineers still debating.

Would fourteen months of silence have followed the conclusion of the test had the figures favored the New York Edison Co.?

Correspondence

Operating Refrigeration Plants Safely

At present there is much needed discussion of safety in refrigeration plants published in POWER. The use of safety valves does not meet with general approval, and there are several good reasons for this. After a safety valve has been set to operate at a certain pressure, say 300 lb., it may be a long time before the pressure from any cause will reach a point that will cause this valve to open. All ammonia plants are troubled with dirt, scale and chunks of litharge and it is almost impossible to clean these completely out of the piping system. Some of this foreign matter will be carried along with the escaping ammonia and deposited on the seat of the safety valve, preventing it from closing tightly, though it be of the best design. The idea of using a body of water as an absorbent has been completely answered by Mr. Fairbanks, of Boston (see POWER, Dec. 15, pp. 849 and 866), and the writer will not touch on that point here. The various laws of different states regulating the operation of steam boilers (notably those of Massachusetts, which some consider to be the best) are useless unless strictly lived up to. This is mentioned only to illustrate that, no matter what safety device may be ordered by law for the safe operation of refrigeration plants, that device will be of no avail unless it is of such design that it can be easily looked after and kept in good working order at all times.



AMMONIA PRESSURE RAISES THE GOVERNOR, GIVING EARLIER CUTOFF, THEREBY REDUCING THE COMPRESSOR SPEED

Investigation of numerous accidents to refrigerating plants has proved that a large percentage were due to the carelessness of someone operating the plant. The most destructive accidents may be summed up as those caused by excessive pressure from the loss of cooling water on the condenser, not opening the discharge valve from the compressor to the condenser after the former had been pumped out for packing the rod or other repairs, or from a heavy charge of liquid being carried over from the low-pressure side of the system, and in a lesser degree the breaking of a follower plate or a valve stem, which in either case must cause the destruction of the compressor regardless of any and all safety devices on the market.

I make it a practice to replace all suction valves that open into the compressor, after they have been in continuous use two years. This is done on the assumption that the constant hammering that they are subjected to must cause crystallization. In fact, I once broke a valve stem that had been, as near as I could learn, in continuous use about five years, by striking it a sharp blow with a small hammer. Within the past year one of our compressors developed a badly cracked follower. I mention these things to show that fatigue or weakening of parts is a cause of danger that cannot receive too careful consideration by owners and operators.

There are two devices for preventing an excess pressure being generated in a refrigeration system that have come under my observation. One consists of a small safety valve piped directly from the compressor cylinder, that discharges into a cylinder fitted with a piston, the crosshead of which engages the governor stem. When the pressure in the compressor cylinder exceeds a predetermined point, say 200 lb., the safety valve admits ammonia to the pressure-regulating cylinder, lifting its piston, which in turn lifts the governor spindle and disengages the hooks so that the steam valves cannot be opened by the valve gear, and the engine comes to a stop. This works well on a machine with one steam cylinder, as this device has no method of breaking the vacuum, as in a compound condensing machine. It is not as quick in action as the method now employed by the writer and which has given satisfaction for over six years. The refrigerating machine has an engine stop, and the ends of the ammonia compressor are piped to a pressure gage so designed as to permit the use of the pointer as an electric switch to close the electric circuit putting the engine stop in motion. This action closes the throttle and breaks the vacuum, stopping the machine in as short a time as seven seconds. The device is adjusted to operate at 200 lb., and in very hot weather, when the working pressure has been close to that point, it has been found impossible to keep the machines in operation until the head pressure had been lowered. The stop is also equipped with a remote control, with six stations located in different parts of the engine room and one general station outside the building, where, by breaking the glass and pulling down a lever, the power plant can be brought to a standstill. A system of this kind that prevents the generation of an excessive pressure in the refrigerating system is the best means of promoting safety in handling large quantities of ammonia.

In case of a fire that would be likely to destroy a building used for refrigeration purposes, there would be little choice between blowing the high-pressure ammonia from a pipe ten feet higher than the building and allowing the building to collapse, bursting the ammonia pipes. It is commendable practice to carry ammonia relief pipes to the top of the smoke-stack.

Repairing Crack in Combustion Chamber

About two years ago a combustion chamber on one of our 1000-hp. gas engines cracked from top to bottom, a distance of about 14 in. This engine is used as an auxiliary and has not been run very much since then. When the crack first developed, the cylinder could be used by starting the engine with no water in the jacket, the crack closing by expansion due to the increased temperature and preventing the water from entering the cylinder. The opening seemed to become larger, however, and finally the cylinder could not be used at all.

At first it was thought useless to try to repair the break, but later, representatives of two welding firms were consulted. One agreed to weld the crack at an exorbitant figure, but would not guarantee the job; the other expressed the opinion that it could not be repaired.

After this I asked permission for a trial at repairing it, which was granted. I began the job with Smooth-On cement and 5/8-in. Norway-iron studs. The second hole was drilled so as to cut into one-third the diameter of the first, and so on all the way up the crack. The studs were screwed in with the iron cement, cut off and slightly peened. The repair proved successful.

Starting a Small Motor

In the Jan. 12 issue Walter S. Griscom tells of difficulty in starting a small motor. This trouble was undoubtedly due to a weak field, which in turn, was probably caused by low voltage at the motor terminals, due to drop resulting from a long length of small wire or bad or loose connections. Such a drop will be aggravated by an increase in amperage, and a shunt motor under these conditions may have little field strength and possibly not enough torque to start the motor. Putting resistance in the armature circuit would partially overcome this difficulty, but I fail to see the necessity for leaving the lamps in circuit after the motor is up to speed.

Several years ago a motor-generator was set up and operated in our plant by a young fellow who didn't care to have anybody advise him. He was never able to start the machine without help and a careful manipulation of the starting box. The machine was later turned over to me, and I found that the connections on the starting box had been made so that the field was in series with the starting resistance. After changing this the motor started promptly.

I have also seen the experiment tried of electrically connecting two 50-kw. shunt-wound machines while idle, and attempting to bring both up to speed together, one acting as a generator and the other as a motor. The main circuit-breaker would invariably trip without noticeable indication on the voltmeters or without producing appreciable torque in the second machine.

Who Gets the Promotion?

Concerning the Foreword in the issue of Dec. 15, 1914, and Mr. Farnsworth's deductions on page 172, issue of Feb. 2, 1915, I can see no reason for saying that only one of the men has made preparation for the position. Neither can I agree with him that the manager has no right to consider his own likes or dislikes in the matter. I think that any engineer will agree that he can do a whole lot better with a plant where he is on good terms with the boss than otherwise. A man who is popular with his mates will be more likely to have harmony among his men when he gets to be the chief than a man who is ill tempered, surly or just plain cranky. I say this from experience. Neither will they resent his authority as much as they would if he were a grouch. I have heard men say behind my back when I was foreman: "Yes, he looks and acts like a kid when he is playing with the boys, but when the whistle blows he knows how to handle his men, and if he tells you to do anything, you had better do it." I could skylark with the boys or men of my crew outside of working hours and maintain discipline among them when on duty, and I have the reputation of getting the best possible service from my men.

Because a man is grouchy, this does not unfit him for the position, but everything else being equal, the cheerful man will have more harmony and stand a better chance of success. Personally, I would feel more like doing my best for the man who would treat me like a chum than I would for one who would hardly say "Good morning" civilly.

If a man is steady, sober and honest, does it not count for many points in the promotion game? Of course, if these are the only points they are not sufficient, but if he has seen long service he must have acquired considerable ability. Of course, there are men who make good assistants but very poor chiefs, and the ideal chief is one who will combine the good qualities of all three; such men are born, however, not made, and this is the reason that we often see a young fellow installed as chief while his assistants are double his age and experience, yet lacking the knack of control.

However, all this does not help the manager to decide, but if I were in his place I believe I would choose the one with the cheerful temper if I liked him personally. I think being a hustler does not imply being always hurrying or on the run.

Oxford, N. J.

Notes on Indicator Diagrams

While it is obvious that the indicator diagrams shown in POWER, Nov. 3, 1914, p. 650, are due to a slipped eccentric, it is not evident that the rod is out of adjustment. Granting that the diagrams were taken from an engine with a simple slide-valve, both adjustments are at fault. While the data given are not complete, it is possible to show that if the shaft were 4 in. in diameter, the engineer would need to lay off with dividers $2^{3}/_{64}$ in. and advance the eccentric that amount. For the engine in question this would need to be multiplied by the ratio of the diameter of its shaft to 4 in.

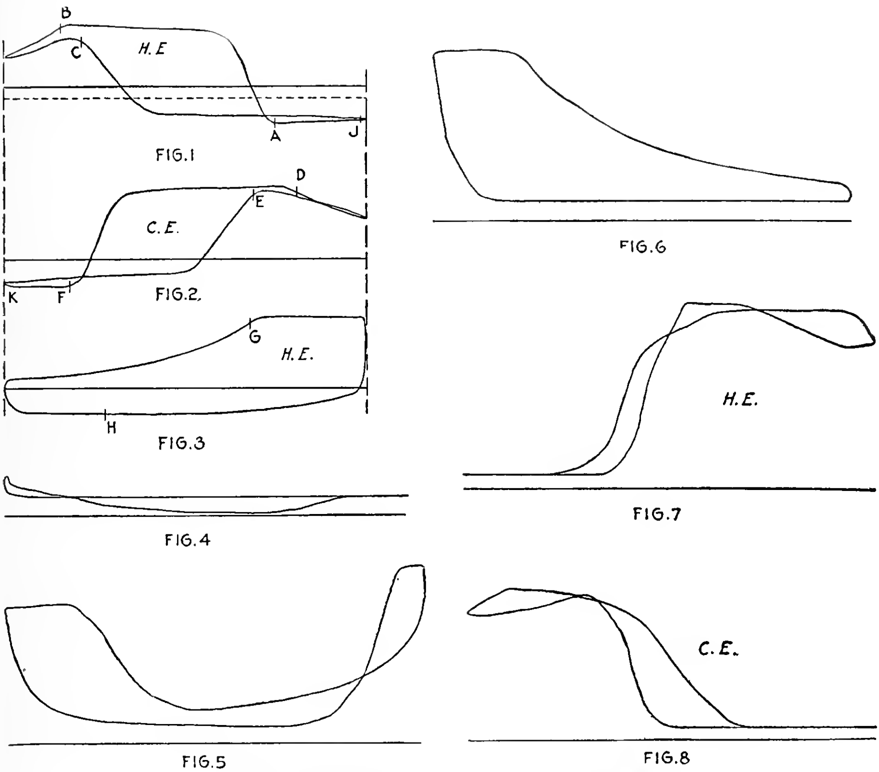
This is easily done graphically by drawing the shaft circle to scale and a 4-in. circle concentric with it. Lay off on the latter a chord as given and continue radial lines through its ends to the shaft circle. It would be easier in laying this out on the shaft to use two chords of $1\frac{1}{16}$ in. (on the 4-in. shaft) instead of one. This ratio is the scale factor of the diagram used to get the data given below. The rod should also be lengthened $\frac{3}{32}$ in. multiplied by this ratio.

Since no information is given regarding the compounding of this engine, no speculation has been made concerning the action of this low-pressure cylinder or the effect on the revised diagram. Figs. 1 and 2 show the original diagrams traced with events marked. Fig. 3 gives the card obtainable under favorable conditions with the correct setting as indicated, but with the same terminal pressures. In the original diagram, Fig. 1, the atmospheric line is about 5½ lb. too high. It should be where the dotted line is, though this does not affect the diagram so far as valve analysis is concerned. The crank-end diagram is similar.

	1	2	3
	Per Cent. Stroke		
Admission.	A - 25	F - 19%	Near dead center.
Cut off. .	B - 84	D - 81	G - 32%
Release	C - 78	E - 64	Near end of stroke.
Compression.	J - 2	K - 0	H - 72%

Interesting freak diagrams, Figs. 4 and 5, are from the head and crank ends of a 7¾x15-in. piston-valve engine, normal speed, 220 r.p.m. This 35-hp. engine was not running over 100 r.p.m. at the time the diagrams were taken. Fig. 6 is from the head end taken after setting the valves. The crank-end diagram is similar, though at this time it was not quite as perfect. Diagrams 7 and 8 were taken under similar circumstances from the same engine. This condition of the valves is one that might result from the breaking of an inner valve ring, where the ring caught between the two valves and slipped the rods and the eccentrics—an accident that has occurred on this type of engine.

To those interested in valve setting, these diagrams should claim attention, for to correct faults it is often necessary to locate all the events, though the action is complicated here by the relative movement of the two valves.



SOME RATHER PECULIAR INDICATOR DIAGRAMS

The valve gear is such that the main valve is indirect, as it takes steam on the inside, has a travel of 2⅜ in. and a nonreversing rocker. The eccentric is some thirty inches behind the crank.

The rider valve eccentric is about thirty degrees ahead of the crank when the governor is down and some ninety degrees ahead when running light. Its valve is also indirect, as its motion is reversed by a rocker pivoted at its center to the center of the main valve rocker. The valve takes steam on the outside and its travel, both relative and absolute, varies. The latter is about 3½ in. when the governor is down and may be from 4 to 4⅜ in. when carrying a load, varying with the load and with the setting.

Because of this variable valve travel a valve diagram does not represent the movements of the parts as well as it does for the simpler valve gears, such as the Meyer.

The results of a Zeuner diagram for the first two diagrams may be of interest. Taking, for convenience, a 4-in. valve travel and a connecting-rod five times the length of the crank, it is found that the events check as shown. For the final setting, which was made for $^1/_{64}$-in. lead on the head end and for equal cutoffs, we have the following:

End	Admission	Cutoff	Release	Compression	Steam Lap, In.	Dead, In	Port Opening Steam, In	Port Opening Exhaust, In
Head	0	32	99	72	$1\frac{11}{16}$	$\frac{1}{64}$	$\frac{5}{16}$	$\frac{3}{8}$
Crank	0 5	32	99	68	$1\frac{13}{16}$	$\frac{3}{16}$	$\frac{33}{64}$	$\frac{3}{16}$

These port openings are the maximum possible and must be compared with the actual ports to get under travel. All dimensions, except the percentages of stroke, must be multiplied by the ratio of the actual valve travel to 4 in.

A. R. NOTTINGHAM.

West Lafayette, Ind.

Stopping a Low-Pressure Complaint

The editorial, "The Wrong Slant," in the Dec. 15 number, calls attention to the status of the steam engineer in most factories. Besides being an "expense" he is often the "goat" for any accident that may occur which reduces the output of the factory. The power item being large in the production of some articles, the engineer is often held accountable for losses, and sometimes when he is in no way responsible. Even when he is not charged directly with the responsibility for losses, he is informed that the loss in department so-and-so was due to a drop in steam pressure or to a few minutes' interruption of light or power service, and this in a tone which leaves him with the impression that life is just one thing after another.

In a factory making food products, where much steam was used for cooking and drying, the foremen of the different departments seemed prone to charge their short or otherwise unsatisfactory outputs to a drop in steam pressure. This so got on the nerves of the master mechanic that he persuaded the manager to buy a recording pressure-gage. This was fixed to the wall above the master mechanic's desk and connected to the steam main in the boiler room, which was in the adjoining building.

A few days later the manager sent for the master mechanic and informed him that the output of Mr. Jones' department had been seriously reduced the night before on account of a great drop in the steam pressure. The master mechanic produced the chart taken from the gage at 7 o'clock that morning and showed that during the previous 24 hr. there had been no abnormal variation in the pressure and that the statement of Mr. Jones was just a plain lie. The manager must have had a heart-to-heart talk with Mr. Jones, because late in the afternoon Jones called on the master mechanic and had quite a lengthy but friendly chat. No reference was made to steam pressures, but Jones kept his eyes on the pressure gage throughout the conversation. As he was about to leave he pointed to the gage and asked, "What is that thing there?" "That?" said the master mechanic; "O, that's a trap to catch four-flushers."

Kansas City, Mo.

Quarter-Turn Rod Coupling

Under the above title, on page 117 of the Jan. 26 issue, there is reference to a device patented by C. P. Hall, of the Rookery Building, Chicago.

If my memory serves me rightly a coupling of this construction was designed by William G. Bond, chief engineer for the National Biscuit Co., Tenth Ave. and Fifteenth St., New York City, some fifteen years ago, and it may now be in service in that plant.

I was in charge of the electrical equipment and assisted Mr. Bond in the preparation of the working drawings of a coupling that I am almost positive was similar in every way to the detail you have shown.

NEWTON L. SCHLOSS.

New York City.

Grouting under Heavy Machinery

I have seen engine erectors use neat cement for grouting under engines. This, I believe, makes a grouting inferior to a mixture of one part cement and one part clean sand, or even two of sand to one of cement. While neat cement gets very hard, it cracks easily.

It is a matter of considerable discussion whether, in setting engines, the leveling wedges should be left in or taken out after the grouting has set. With the wedges in, almost the entire weight of the engine remains on them, as the grouting will not set up tight enough to take the weight and the engine is much more apt to work loose on its foundation.

I once had a three-cylinder vertical, direct-connected engine that worked badly. The engine was raised a quarter of an inch, the old grouting knocked out and some four hundred pounds of sulphur run under the base. Sulphur was used because the foundation had become so oil-soaked that it would have been impossible to get a cement grouting to bond. That job was done more than four years ago and the engine does not show the slightest movement.

In doing this work it was found that a wedge had been left under each side of the base at about the center of the engine. If these wedges had been pulled out in the first place, the engine would never have started working as it did; it was simply rocking on the wedges.

Pittsburgh, Penn.

Inquiries of General Interest

Rerolling of Boiler Tubes—When a return-tubular boiler has been in continuous use for five years, the tubes having been rerolled a number of times, is it possible to cut off the tube ends by further rerollings?

F. C. T.

If the boiler tubes are rerolled in such a manner that they are each time expanded inside of the tube sheet, then a sufficient number of rerollings will cause the tube ends to split or to break off, especially if the tube material has become weakened by corrosion.

Breakage of Shafts in Hubs of Pulleys—What reason is to be assigned for repeated breakage of our shafting inside of the hubs of driving and receiving pulleys?

J. O. B.

The shafts break in the hubs of the pulleys because those are the points where, mainly from tension of belts, the shafts are subjected to greatest bending stresses. The remedy is to reduce the bending stresses by placing bearings closer to the pulleys or using larger pulleys, thereby transmitting the same power with less belt tension and also less journal friction.

Relative Water Used by Refrigerating Systems—Is there any difference in the quantities of water required by absorption and by compression systems of refrigeration of like capacity?

G. B.

It is customary to use a little more water for absorption systems than for compression systems having simple steam engines. When compound condensing engines are used for driving compressors the water used to obtain 26 in. vacuum is about the same as required for a standard absorption system of equal refrigerating capacity.

Latent Heat of Fusion and of Evaporation—How many B.t.u. must be added to 1 lb. of ice at 32 deg. F. to melt it to water at the same temperature; and how many B.t.u. must be added to 1 lb. of water at 212 to convert it into steam at atmospheric pressure?

F. A.

The heat required to melt a pound of ice at 32 deg. to water at the same temperature is 144 B.t.u., this being the latent heat of fusion of ice. Conversion of a pound of water at 212 deg. F. into dry saturated steam at atmospheric pressure, requires the addition of 970.4 B.t.u., called the latent heat of evaporation at atmospheric pressure, one B.t.u. being taken as $^{1}/_{180}$ of the heat required to raise a pound of water from 32 to 212 deg. F.

Conversion of Gage Readings into Absolute Pressures—With a barometric reading of 29.4 in. what would be the absolute pressures corresponding to 100-lb. gage pressure and 26-in. vacuum?

C. R.

Assuming that the barometric and vacuum gage readings are, as usual, based upon heights of mercury columns at a temperature of 62 deg. F., at which temperature an inch of mercury column is equivalent to 0.491 lb. per sq.in., then for a barometric reading of 29.4 in. a gage pressure of 100 lb. would correspond to

$$100 + (29.4 \times 0.491) = 114.435 \text{ lb. per sq.in. absolute}$$

and 26-in. vacuum would correspond to

$$(29.4 - 26) \times 0.491 = 1.669 \text{ lb. per sq.in. absolute.}$$

Temperature of Steam at Reduced Pressure—If dry saturated steam at 85-lb. gage pressure is passed through a reducing valve what will be its temperature if reduced to 4-lb. gage pressure?

Q. W. D.

By referring to Marks and Davis' steam tables it may be seen that each pound of dry saturated steam at 85-lb. gage pressure, or 85 + 15 = 100 lb. absolute, contains 1186.3 B.t.u. above 32 deg. F. Neglecting the heat lost by radiation and in work overcoming friction in passing through the reducing valve, which under ordinary circumstances would be negligible, each pound of the steam at the reduced pressure of 4 lb. gage, or 4 + 15 = 19 lb. absolute, may be regarded as containing the same number of heat units as in the original condition, viz., 1186.3 B.t.u. above 32 deg. F. Referring to the same tables of heat of steam at various pressure and with different degrees of superheating, it is found that the temperature of dry saturated steam at 19 lb. absolute, when saturated, contains only 1155.2 B.t.u. per pound above 32 deg. F., and the temperature is 225.2 deg. F., but when superheated 60 deg. F. each pound contains 1183.6 B.t.u., and when superheated 70 deg. F. each pound contains 1188.3 B.t.u. The degree of superheat corresponding to 1186.3 B.t.u. is therefore found by interpolation to be

$$60 + \left[\frac{1186.3 - 1183.6}{1188.3 - 1183.6} \times (70 - 60)\right] = 65.7 \text{ deg. F}$$

and the actual temperature would be

$$225.2 + 65.7, \text{ or about } 291 \text{ deg. F.}$$

Efficiency of Boiler and Grates—What would be the efficiency of a boiler and grate if the evaporation of 37,968 lb. of water from feed water at 170 deg. F. into dry saturated steam at 110 lb. per sq.in. gage pressure required the combustion of four tons of coal of a calorific value of 13,000 B.t.u. per lb.?

V. K. S.

Each pound of feed water at 170 deg. F. would contain

$$170 - 32 = 138 \text{ B.t.u. above } 32 \text{ deg. F.}$$

and as a pound of dry saturated steam at 110-lb. gage pressure, or about 125 lb. per sq.in. absolute, contains 1190.3 B.t.u., then each pound of water evaporated into steam would require

$$1190.3 - 138 = 1052.3 \text{ B.t.u.}$$

so that under the conditions stated the evaporation of 37,968 lb. of feed water would require

$$37{,}968 \times 1052.3 = 39{,}953{,}726.4 \text{ B.t.u.}$$

Allowing 2000 lb. per ton, then in using four tons of coal the heat absorbed per pound of coal would be

$$\frac{39{,}953{,}726.4}{4 \times 2000} = 4994.2 \text{ B.t.u.}$$

As the efficiency of the boiler and grate would be equal to

$$\frac{\text{Heat absorbed per pound of coal}}{\text{Calorific value of 1 lb. of coal}}$$

the efficiency would be

$$\frac{4994.2}{13{,}000} = 38.41 \text{ per cent.}$$

Piston Speed Assumed in Pump Formula—What pump piston speed would have to be assumed for figuring pump capacity by the formula, Gallons pumped per minute = $d^2 \times 4$, in which d represents the diameter of water piston in inches?

K. H.

Without allowing for slippage or reduction of piston area by the piston rod, the delivery would be expressed by the formula:

$$(1)\quad \text{Gallons per min.} = \frac{d^2 \times 0.7854 \times L \times n}{231}$$

in which

d = Diameter of water piston in inches;
L = Length of stroke in inches;
n = Number of single strokes per minute;
231 = Number of cubic inches per gallon.
Calling S = Piston speed in feet per min., then as

$$S = \frac{L}{12} \times n \text{ or } 12\,S = L \times n,$$

formula (1) might be written

$$(2)\quad \text{Gallons per min.} = \frac{d^2 \times 0.7854 \times 12\,S}{231} = d^2 \times 0.0408 \times S$$

Therefore, the given formula would be true when

$$d^2 \times 4 = d^2 \times 0.0408 \times S,$$

i.e., when S = 98.04; or, in other words, the given formula would be correct for an assumed piston speed of 98.04 ft. per min. without any allowance for slippage or piston rod, which would be equivalent to assuming a piston speed of 100 ft. per min., with an allowance of

$$\frac{(100 - 98.04) \times 100}{100} = 1.96 \text{ per cent.}$$

reduction of capacity by slippage and piston rod.

The Effect of Vacuum in Steam Turbines*

By G. Gerald Stoney

SYNOPSIS—An interesting article dealing with the thermal gains and losses due to vacuum in land and marine turbines.

The degree of vacuum which gives the same velocity ratio at the exhaust end as throughout the whole turbine is the vacuum under which the best results are obtained; consequently, a turbine designed for 29 in. vacuum, barometer 30 in., requires more rows of blades or wheels than one designed for 27 in., the number of rows or wheels of a given diameter in each case being proportionate to the B.t.u. available in the range between the initial and final pressures and temperatures through which the turbine works. There may be considerable latitude in the velocity ratio at the exhaust end without seriously affecting the available economy. Neglecting the effect of the reheat factor, which is small in modern high efficiency turbines, and also neglecting terminal losses, with 175 lb. absolute initial pressure and a superheat of 150 degrees, the gains per inch of vacuum in the B.t.u. available during adiabatic expansion are as shown in Fig. 1 and are:

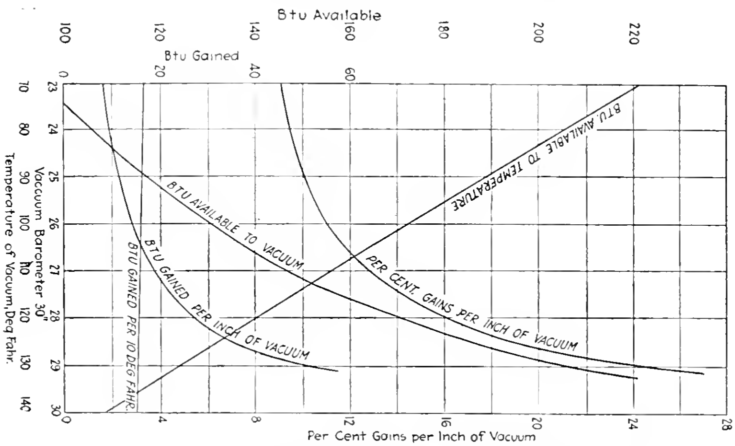

Fig. 1. Distribution of Heat during Adiabatic Expansion; Initial Pressure 175 Lb. Absolute; 150 Deg. F. Superheat

TABLE 1

Between 23 in. and 24 in., 3 per cent. or an increase of 9 B.t.u. on about 300 B.t.u. available at 23 in.

Between 24	in. and 25	in.,	3 per cent.	or	10	B.t.u.
Between 25	in. and 26	in.,	4 per cent.	or	12	B.t.u.
Between 26	in. and 27	in.,	5 per cent.	or	15	B.t.u.
Between 27	in. and 28	in.,	6 per cent.	or	21	B.tu..
Between 28	in. and 28½	in.,	8 per cent.	or	29	B.t.u.
Between 28½	in. and 28¾	in.,	9 per cent.	or	36	B.t.u.
Between 28¾	in. and 29	in.,	11 per cent.	or	42	B.t.u.
Between 29	in. and 29¼	in.,	13 per cent.	or	54	B.t.u.

For saturated steam at 175 lb. absolute, the figures are approximately the same.

In the case of an exhaust turbine working with, say 15 lb. absolute, the gains per inch of vacuum as shown in Fig. 2 are:

TABLE 2

Between 23 in. and 24 in., 9 per cent. or an increase of 10 B.t.u. on about 110 B.t.u. available at 23 in.

Between 25	in. and 26	in.,	11 per cent.	or	13	B.t.u.
Between 26	in. and 27	in.,	12 per cent.	or	17	B.t.u.
Between 27	in. and 28	in.,	14 per cent.	or	22	B.t.u.
Between 28	in. and 28½	in.,	17 per cent.	or	30	B.t.u.
Between 28½	in. and 28¾	in.,	20 per cent.	or	38	B.t.u.
Between 28¾	in. and 29	in.,	23 per cent.	or	45	B.t.u.
Between 29	in. and 29¼	in.,	27 per cent.	or	57	B.t.u.

*From a paper read before the Institution of Mechanical Engineers, England.

For each degree Fahrenheit that the temperature due to the vacuum is reduced, there are approximately 1.5 more B.t.u. available, and this is approximately the case through the whole range considered in tables 1 and 2 and Figs. 1 and 2. These gains due to vacuum are attainable when the turbine can be suitably designed, but, in the case of high-speed, large output land turbines, allowance must be made for increased terminal losses.

For example, in a 3000-kw. land turbine at 3000 r.p.m. with an initial pressure of 175 lb., 150 degrees F. superheat and a vacuum of 29 in., the consumption will be about 12 lb. per kw.-hr., and the steam per hour will be 36,000 lb. or 10 lb. per second. The volume at exhaust, allowing for condensation, will be about 6000 cu.ft. per second. With present materials available, it is not in general customary to go above about 550 ft. per second for the mean velocity of the blades at the exhaust end, giving a mean diameter of 42 in., and as the blade height cannot be more than one-fifth of this, or 8.4 in., the area of the annulus is 7.7 sq.ft. The velocity of the steam leaving the blades through the restricted area will then be 780 ft. per second and involve a loss of 12 B.t.u., assuming that the velocity ratio and angle of the blades are such that the steam leaves them axially, as it should, to give the minimum loss. Even under these conditions there is still a gain of 6½ per cent. between 28 and 29 in. vacuum. For still larger powers these effects become more pronounced, until conditions are eventually reached in this class of turbine having a highly restricted exhaust end when an increase in vacuum causes no gain. It is the aim of designers to increase the limiting vacuum by using higher blade speeds and enabling an exhaust end of larger dimensions to be employed. This is undoubtedly a direction in which increased efficiency in large power high-speed turbines is to be found. The effect of increased blade speed is appreciable, as for a given vacuum the reduction in available gain varies inversely as the fourth power of the blade speed, since as the blade height cannot well be more than one-fifth of the mean diameter of the blades, the area at the exhaust will vary as the square of the diameter, or as the square of the mean blade velocity. Therefore the longitudinal velocity varies inversely as the square of the mean blade velocity, or the B.t.u. lost, inversely as the fourth power. Of course, the reduction can be halved by adopting a turbine with double flow at the exhaust, but this often introduces complications, although many economical land turbines of large power have been designed on these lines. Something can also be done by shaping the exhaust suitably, so as gradually to reduce the velocity of the steam on leaving the blades.

The case of reduced loads will now be considered. With throttle governing, the initial steam-pressure is reduced in accordance with a right-line law similar to the Willans law for the steam consumption, and it may be taken that in this case the initial pressure at no load is approximately atmospheric. If at full load the initial pressure is 175 lb. absolute, at half load it will be about 95 lb., and at quarter load, 63 lb. At half load, with a vacuum of 28 to 28½ in., the percentage gains in consumption per inch of vacuum would be increased by about one per cent., and at quarter load by about two and one-half per cent. above those given in tables 1 and 2, owing to the reduced B.t.u. available by reason of the reduced initial steam-pressure. The amounts of these gains will depend on the velocity ratio throughout the turbine, which has been assumed to be constant at full load.

At reduced loads with throttle governing, the velocity ratio will be approximately the same as at full load throughout the turbine, except near the exhaust end, where it will be greater at reduced loads. This may either slightly increase or diminish the efficiency at the exhaust end, according as the general velocity ratio is high or low, but in general the effect will be small.

With nozzle governing, the gains due to increased vacuum at reduced loads are somewhat less than with throttle governing, and the amount depends on the type of nozzle governing used, but broadly, at full load and at reduced loads the gains in consumption per inch of vacuum are more nearly equal with this type of governing. When a turbine is not bladed so as to give the full velocity ratio up to the exhaust end at full load, it is obvious that the above gains due to vacuum must be modified.

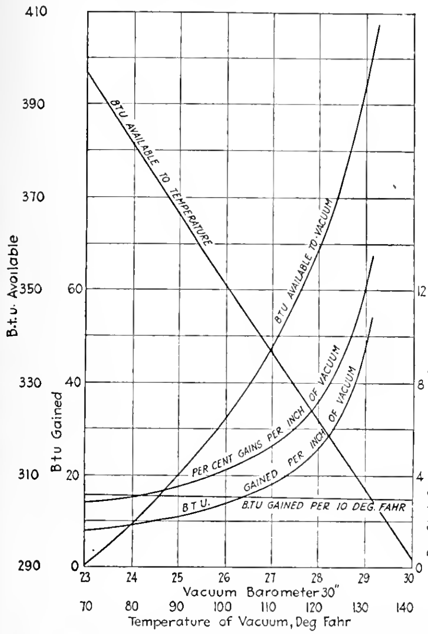

FIG. 2. DISTRIBUTION OF HEAT DURING ADIABATIC EXPANSION; INITIAL PRESSURE 15 LB. ABSOLUTE; SATURATED

Direct-coupled marine turbines especially, from considerations of weight and space, are often bladed to give uniform velocity ratio at full speed with about 26 in. vacuum, and from various causes many land turbines have been similarly bladed. In turbines so bladed and with ordinary steam pressures, it has been found by experience that the gain per inch of vacuum at full load is as follows:

Between 26 in. and 27 in., 4 per cent. or 12 B.t.u.
Between 27 in. and 28 in., 5 per cent. or 17 B.t.u.
Between 28 in. and 28½ in., 6 per cent. or 22 B.t.u.
Between 28½ in. and 29 in., 7 per cent. or 27 B.t.u.

In the turbines so bladed and at constant speed, as in land work, the velocity ratio at the exhaust end would automatically become at half load uniform with the rest of the turbine at about 28 in., and for quarter load, at about 28¾ in., so that in general it may be said that the theoretical gains as given will be completely obtained at reduced loads, but for strict accuracy, each case should be considered on its merits. It may be noted here that, although there is a decrease in efficiency at the exhaust end by having a cramped exhaust and low velocity ratio, there is but little loss when the exhaust end is large and has an unnecessarily high velocity ratio.

Marine turbines running at reduced speeds when the load is reduced may now be considered. Geared turbines can be and should be bladed for high vacuum, and the blading should be for nearly the highest vacuum obtainable in the waters in which the ship trades, as there is but little loss by running a turbine bladed for high vacuum at a lower one. For example, it should be bladed for 28½ to 29 in., the vacuum obtainable in home waters and the like, and not for 27½ to 28 in., which will be the vacuum obtainable in the tropics with a good condensing plant. In such turbines the full theoretical gain due to vacuum will be attained at full speed. At half speed and one-eighth power, if the consumption at full load is assumed to be 12 lb. per shaft horsepower, and at half speed 16 lb., the steam at half speed will be one-sixth that at full speed, and the velocity ratio three times that at full speed for the same vacuum, so that the exhaust end is amply large enough for the highest vacuum which can be attained, and therefore the gain due to increased vacuum will be somewhat more than that at full speed.

In most cases, blading a geared turbine for high vacuum as compared with low vacuum adds little to the weight, and generally only necessitates the exhaust end being made somewhat larger. It is important that the exhaust between the turbine blades and the condenser should be free and unrestricted, so that the loss of vacuum between the last row of blades and the steam space in the condenser should be a minimum. This applies to all classes of turbines.

It is equally important that the loss of vacuum between the steam space in the condenser and the air-pump suction should also be a minimum. In other words, given a condenser and an air pump of the highest efficiency, the difference in vacuum between the air-pump suction and exhaust end of the turbine should be reduced to an absolute minimum. The importance of this requirement should be carefully noted when analyzing data obtained from any particular turbine installation, whether land or marine, as otherwise erroneous conclusions may be formed. For example, if any of the many factors in design which influence the efficiency of any given installation as a whole are not provided for, it is futile to carry a vacuum higher than such provisions warrant: the consequent sacrifice in economy is measured in such cases by what is obtained and what is obtainable Sometimes a definite velocity is fixed on for the velocity of the steam in the exhaust, but this has the difficulty that it depends on the vacuum for which the condenser is designed. A better way is to make the area of the exhaust have a definite ratio to the area of the annulus of the last row of blades, and in direct-coupled marine turbines this ratio is generally 1.5 to 1.7, but in geared turbines it can be increased to about 2.

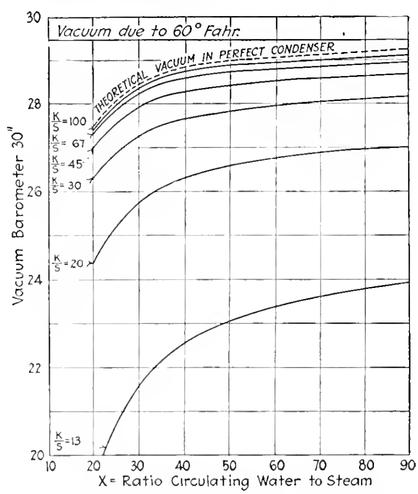

FIG. 3. VACUUMS WITH DIFFERENT AMOUNTS OF COOLING WATER

This means that, if the reduction of velocity can be made to take place gradually as in a diverging orifice, most of the terminal loss at the blades will be recovered, and much can be done in this direction by careful attention to having gradually diverging stream lines of steam from the blades to the condenser. A rule sometimes used on land is to have 18 to 20 lb. of steam per hour per square inch of exhaust area, and in many cases this works well. More careful attention is required in the future as to the shape of the exhaust, for at present many exhausts are so shaped as to cause considerable and unnecessary loss of vacuum.

The case of a direct-coupled marine turbine, only bladed for 26 in. at full speed, is rather different. Here, at full speed, the effect of vacuum will be as given on page 312, but the cases of half speed and one-eighth power have to be specially considered, more particularly on account of such devices as cruising turbines, etc. If we assume the steam per shaft horsepower with Parsons turbines to be 13 lb. at full speed and 21 lb. at half speed, and that the shaft horsepower at half speeds is one-eighth that at full speed, the steam per hour will be one-fifth that at full speed. Assuming that throughout the main turbines generally the velocity ratio is 0.5 at full speed, then at half speed the velocity ratio throughout the main turbines will be 0.25, except at the exhaust end, where it will be 1.25. This means that the full effect of vacuum will be obtained up to over 29 in., and on account of the low velocity ratio, the effect, provided the condensing plant will respond, will considerably exceed the theoretical at lower vacuums.

Up to the present the turbine alone has been considered, but in a complete installation, whether land or marine, there are many other factors to be taken account of. As increase in vacuum is associated with a correspondingly lower temperature of condensate, it follows that if the vacuum is raised

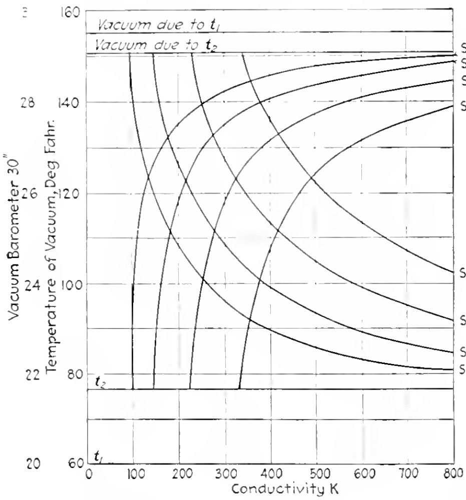

FIG. 4. VACUUMS AND TEMPERATURES WITH VARYING CONDUCTIVITY: CIRCULATING WATER (60 DEG. F.) 60 TIMES AMOUNT OF STEAM CONDENSED

and the condensate is delivered to the boiler at the same temperature at which it leaves the condenser, either the quantity of steam generated in the boiler per unit of coal is decreased or the quantity of coal per unit of steam generated is increased. If the difference between the temperature due to the vacuum and that of the condensate is taken as constant, a reduction of 10 degrees in the temperature of the feed-water delivered to the boiler is equivalent to an increase of about one per cent. in coal consumption per unit of steam generated, or

Between 26 in. and 27 in. = 1 per cent.
Between 27 in. and 28 in. = 1½ per cent.
Between 28 in. and 29 in. = 2 per cent.

Such a condition never arises in practice on land or at sea, as the condensate is invariably heated either by the waste gases from the boiler or by the exhaust steam from the auxiliary engines, or by both. Land installations usually include an economizer in the boiler uptake, and the practical requirement in such a case is that, in order to prevent sweating on the tubes, the feed water should be delivered to the economizer at a temperature of about 120 degrees F. But even at the highest vacuum there is usually sufficient exhaust steam from the auxiliaries to raise the condensate to this temperature, so that such a system represents the highest economy attainable with any given plant.

Marine installations present a different problem by reason of the large quantity of exhaust steam available from the auxiliary engines, and it may be noted that the heat in exhaust steam is used to the greatest advantage possible when it is redelivered to the boiler with the feed water. It follows that in order to attain maximum economy on shipboard, all the exhaust from auxiliary engines should be condensed by the feed water. A perfect installation from this point of view would be one in which the turbine works under the highest attainable vacuum with efficiency, and in which the exhaust steam is maintained at such pressure as will enable its heat to be wholly transferred to the feed water. In fact, the economic pressure for the auxiliaries to exhaust at is that in which the whole of their exhaust can be condensed by the feed. Obviously there should be no surplus exhaust, and if there is, it should never be discharged into the main condenser, because of the highly prejudicial effect of oil on the heat-transferring efficiency of the condenser tubes and on the vacuum. The direction in which progress is to be made on marine turbine installations would, therefore, appear to be, (a) high vacuum turbines; (b) high efficiency condensing plant; (c) economical auxiliaries; (d) efficient exhaust-steam feed-heaters.

In some cases where there is a surplus of auxiliary steam it is turned into the low-pressure turbine, and here there is an apparent partial recovery of the loss, but this arrangement has the defect of fouling both the turbines and the condenser with oil and reducing their efficiency, so that the power of the turbine may easily be reduced to a far greater extent than it can be increased by the use of such surplus steam. If, however, the steam is used in this way, it should be carefully filtered.

In order to consider further the effect of vacuum on an installation, it is necessary to consider the question of the condensers and the power necessary to work them. In a surface condenser there are three losses to be considered: (a) the temperature rise in the circulating water; (b) the resistance of the tube to heat transmission from the steam to the water; (c) air insulation of the condensing tubes.

These may be summed up in the apparent conductivity K of the condenser—that is, the B.t.u. transmitted per square foot per hour per degree Fahrenheit difference of temperature between the steam and the water.

Let

- t_1 be the temperature in degrees Fahrenheit of the inlet water to condenser.
- t_2 be the temperature in degrees Fahrenheit of the water leaving the condenser.
- T be the temperature in degrees Fahrenheit due to the vacuum.
- X the ratio of circulating water to steam condensed.
- S steam condensed per square foot of condenser surface per hour.

(For convenience this is reckoned on the outside of the tubes.)

Then

$$K = 2.3\, S\, X \log \frac{T - t_1}{T - t_2}$$

As it takes in ordinary practice about 1000 B.t.u. to condense each pound of steam we may write

$$1000 = X\,(t_2 - t_1)$$

and writing

$$T - t_2 = \delta$$

the equation becomes

$$K = 2.3\, S\, X \log \frac{\delta + \frac{1000}{X}}{\delta}$$

As the maximum vacuum a condenser can produce is that due to the temperature of the exit water, the object of the designer is to have δ as small as possible. With a condenser in average conditions of cleanliness and efficient air withdrawal, the value of the conductivity K is obviously much higher than with inferior air extraction or a dirty condenser. The conductivity is also influenced by the load. For example, in a heavily loaded condenser, under the best conditions, a value of K of 1500 or even higher has been reached, while in condensers under low load it may be no higher than 300, so that this method of comparison requires to be used with some discretion.

Fig. 3 shows the vacuums obtainable with various values of K, S and X, and Figs. 4 and 5 the effect of conductivity at various rates of condensation for X = 60 and X = 30. All these are for an inlet temperature of 60 deg. F. and similar curves can be plotted for any other temperature, but as they are all similar in character, those for 60 deg. F. are alone given. It will be observed from Figs. 4 and 5 that the effect of reduced conductivity, such as is caused by air, is much more at high rates of condensation than at low, showing that the effect of a faulty air pump or dirty condenser is much more when the rate of condensation is high. It will also be seen that, approximately, the loss of vacuum below that theoretically obtainable depends only on the rate of condensation and on the amount of air insulation, and not on the quantity of circulating water—that is, that δ is approximately independent of X, always assuming a condenser free from oil on the outside of the tubes and scale on the inside. From the curves it follows that there is not much use in having more circulation water than about sixty to eighty times the steam condensed at full load in home waters and the tropics respectively.

Figs. 4 and 5 also show the importance of having ample surface, and confirm what has often been found, that money put into a condenser of ample size is money well spent. Ample surface also gives a good margin to allow of the condenser getting dirty or for overloads. With a high rate of condensation, especially if the condenser is dirty, when an overload is required the vacuum will drop so much that not only is there often difficulty in getting the overload out of the turbine, but the boilers are still further overtaxed due to increased steam consumption causing the steam pressure to drop just at the time it is most important to have full pressure. It is usual in modern power stations to have a vacuum of about 29.1 in., barometer 30 in., with 50 deg. F. cooling water and circulating water 65 times the steam condensed, and 28 in. with 80 deg., 70 times, and it seems as if these conditions cannot be much improved upon, as, if the circulating water were increased in this case from 65 to 100 times the steam, the improvement in vacuum would only be about ⅛ in., and the pumps and circulating pipes would have to be increased 50 per cent. With 65 times as much and a moderate rate of condensation, such as 6 to 8 lb. per square foot at normal load, there is an ample margin for overload, an overload of 50 per cent. only reducing the vacuum by about half an inch.

In cases where there is not a supply of natural cooling water or only a restricted supply, or where cooling towers are used, the question of the best vacuum must be most carefully considered, and so many factors come into the case that each problem must be considered on its merits and alternative schemes worked out to find which is best. Such cases it is not proposed to deal with in this paper.

In the mercantile marine, the only question that has to be considered is the case of full speed at sea, and everything has to be arranged for the highest economy at that speed. In a recent geared turbine meat-carrying ship, the turbine is bladed for about 28½ to 28¾ in. vacuum, and the condensers have a surface of 8 lb. per square foot or 1½ sq.ft. per shaft horsepower, or equivalent to, say, 1.35 per i.h.p., and circulating water equal to 75 times the steam condensed, so as to provide for tropical waters. The vacuum is 29.1 in. with 50 deg. F. sea temperature, 28.8 in. with 60 deg. F., and 28 in. with 80 deg. F.

The weight of the Scotch boilers is 62 per cent., of the main turbines 12 per cent., of the condensers 3 per cent., of the circulating and air pumps with their pipes 5 per cent., and of other auxiliaries, pipes, etc., 18 per cent. of the total weight in engine and boiler rooms.

If the surface of the condensers were halved, giving 16 lb. per square foot, keeping the same circulating water, there would be a loss of vacuum of about one-half inch, and a saving on the total weight by the smaller condensers of 1½ per cent. This would increase the steam consumption by, say, 5 per cent., and therefore the weight of the boilers, by 5 per cent., and the total weight by 1½ per cent., not to speak of the 5 per cent. extra coal that would have to be carried. A reduction in the circulating water would also tend the same way. It is much more economical to save at the low temperature or condenser end of the system than at the high temperature or boiler end, and therefore to have as high an efficiency in the condensing plant as possible and turbines made to suit. The increase of weight in the condensers and turbines is much more than counterbalanced by the saving of weight in the boilers and coal to be carried. High efficiency in the condensing plant means not only sufficient surface and sufficient circulating water, but also most efficient air withdrawal, as, for example, by a steam jet.

The case of warships has also to be considered. In the case of a battleship with direct-coupled turbines, the weight of the water-tube boilers is 35 per cent., turbines 25 per cent., condensers 3 per cent., circulating and air pumps, etc., 4 per cent., and other auxiliaries, etc., 33 per cent. of the total engine and boiler room weights. The condensers condense at full power 18 lb. per square foot, and the circulating water is 65 times the steam. This gives, with 60 deg. F. sea temperature, a vacuum of 28¼ in. Direct-coupled warship turbines are bladed for about 26 in. for reasons given before, but with geared turbines bladed for higher vacuums, it is evident that it would pay to reduce the boilers and increase the condensers. At reduced speeds the condensers are lightly loaded, and here, as explained before, the highest vacuums can be taken advantage of by the turbines. With the lightly loaded condensers, the loss of temperature and vacuum due to the conductivity between the water and the steam through the tubes becomes small, and the important point is efficient air withdrawal.

At half speed or one-eighth power the condensers are only loaded to about 4 lb. per square foot, and as the vacuum is generally only about 28½ in., this means a conductivity of about 150 as against 600 to 800 B.t.u. at full load. But if greater care were taken to install air-withdrawing apparatus of the highest efficiency and ample capacity, such, for example, as is obtainable with a steam-jet combination, this vacuum could be raised to 28¾ or 29 in. with sea water at 60 deg. F., provided the condenser was of suitable design, thereby effecting a gain of at least 3 per cent. on the coal consumption, an amount which would far outweigh the comparatively slight additional cost and weight of the apparatus. This gain is independent of the drop of temperature of the condensate, as at low powers there is always more exhaust steam available than can be condensed by the feed water. Other types of warships can be similarly considered, but the case of the destroyer is especially difficult, as it is essentially a compromise, and here it has been considered economical to load up the condensers at full speed to about 27 lb. per square foot and reduce the circulating water to about fifty times.

With the advent of geared turbines the case becomes different, since they can be bladed for high vacua with little increase in the weights and sizes of the turbines, and it is clear that the greatest benefits from the highest vacua will be found. It is to be expected that in such cases there will be a large increase in the surface of the condensers and improvement in air withdrawal, with a consequent reduction in the boilers and fuel carried.

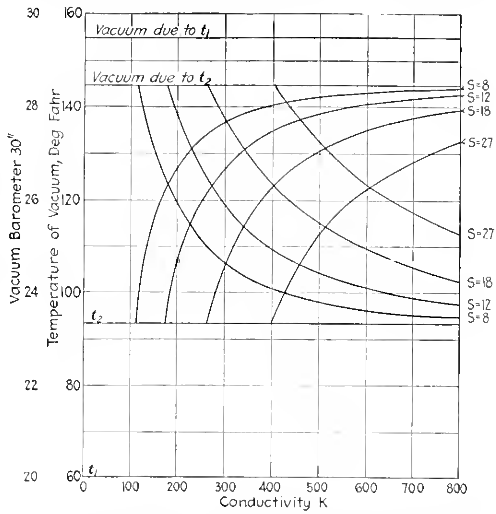

FIG. 5. VACUUMS AND TEMPERATURES WITH VARYING CONDUCTIVITY; CIRCULATING WATER (60 DEG. F.) 30 TIMES AMOUNT STEAM CONDENSED

The aims of an efficient condenser are to have the maximum of heat transfer from the steam to the circulating water—that is, a minimum difference between the temperature due to the vacuum and the temperature of the circulating water leaving the condenser, and also to deliver the condensate to the hotwell as near the temperature due to the vacuum as possible. And here it is important to consider the steam consumption of the auxiliaries and the air-withdrawal arrangements which comprise air pumps in some form, together with the withdrawal of the condensate from the condenser. It is not proposed to enter into the different types of air pumps, but as the driving power of these pumps is at most only about one per cent. of the power of the turbine at full load, and in general much less, the importance of the steam used per unit of power required for driving an air pump is negligible compared with its vacuum-producing qualities. The steam required by the circulating pumps depends on the steam consumption W in lb. per water horsepower-hour, of the engine driving the circulating pumps, the ratio X of the circulating water to the steam condensed, and the total head h in feet on the pumps. We have then

$$\text{percentage of steam used by pump} = \frac{WXh}{20,000}$$

For example, if we take W = 60, X = 60, and h = 20 feet, we have percentage used = 3.6.

For X = 30, the percentage is 1.8.

The difference in the hotwell temperature, between condensers using these quantities of circulating water, is about 17 deg. F., so that without allowing for condensation it may be said that in this case the temperature of the feed, after it has condensed the steam from the circulating pump, is largely independent of the quantity of circulating water, and this has to be considered in making up the final balance sheet, which alone enables the most difficult problem of the best vacuum for any particular installation to be considered.

Midwinter Convention of A. I. E. E.

The third midwinter convention of the American Institute of Electrical Engineers was held at the Engineering Societies Building, New York City, on Feb. 17 to 19. In his opening address, President Paul M. Lincoln referred to the great service of an engineering society in promoting exchange of ideas, the idea usually being worthless unless passed along to receive the benefit of other minds.

The application of electric motors was the topic of the first session, D. B. Rushmore opening it with a paper on "The Characteristics of Electric Motors." This paper, in the nature of an outline, was followed by carefully prepared discussions on different types of motors, each speaker selecting a particular type.

On Wednesday afternoon five papers were presented: "Effect of Moisture in the Earth on Temperature of Underground Cables," by S. E. Imlay; "Oil Circuit-Breakers," by K. C. Randall; "Comparison of Calculated and Measured Corona Loss Curves," by F. W. Peek, Jr.; and "A 100,000-Volt Portable Substation," by C. I. Burkholder and Nicholas Stahl.

Three papers comprised the Thursday morning program: "Distortion of Alternating-Current Wave Form Caused by Cyclic Variation in Resistance," by Frederick Bedell and E. C. Mayer; "Dimmers for Tungsten Lamps," by A. E. Waller; and "Searchlights," by C. S. McDowell.

The Friday morning session was devoted to "Electrical Precipitation," three papers being presented, namely: "Theory of the Removal of Suspended Matter from Fluids," by W. W. Strong; "Theoretical and Experimental Considerations of Electrical Precipitation," by A. F. Nesbit; and "Practical Applications of Electrical Precipitation," by Linn Bradley. The last technical paper was on "Electrical Porcelain," by E. E. F. Creighton.

STATUS OF THE ENGINEER

The most interesting feature of the convention program was the discussion on Wednesday evening of the "Status of the Engineer." The list of speakers showed that care had been exercised to have the subject dealt with from several angles. A. C. Humphreys, president of Stevens Institute, and Prof. G. A. Swain, of Harvard, represented those responsible for the training of engineers; E. W. Rice, Jr., president of the General Electric Co., and E. M. Herr, president of the Westinghouse Electric & Manufacturing Co., represented the largest employers of engineers, and L. B. Stillwell, H. G. Stott and J. J. Carty represented successful engineers now actively engaged in the profession.

Mr. Stillwell in opening the discussion predicted that if the engineer would take a more active part in public affairs, proper recognition would follow. To this end, however, more liberal and less technical education is needed in the colleges. He charged the national engineering societies with having failed to raise the prestige of engineers, pointing out by way of comparison what the Bar Association has done for the legal profession. In this connection he suggested that the engineering societies jointly formulate a code of ethics, which should be enforced strictly, even to the point of expulsion from membership for any violations of the rules. Furthermore, the societies should adopt a policy with regard to license legislation and also advise on public questions such as water-power development, etc.

Mr. Rice in taking up the discussion reviewed some of the engineering achievements and their effects upon modern civilization; yet engineers have practically no voice in running the Government. In the present Congress there is only one engineer out of a total of 435 members in the House and none in the Senate, about 70 per cent. being lawyers. In view of the number of public problems directly or indirectly related to engineering, which are up for consideration it would seem advisable that the representation include some who have had engineering training. "This training," said Mr. Rice, "makes a man search for facts and represents a blending of conservatism and radicalism."

E. M. Herr, speaking from the standpoint of the manufacturer, believed that mathematical training and analysis tend to unfit a man to deal with the human element, and attributed to this fact the failure of many engineers in successfully handling men. He advised the application of the "Golden Rule" as the best solution to this phase of the problem.

Speaking from his experience as an educator, Doctor Humphreys was of the opinion that boys now come to college poorly prepared, because much of their time has been taken up in the preparatory schools with irrelevant studies. He believed that the engineer should receive a more liberal education, but did not advocate a six-year course, adding: "The sooner a man gets out of college after learning the fundamentals, the sooner will he become a specialist." With regard to present regulative tendencies of the government through commissions, Doctor Humphreys seemed to think that it was being carried too far, and often took the form of control rather than regulation. He especially lamented the apparent disposition in some circles to regard business as dishonest, and expressed the belief that with engineers occupying a prominent part in the Government and on commissions, this country would be brought back to a sane regulation of its affairs.

Professor Swain endeavored to show why engineers as a class are not recognized to the same extent as men in many other professions. "Leadership," he said, "depends upon personal qualities, some inherent and others received by training, and it is doubtful whether engineers think straighter than lawyers or business men, or have greater breadth of view. In fact, the engineer is apt to confine himself too closely to technical subjects to the exclusion of outside affairs." As a remedy for this condition, he suggested a broader curriculum in the technical schools, with less details, which can be learned later, and a better training in English and in such liberal subjects as will promote personal qualities. The speaker believed the remuneration in engineering to be fair and comparable with the average in other professions, although admitting that large fees were the exception rather than the rule in engineering. The ability of doctors and lawyers to command large fees was probably due to the character of their work appealing to the emotions, or in the case of the architect to the vanity of the client; whereas in the case of the engineer his work is a cold business proposition and its value is measured accordingly.

Mr. Stott seemed to think the present status of engineers fairly satisfactory, although he believed that engineers in the government service are often deprived of proper credit by their superiors, who often have no technical training whatever. He believed engineers should specialize and, in doing so, should follow their own inclinations.

Mr. Carty spoke of the engineer as concerned with problems of organization, but warned against "scientific management" masquerading as engineering.

The entertainment included a trip to the new power house of the United Electric Light & Power Co. on Thursday afternoon and a dinner dance at the Hotel Astor that evening.

Boiler Inspectors' Banquet

Probably the most successful and most enjoyable so far was the fifth annual dinner of the New York Section of the American Institute of Steam Boiler Inspectors, held at Rectors in New York, Feb. 20. The attendance was large, 110, made up of people interested directly or indirectly in the inspection of boilers. In the role of toastmaster Michael Fogarty distinguished himself as usual. The speakers in addition to the incoming, retiring and past officers of the Institute were: Dr. D. S. Jacobus, of the Babcock & Wilcox Co., who rehearsed something of the history of the American Society of Mechanical Engineers' Proposed Boiler Code, with which he, as a member of the advisory committee, was very familiar; Fred R. Low, editor of "Power," and Herman Van Ormer and John H. Gleason, both of the Boston office of the Hartford Steam Boiler Inspection & Insurance Co., and Inspector Lanigan of the New York boiler squad.

Shrinkage During Solidification—A few exceptions to those substances which undergo the usual shrinkage during the process of solification are pointed out by the "Mechanical World." These exceptions include cast iron, antimony and bismuth. When melted cast iron is poured into a mold it expands in solidifying and presses into every part of the mold. The pattern in the casting is, therefore, as clearly traced as it was in the mold. After it has changed from a liquid to a solid, however, the order is reversed, and in cooling down from the first stage of solidification to normal temperature a shrinkage of about ⅛ in. to the foot takes place.

A clear-cut cast cannot be obtained from lead, which is one of the reasons why antimony is made a constituent of type metal. Gold coins have to be stamped; they cannot be cast so as to produce a clear-cut design, for the same reason.

Opening of the Exposition

At noon, Pacific Coast time (3 p.m. Eastern time), Saturday, Feb. 20, President Wilson pressed a button in Washington giving an electric signal for the opening of the Panama-Pacific International Exposition in San Francisco. In last week's issue a number of the features of the Fair were given as most likely to interest "Power" readers, and more is yet to be printed of certain of the exhibits and the lessons to be drawn from them with respect to past, present and future.

As the day of opening dawned, the city which had been looking forward to it so long seemed fairly to break out with its pent-up enthusiasm. For an hour from 6:30 o'clock, all means of noise-making seemed to be in commission, from steam whistles, automobile horns, car gongs and church bells down to rattles, tin horns and the usual facilities available to the individual. A large crowd had gathered on the grounds hours before the opening, and before the end of the day the attendance had broken all records of like kind, exceeding 300,000, in spite of the clouds and showers.

The dedicatory ceremonies were short and simple. The citizens, headed by Governor Hiram W. Johnson and Mayor Rolph, representing the state and city, were welcomed to the grounds by the officers and directors of the Exposition and officers of the Federal Government. Addresses were delivered by President C. C. Moore of the exposition, Dr. Frederick J. V. Skiff, director-in-chief; Governor Johnson, Secretary of the Interior Frank K. Lane representing President Wilson, and a few others. Invocations and benedictions were pronounced by clergymen representing the Roman Catholic, Protestant and Jewish faiths. President Wilson forwarded a message of congratulation to the directors, which was read to the crowd.

At the Washington end the ceremony was staged in the East Room of the White House, where places were reserved for members of the Cabinet and the California delegation in Congress. Assistant Secretary of the Navy Roosevelt represented the Government Exposition Board. At the President's touch, two signals were sent, one by telegraph to San Francisco and one by wireless to Tuckerton, N. J., and relayed thence to San Francisco.

With the receipt of the signal the Fountain of Energy was started, flags of all the nations were raised on the various poles and pinnacles, signal bombs were exploded from towers, an aëroplane circled the Tower of Jewels, scattering doves of peace, and the doors of the Palace of Machinery swung open, revealing the exhibits within in motion.

PERSONALS

James Smieton, Jr., who has been acting in that capacity for the past year, has been appointed secretary-treasurer of the Society for Electrical Development.

N. H. Brown, until recently Chicago representative of the Bury Compressor Co., has been made sales engineer of the Erie Pump & Equipment Co., Erie, Penn., successor to the Northern Equipment Co. and the Erie Pump & Engine Works.

John S. Huey, formerly with the Allis-Chalmers Manufacturing Co., and more recently with Woodward, Wight & Co., has been appointed by the Kerr Turbine Co., Wellsville, N. Y., as its district sales agent for Louisiana and southern Mississippi. His office is in Room 418, Hibernia Bank Bldg., New Orleans, La.

Matthew T. Slattery, an Ohio state boiler inspector in general charge of the district which includes Cleveland, has been appointed commissioner of the Cleveland smoke prevention division to succeed E. P. Roberts, whose resignation was recently noted.

William M. Davis, an occasional contributor to "Power," has accepted a position as efficiency engineer for the Texas Co. He will have a force of a dozen or more in service, who under his direction will be trained to make surveys and inspections of customers' plants and prepare reports showing how to obtain the best service with the lubricants in use.

John W. Exler has been elected president of the James Lappan Manufacturing Co., of Pittsburgh, Penn. Mr. Exler has been employed as a boiler maker and iron worker for over 40 years. In the '80s he was engaged as foreman with the Niles (Ohio) Boiler Co., and later with Reeves Bros. Co., at Alliance, Ohio. He has also filled some important positions with large Pittsburgh manufacturing concerns.

A. S. Baldwin has resigned as manager of the Best Manufacturing Co., to take effect not later than Apr. 1. This company has recently been absorbed by the Kennedy-Stroh Corporation, which has its complete organization. Mr. Baldwin was for two years superintendent of the American & British Manufacturing Co., Bridgeport, Conn.; four and one-half years general superintendent of the Driggs-Seabury Ordnance Corporation, Sharon, Penn., and for three years general manager of the Alberger Pump & Condenser Co., Newburgh, N. Y. For the present his address is General Delivery, Oakmont, Penn.

Erasmus Darwin Leavitt, of Cambridge, Mass., has been elected an honorary member of the American Society of Mechanical Engineers, of which he was the second president. Mr. Leavitt was assistant engineer in the United States Navy from 1861 to 1867, consulting engineer for the Calumet & Hecla Mining Co. from 1874 to 1904, and has acted as consulting engineer in many large capacities. He is a member of all of the professional engineering societies, and was awarded the degree of Doctor of Engineering by Stevens Institute of Technology in 1884.

ENGINEERING AFFAIRS

Technical Associations' Secretaries—Technical societies and associations have become so numerous and important that a society of Technical Associations' Secretaries has been organized, and held its first annual meeting in the rooms of the American Society of Mechanical Engineers, Engineering Societies Building, 29 West 39th St., New York, on Saturday, Feb. 27.

Transactions of the International Engineering Congress (to be held Sept. 20-25, at San Francisco, Calif.)—Volume I will comprise a unique series of papers on the engineering of the Panama Canal. The various topics and subdivisions of the work have been arranged by Col. G. W. Goethals, chief engineer of the canal, and now governor of the Canal Zone. Col. Goethals has also selected the author for the treatment of each paper, and he will himself contribute the introductory chapter. The various authors are, in general, the officers who were in direct charge of the actual work of construction, and the collection of papers thus becomes a first-hand account of the engineering of the canal, written by the men who were in immediate and responsible charge of the undertaking. There will be 24 papers in all, profusely illustrated, 22 of which deal with actual constructive and engineering problems connected with the work, one with the preliminary work in municipal engineering in the Canal Zone, and one with the commercial and trade aspects of the canal. This volume can be obtained only through enrollment in the congress. The transactions of the congress as a whole will include from seven to nine other volumes, covering all important phases of engineering work. Membership in the congress, with the privilege of purchasing any or all of the volumes of the proceedings, is open to all interested in engineering work. Full particulars can be had upon application to W. A. Cattell, secretary, 417 Foxcroft Building, San Francisco, Calif.

NEW PUBLICATIONS

HOW TO RUN AND INSTALL A GASOLINE ENGINE. By C. Von Culin. Published by Norman W. Henley Publishing Co., 132 Nassau St., New York City, 1915. Revised Edition. Size, 3¼x6 in.; 96 pages, illustrated. Price, 25c.

This little book is printed as a pocket instructor for the beginner or the busy man who uses a marine engine for pleasure and who does not have the time or the inclination for a complete technical perusal of the subject. The method of treating the various topics by the author is such that a man who has no technical knowledge of a gasoline engine may obtain enough information to enable him to operate one successfully, either of the two- or four-stroke-cycle type. Many pointers are given regarding the causes of trouble in gasoline engines, and the remedies. If the reader absorbs all the information contained in the book he should be able to operate his gasoline engine without any particular trouble. The book is well illustrated and contains a remarkable amount of information for such a small volume.

HAND FIRING SOFT COAL UNDER POWER-PLANT BOILERS is the title of Technical Paper 80, by Henry Kreisinger, issued by the U. S. Bureau of Mines, as an aid to firemen throughout the United States. Copies may be obtained without cost by addressing the Director of the Bureau of Mines, Washington, D. C.

The paper, which contains descriptions of methods of firing soft coal under power-plant boilers and of handling fires so as to have the least smoke and to get the most heat from the fuel, seeks to meet the needs of the men, many without technical education, who are employed in small plants. For this reason the language used is plain and simple, and technical terms have been avoided as far as possible.

Under "General Directions on Firing Soft Coal," the following statements are made:

When burning bituminous coal under power-plant boilers the best results are obtained if the fires are kept level and rather thin. The best thickness of the fires is four to ten inches, depending on the character of the coal and the strength of draft. The coal should be fired in small quantities and at short intervals. The fuel bed should be kept level and in good condition by spreading the fresh coal only over the thin places where the coal tends to burn away and leave the grate bare.

Leveling or disturbing the fuel bed in any way should be avoided as much as possible; it means more work for the fireman and is apt to cause the formation of troublesome clinker. Furthermore, while the fireman is leveling the fires a large excess of air enters the furnace, and this excess of air impairs the efficiency.

The ashpit door should be kept open. A large accumulation of refuse in the ashpit should be avoided, as it may cause an uneven distribution of air under the grate. Whenever a coal shows a tendency to clinker, water should be kept in the ashpit. All regulation of draft should be done with the damper and not with the ashpit doors.

In firing, the fireman should place the coal on the thin spots of the fuel bed. Thin and thick spots will occur even with the most careful firing, because the coal never burns at a uniform rate over the entire grate area. In places where the air flows freely through the fuel bed the coal burns faster than in places where the flow of air is less. The cause of this variation in the flow of air through the different parts of the fuel bed may be differences in the size of the coal, accumulations of clinker, or the fusing of the coal to a hard crust. Where the coal burns rapidly, the thin places form.

Before throwing the fresh coal into the furnace the fireman should take a quick look at the fuel bed and note the thin spots. In a well-kept fire these spots can be usually recognized by the bright hot flame. The thick places have either a sluggish smoky flame or none at all. In order to place the coal over the thin places the fireman should take a rather small quantity of coal on his scoop, for it is much easier to place the coal where it is needed with small shovelfuls than with large ones.

The coal should be placed on the thin places in rather thin layers. If the fireman attempts to fill up the deep hollows in the fuel bed at one firing, the freshly fired coal may fuse into a hard crust, thus choking the flow of air, causing the fuel to burn slowly and starting new high places. If the high places in the fuel bed are missed on one or two firings the hard crust at the surface will gradually burn through or crack, thus allowing more air to flow through, and the place will get back to its normal condition. Of course, if the high place in the fuel bed is caused by clinker the flow of air will not be free until the clinker is removed with the fire tool. Whatever may be the cause of the high places in the fuel bed, the fireman should remember that they are places where the coal does not burn. There is no use in putting coal on such a place.

If the firings are too far apart the coal in the thin spots may burn out entirely, allowing a large excess of air to enter the furnace in streams. If those streams of air are not properly mixed with the gases from the coal, only a small percentage of the air is used for combustion, and most of it passes out of the furnace, depriving the boiler of considerable heat. If, for instance, air enters the furnace at atmospheric temperature, say 75 deg. F., and leaves the boiler at about 575 deg. F., it carries away the heat that was absorbed in raising its temperature 500 deg. F. This heat is lost to the boiler. Another loss of heat occurs when holes form in the fuel bed, because pieces of unburned coal fall through the grate when the fireman attempts to cover the holes with fresh coal. Therefore, in order to avoid the formation of holes, firings should be made at short intervals, particularly if, for any reason, the fuel bed must be kept thin.

NEW PUBLICATIONS OF THE BUREAU OF MINES

Fourth Annual Report of the director of the Bureau of Mines to the Secretary of the Interior, for the fiscal year ended June 30, 1914; 101 pages.

Bulletin 84, Metallurgical Smoke. By Charles H. Fulton; 92 pages; 6 plates; 14 figures.

Bulletin 85, Analyses of Mine and Car Samples of Coal Collected in the Fiscal Years 1911 to 1913. By A. C. Fieldner, H. I. Smith, A. H. Fay and Samuel Sanford; 44 pages; 2 figures.

Technical Paper 80, Hand-firing Soft Coal under Power-Plant Boilers. By Henry Kreisinger; 83 pages; 32 figures.

Miners' Circular 21, What a Miner Can Do to Prevent Explosions of Gas and of Coal Dust. By G. S. Rice; 24 pages.

Publications should be ordered by number and title. Applications should be addressed to the Director of the Bureau of Mines, Washington, D. C.

A Simple Test for Animal and Vegetable Contents in oil is to shake up with the sample in a test tube about one-fifth or one-quarter of its own volume of a saturated solution of borax in water. The presence of animal or vegetable matter is indicated by an opaque white line of saponification, which forms between the water and the oil after they are allowed to separate. Paraffin in oil may be detected by heating a sample up to 450 deg. The presence of paraffin is indicated by a material darkening in the color of the oil.

TRADE CATALOGS

Chain Belt Co., Milwaukee, Wis. General Catalog No. 56. Elevating, conveying and concrete machinery. Illustrated, 304 pp., 6x9 in.

Jeffrey Mfg. Co., Columbus, O. Bulletin No. 147. Swing hammer pulverizers for coal, etc. Illustrated, 48 pp. Bulletin No. 167. Belt conveyors. Illustrated, 24 pp.

Wm. B. Scaife & Sons Co., 221 First Ave., Pittsburgh, Penn. Pamphlet. "Pure Clear Ice." Illustrated, 12 pp., 5x8 in. Pamphlet. Central Power Station Economy. Illustrated, 8 pp., 4x9 in.

CATALOGS WANTED

The Compressed Gas Manufacturers' Association, Incorporated, requests manufacturers of valves, cylinders, recording gages, filling and weighing stands and of material and appliances which enter into the manufacture, transportation and sale of compressed gases to send catalogs, price lists and full descriptive details to the secretary of the association, 25 Madison Ave., New York City.

BUSINESS ITEMS

The Kerr Turbine Co., Wellsville, N. Y., has appointed W. E. Storey as its Toronto, Canada, representative, with offices in the Kent Building. Mr. Storey was formerly identified with the Underfeed Stoker Co., and more recently with Goulds Manufacturing Co.

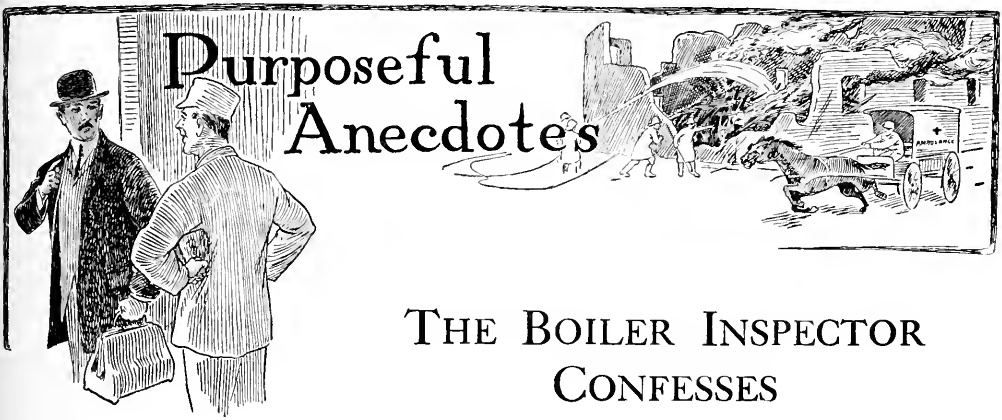
The Nelson Valve Co., of Chestnut Hill, Philadelphia, has issued a revised edition of its twelve page folder entitled "Double Disc vs. Solid Wedge." It contains an interesting history of the development of the gate valve. Copies will be mailed on request

A very attractive circular has just been issued by the Homestead Valve Mfg. Co., Pittsburgh, Penn., illustrating many styles of Homestead Valves. "Here is Your Opportunity to End Your Valve Troubles" is the title. It is being sent to steam users everywhere.

The Yarnall-Waring Co., of Chestnut Hill, Philadelphia, has recently secured an order for "Lea" V-notch meters from the Philadelphia Electric Co., for its great new Christian St. power house, for what is believed to be the largest feed-water V-notch metering installation in the world, comprising two 800,000-lb. per hr. "Lea" V-notch recording meters combined with two 20,000-hp. Webster feed-water heaters and purifiers, to heat and measure 20,000 boiler hp. of feed water. Make-up water for this plant will be measured by a 175,000-lb. per hr. "Lea" V-notch recording meter.

POWER

Vol. 41 NEW YORK, MARCH 9, 1915 No. 10



The Boiler Inspector Confesses

The old boiler inspector looked at me over his glasses with all the seriousness of a strong man approaching the confessional. He WAS going to confess.

° ° ° °

"NO, SIR, I never made half-way inspections. But as a young man I passed conditions I knew were not real bad, but bad enough to warrant giving attention. If a boiler were shut down at such a time, it meant delay. The engineer or the superintendent complained and everybody got a grouch. If I felt that the boiler would go until my next visit, which might be in six months, I'd pass it to make everybody happy. There was nothing seriously wrong in doing this, for if I doubted that the boiler would last until my next visit, it had to be made right, kick or no kick.

"This went on for years. In one plant, the B—— works, I'd thus favored the engineer a few times. The next time I was in the town I was anxious to get over to this plant for I knew the boilers needed inspection. About four o'clock that day and just as I was washing up after I'd finished the A—— company's boilers, Wilkens, the engineer, came rushing into the washroom and asked:

"'Did you hear about it?'"

"'About what?'"

"'Why, two boilers at the B—— works just exploded. They say 14 women were killed.'"

"I didn't reply; I couldn't. My knees shook; I grew hot and cold—I was sick! When I arrived at the works, fire lines had been established and there was a heavy police guard which wouldn't let me through. I looked into an ambulance and saw three forms covered with a sheet.

"Walking around to the next block I got into the yard through an alley. In the débris I hunted for the remains of the boilers, one of which I knew had a thin crown sheet—the sheet I'd inspected and passed. As I stooped to pick up a steam gage, my hand nearly touched an arm, the hand of which bore a wedding ring. I drew back trembling until the dampness at my feet caused me to look down. My shoes were soaked in blood! Oh! but I was sick. I felt worse than a murderer—I had murdered fourteen!

"Nearly crazed, I ran to the street and boarded a car for the hotel. I tried to hide behind a newspaper, but it rustled loudly in my shaking hands. I turned, pretending to look out the window, but the reflection of my face in the glass frightened me more than the staring eyes across the aisle.

"Investigation showed that the fireman had opened the blowoff valve, and before closing it rushed away on a signal from the engineer. Before he returned the explosion had happened. This knowledge relieved my mind, but I had learned my lesson.

"Now I take no chances; I strike the sheets or blowoff pipes solidly. If they are badly corroded, I must know it. Yes, they say I'm too exacting. Some complain to our head office, but I'm going to inspect rightly or I'm not going to inspect at all.

"A good engineer never complains about a thorough inspection. Some poor ones do, but we must protect them against their own shortsightedness."

Salmon River Power Plant

By Warren O. Rogers

SYNOPSIS—The principal features of this hydro-electric development are: A concrete dam 50 ft. high and 675 ft. long, which creates a storage reservoir having a capacity of 2,600,000,000 cu.ft.; two miles of conduit for conveying the water from the dam to the power plant, consisting of a section of reinforced-concrete-lined tunnel, a section of 11-ft. and 12-ft. diameter wood-stave pipe and a section of 11½-ft. diameter steel pipe; a gigantic surge tank 50 ft. in diameter and 105 ft. high, mounted on a structural tower 100 ft. high; four 8-ft. diameter steel penstocks equipped with valves of a new design; the power house, containing four 10,000-hp. horizontal turbines equipped with heavy flywheels, each driving a 6600-kv.-a. generator, together with the transforming, switching and control apparatus; and, finally, a transmission line 42 miles in length operated at 60,000 volts.

The completion of the new Salmon River hydro-electric plant (Fig. 1), of the Salmon River Power Co., located near Altmar, N. Y., and about forty-five miles northeast of Syracuse, has attracted considerable attention to this source of water power, which, with the exception of Niagara Falls, is the greatest in the State of New York.

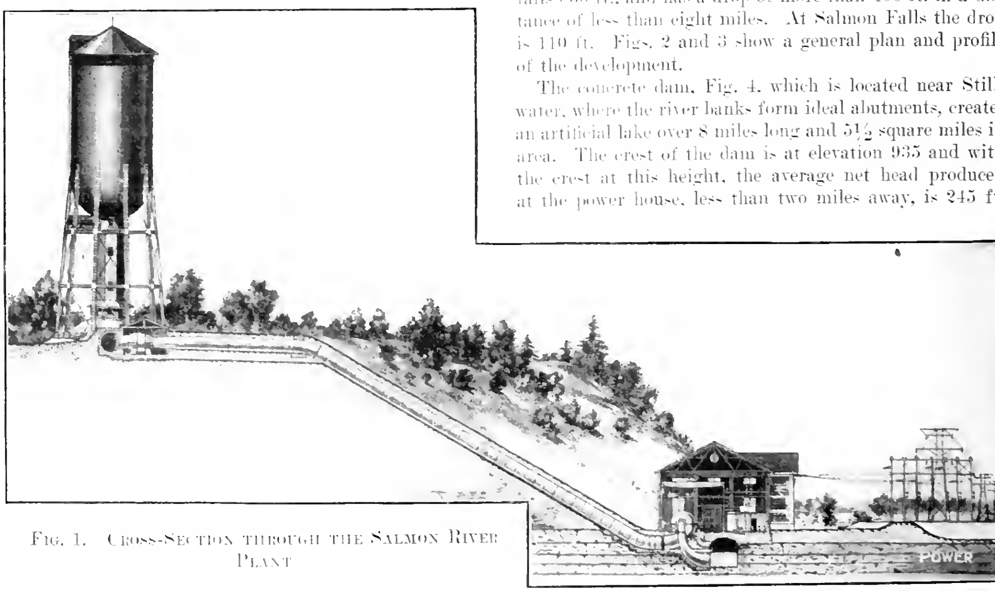


Fig. 1. Cross-Section through the Salmon River Plant

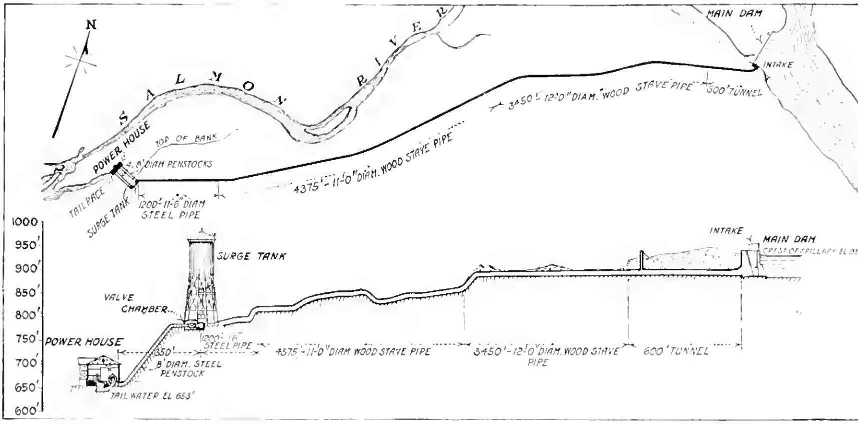
The power from the Salmon River will join that coming from Niagara, as the Salmon River plant has been designed to operate in parallel with the Ontario Power Co., of Niagara Falls. The latter, located in Canada, generates power for transmission over lines owned and controlled by separate and independent companies. All lines in Canada are owned by the Ontario Transmission Co., Ltd., a subsidiary corporation. In the United States the power coming from the Ontario Power Co. is distributed by the Niagara, Lockport & Ontario Power Co., over about 816 miles of transmission lines through the western and central sections of New York State. The latter company has leased the entire property of the Salmon River Power Co. in perpetuity and acquired all its capital stock, thus securing for itself a new source of power at the eastern end of its transmission lines, supplementing that which it now receives from Niagara and from its own steam plants at Lyons and Auburn.

Water Supply

The Salmon River, which is 44 miles long, has its source in the foothills of the Adirondack Mountains and flows through the north-central part of New York State, discharging into the eastern end of Lake Ontario. The river drains a watershed, the tributary area of which is 190 square miles and in which there is an average annual rainfall of about sixty inches. In the 17 miles between Stillwater, where the dam is built, and Lake Ontario, the river falls 650 ft., and has a drop of more than 400 ft. in a distance of less than eight miles. At Salmon Falls the drop is 110 ft. Figs. 2 and 3 show a general plan and profile of the development.

The concrete dam, Fig. 4, which is located near Stillwater, where the river banks form ideal abutments, creates an artificial lake over 8 miles long and 5½ square miles in area. The crest of the dam is at elevation 935 and with the crest at this height, the average net head produced at the power house, less than two miles away, is 245 ft. The dam, constructed of concrete, is 675 ft. long and has a maximum height of 50 ft., with an average thickness of 51 ft. The cubical contents are 30,000 yd.

Water is conveyed from the reservoir first through the intake where the screens and head gates are located, into a 600-ft. section of reinforced-concrete-lined tunnel drilled through the rock and having an internal diameter of 12 ft. The lining of the tunnel is in no instance less than one foot in thickness and is reinforced with circumferential rods closely spaced. From the tunnel the water passes into a 7825-ft. length of wood-stave pipe, 3450 ft. having an internal diameter of 12 ft. and the remainder 11 ft. Fig. 5 shows the manner in which the wood-stave pipe is held circumferentially with ⅞- and 1-in. steel bands. Each band is in three sections, all united by malleable-iron shoes. Where the soil is soft the pipe is supported by timber cradles. At all other points it is laid on the ground and banked with earth. To equalize external pressure when emptying the pipe and to permit air to escape when filling, relief valves are provided at intervals. The lower end of the wood-stave pipe is connected through a specially constructed joint, packed with oakum and lead wool, to a 1200-ft. section of 11½-ft. steel pipe, which conveys the water to the crest of the hill behind the power house. At this point, Fig. 6, there are a number of novel and original features.



FIGS. 2 AND 3. GENERAL PLAN AND PROFILE OF THE SALMON RIVER DEVELOPMENT

SURGE TANK

First, there is a distributor, Fig. 7, which is a 12-ft. steel pipe of ⅝-in. steel plate, 210 ft. long and joined at one end to the pipe line in a huge concrete anchor block, the other end being closed by a bulkhead. The bottom of the distributor is 160 ft. below the crest of the dam. From the center of the distributor a 12-ft. riser branches off to the surge tank, Fig. 8, the largest of its type yet constructed. The surge tank consists of a cylindrical shell 50 ft. in diameter and 80 ft. high, surmounting a bowl bottom of 25 ft. in depth, making a total height of 105 ft. and having a capacity of 1,400,000 gal. of water. It is supported on 10 massive steel columns spaced as shown in Fig. 7, which elevate the bottom of the tank 80 ft. above the ground level. The total height of the complete surge-tank structure is 205 ft.

The thickness of the bowl bottom plates is ⅞ in. and the longitudinal seams are triple-riveted butt-strap joints; the horizontal seams are quadruple-riveted lap joints. The first, or bottom course of the shell, is of 1-in. plate with triple-riveted butt joints. The thinnest plate in the tank is ½ in. thick. The portion of the riser inside the tank is stiffened every 4 ft. by 4x4x½-in. angles to take care of any temporary differences in the elevation of water inside the riser and in the tank proper.

The 12-ft. riser from the distributor connects with the surge tank by means of a special expansion joint. In order that the accelerating or retarding head required to produce the new velocity in the pipe line and demanded by a change in load on the plant may be more quickly established, the 12-ft. riser is reduced to a diameter of 10 ft. inside the tank. This interior riser is flared at the top to a diameter of 15 ft. and terminates 5 ft. below the top of the tank proper. In the annular opening formed between the 12-ft. riser and the 10-ft. riser at the bottom of the bowl, ports have been provided, so that water moving toward the tank flows partly into the main tank and partly into the interior riser, and conversely, water flowing downward through the 12-ft. riser flows partly from the 10-ft. riser and partly from the main tank through the ports.

FIG. 4. SALMON RIVER CONCRETE DAM

The surge tank acts as a hydraulic regulating device for the plant and to protect the long pipe line from shock. When the plant is in operation and a sudden demand for more power occurs, requiring more water, this

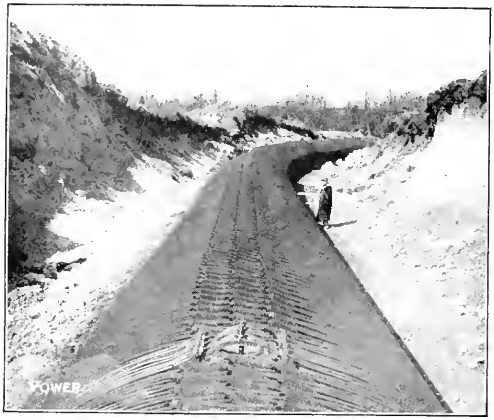


Fig. 5. Twelve-Foot Wood-Stave Penstock

is supplied largely from the surge tank, while the velocity in the pipe line is increasing to the required degree. When the power load is suddenly diminished or thrown off the plant, the surplus water surges into the tank, producing a rapid rise in the interior riser and a slower rise in the main tank. The head produced in the riser checks the velocity of flow in the pipe line and limits the pressure.

If, under very severe and unusual conditions of load change, the water in the riser should reach the top, it would spill over into the main tank and be retained.

The ports at the bottom of the tank are carefully designed so as to introduce just the right amount of resistance to the flow of water to or from the tank proper in order that any surges produced in the hydraulic system by sudden demands for and rejections of power may be effectively damped before serious oscillations in the water column are set up. Also, by the use of this "differential" principle both the maximum head and the required storage capacity in the tank are reduced, making

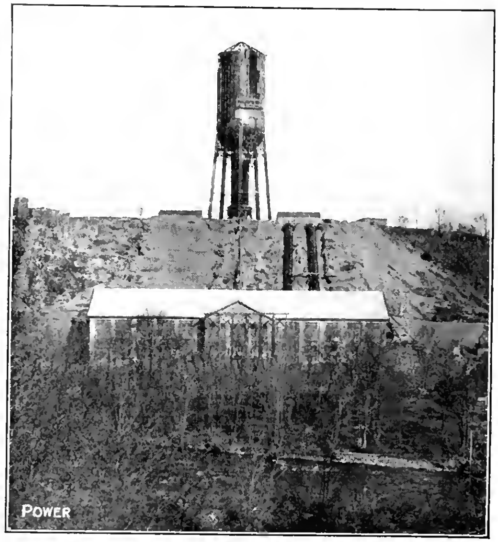

Fig. 6. Surge Tank on Hill Back of the Power Plant

possible lower construction costs and better hydraulic regulation.

Another interesting feature in connection with the surge tank is the provision which has been made to prevent freezing. The tank is housed in with a framed wooden structure, which provides a series of air spaces

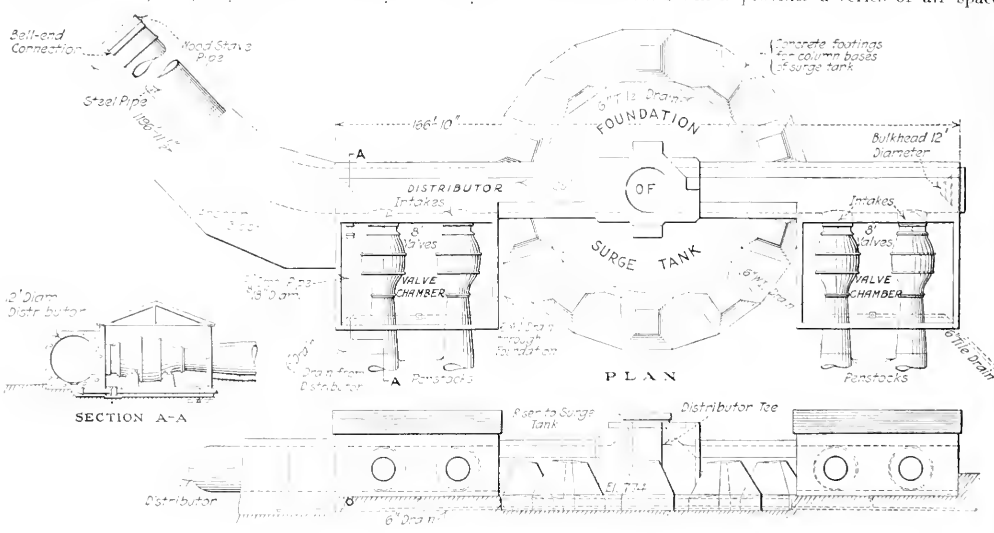

Fig. 7. Plan and Elevation of the 12-Ft. Distributor

through which warm air is blown whenever necessary by fans located at the base of the tank.

Hydraulic Valves and Penstocks

Four 8-ft. penstocks are connected to the distributor through hydraulic valves of a new design. The normal head under which these valves operate is 154 ft. An exterior view of one of the valves is shown in Fig. 9; a sectional view in Fig. 10. The valve consists of a casing which supports an internal stationary shell *A*, headed against the flow of water, as indicated by the arrow. A hollow movable plunger *B* carries a bronze ring *C*, which seats against a ring *D*. The movement of the plunger is controlled by a four-way valve and suitable piping. The pipe *E* is connected to the penstock on the intake side of the valve, the pipe *F* is piped into the space behind the plunger, *G* into the space between the plunger and the shell, and *H* discharges to the air.

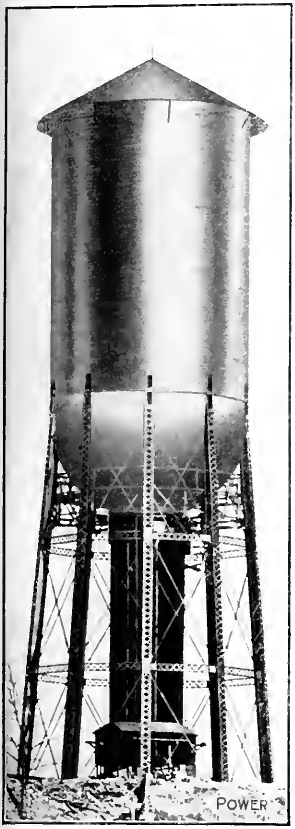

Fig. 8. Near View of the Surge Tank

To close the valve the pressure in the pipe *E* is put in communication with the pipe *F*, and pipe *G* with *H* by means of the four-way valve, thus putting pressure behind the plunger and gradually closing the valve. When opening the valve the pipe *E* is put in communication with *G*, and *F* with the pipe *H*. The plunger can be stopped at any point between its full open and closed position, its exact position at any time being designated on the indicator shown in Fig. 9. The four-way valve is either hand or motor driven and can be electrically controlled from the main switchboard in the power house. In order that the switchboard operator may know that the valve is operating properly, a pilot lamp, controlled by suitable contacts on the valve indicator, is installed on the control switchboard in the power house.

From the valve chambers four 8-ft. steel penstocks, which are anchored above and below in heavy concrete blocks and laid in trenches which are back-filled, run to the power house. Two are seen in Fig. 6, as they had not been covered with earth at the time the photograph was taken. The thickness of the steel plate of which the penstocks are constructed varies from $\frac{1}{2}$ in. on the upper horizontal end to $\frac{7}{8}$ in. at the lower end, where they enter the power house.

Power House

The power house is constructed of reinforced-concrete columns connected with heavy concrete beams. The panels around the large window areas are filled on the inside with sand-lime brick and with red brick on the outside. The building is rectangular, with a projecting feeder bay. In the feeder bay and along one side of the main generator room is a gallery about 12 ft. above the main floor. A 10-ton electric crane, with main and auxiliary drive of 250-volt direct-current motors, spans the generator room, which is 38 ft. wide.

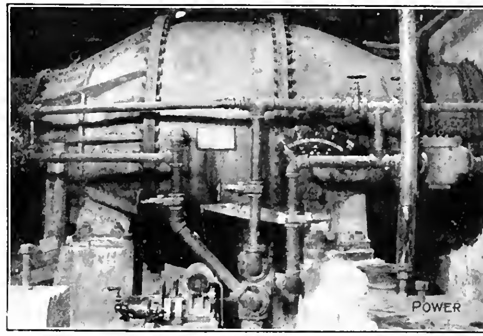

Fig. 9. An 8-Ft. Johnson Penstock Valve

All intake pipes, draft tubes and discharge tunnels are under the building, embedded in or formed of concrete which rests on solid rock; the arrangement of this is shown in the plan and elevation views, Figs. 11 and 15.

Main Units

There are four turbines of 10,000-hp. normal rating of the Francis horizontal, single-spiral, double-discharge type, which are provided with outside-balanced wicket gates operated by hydraulic governors.

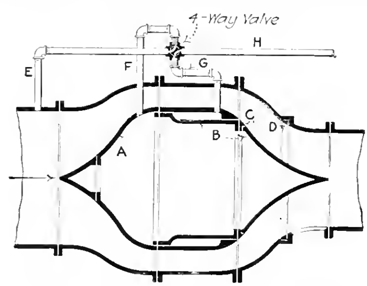

Fig. 10. Sectional View of the Penstock Valve

The turbines have guaranteed efficiencies of 82 per cent. at full load, 85 at three-quarter load, 80 at half load and 70 at quarter load. On the turbine shafts are mounted heavy flywheels to assist in governing and to facilitate the operation of the electrical equipment of the plant in parallel with other plants on the transmission system. Relief

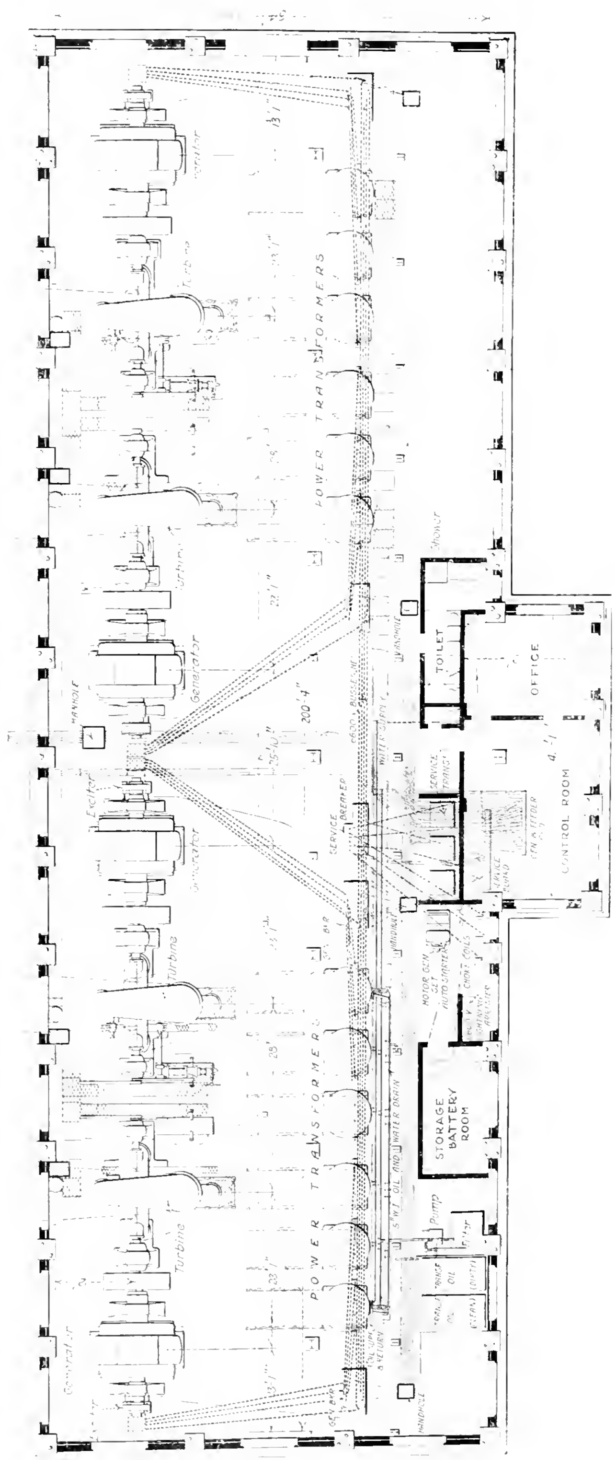

Fig. 11. Plan of the Power Plant Showing the Arrangement of the Main Units and Accessories

valves on the turbines, operated by the governors, prevent excessive pressure rises upon sudden closure of the turbine gates. Nos. 1 and 2 units are shown in Fig. 14.

The hydraulic governors, Fig. 12, are adjusted to permit of not more than 15 per cent. increase in speed above normal on the sudden removal of the full load carried by the generator, 6 per cent. for half load, 3 per cent. for quarter load and 1.5 per cent. for one-tenth load.

The turbines discharge into a tailrace through short concrete draft tubes, entering at an obtuse angle to prevent eddies. The tailrace is under the power house, which is built over the bed of a branch of the river. The exit of the tailrace from the building is closed by a curtain wall which prevents the ingress of cold air.

The four generators directly coupled to the turbine shafts are 6600-kv.-a. capacity, 6600-volt, 25-cycle, three-phase units. The exciter of each machine is mounted on an extension of the shaft, Fig. 14, and is adapted to voltage and power-factor control by a voltage regulator. The pole faces of each generator are provided with damping grids. The generators are of the semi-inclosed type, and the cooling air is discharged through a large opening in the top of the casings. They are designed to operate either as generators or synchronous condensers, in order that they may be used both for generating electrical energy and for power-factor correction on the long transmission line from Niagara. Each is designed to carry 20 per cent. overload and is also capable of operating at full current output up to 7500 volts. The limits of voltage regulation allowed at normal kv.-a. load were for 100, 90 and 80 per cent. power factor, 12, 25 and 28 per cent., respectively.

Station Electrical Equipment

The electrical equipment for each generator further consists of three 2200-kv.-a. single-phase, 25-cycle, oil-cooled transformers, Fig. 13, with a normal ratio of 6600 to 34,650 volts, the high tension in star giving 60,000 volts on the line; a 6600-volt, 1200-amp., triple-pole, single-throw circuit-breaker, automatic for reverse power, and the necessary connecting cables and auxiliaries. The duplicate high-tension busbars are hung from the roof, over the gallery, upon which are located the high-tension line and the transformer circuit-breakers and line choke

coils. Directly under the buses are the necessary disconnecting switches.

For station service there are three 100-kw. self-cooled transformers which step the voltage from 6600 down to 220 volts. They are delta connected on both sides.

On the main floor, under the gallery, are the generator circuit-breakers, main and service transformers and a storage battery for switch operation. The control switchboard is on the lower floor of the feeder bay, and is of the vertical panel, remote-control type.

Transmission Line

The transmission line from the power house to the substation of the Niagara, Lockport & Ontario Power Co., at Solvay, N. Y., is about 42 miles long and comprises two circuits carried on steel towers with suspension insulators.

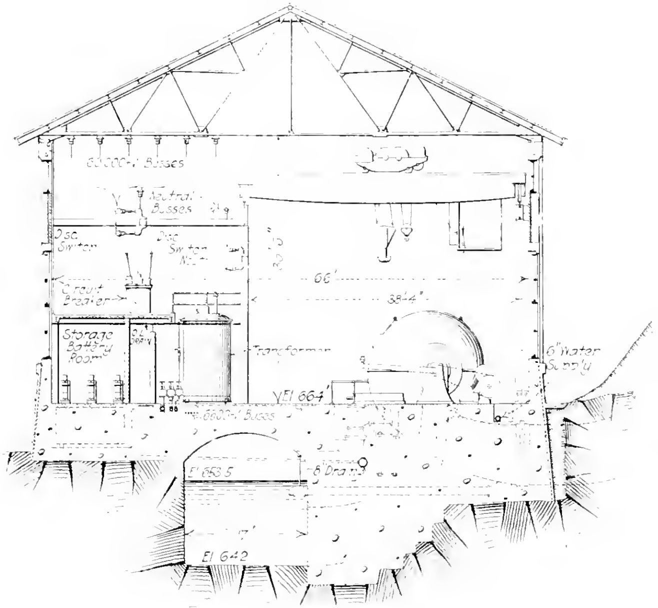

Fig. 15. Elevation of the Power Plant

The plant was first put into commercial operation in April, 1914, with two units running. The third and fourth units were placed in service in October, 1914, and the plant is now carrying a maximum load of 23,000 kw.

The engineering work was carried on under the direction of V. G. Converse, chief engineer of the Salmon River Power Co. Messrs. Barclay Parsons & Klapp had charge of the engineering and construction of the dam, and also acted as consulting engineers for the entire work.

Human Energy in Electrical Units—On an average a man dissipates about 2.5 kw.-hr. per day. This is spent partly in muscular action, partly in the production of heat in the maintenance of the body temperature against radiation. There is thus a continual power consumption of about 100 watts, or one-seventh of a horsepower. About one-half of this is spent in maintaining the body temperature. The human body has about the same heating effect upon the surroundings as a 16-cp. carbon filament lamp.—"Scientific American."

A Low-Pressure Turbine Manifestation

By Ide L. Benedict

Instances are frequent where power-plant machinery has been improperly selected. This may not have been the result of ignorance or misrepresentation, but of failure to give due consideration to the probable operating conditions. Cases of the installation of units of incorrect size are probably more numerous than those in which an unwise choice of the type of prime mover has been made. It would seem that we rely too much upon attaining ideal conditions, when estimating the performance of a new type of machine. There may sometimes be good reason for this and the expectation is realized. On the other hand the conclusion may have been reached from a superficial survey of the operating factors, and the actual results fall far short of the prediction. Examples can be cited of new gas-engine installations of excellent operating record which were soon displaced by steam turbines on account of the rapid increase in the price of gas.

On the advent of the low-pressure turbine too much was expected of it, not only in effecting a remarkable saving in fuel consumption, but also in providing a new lease of life, from an economical viewpoint, for existing engine equipment. While the majority of the low-pressure turbines have been economic successes, there are one or two exceptions from which a lesson may be drawn

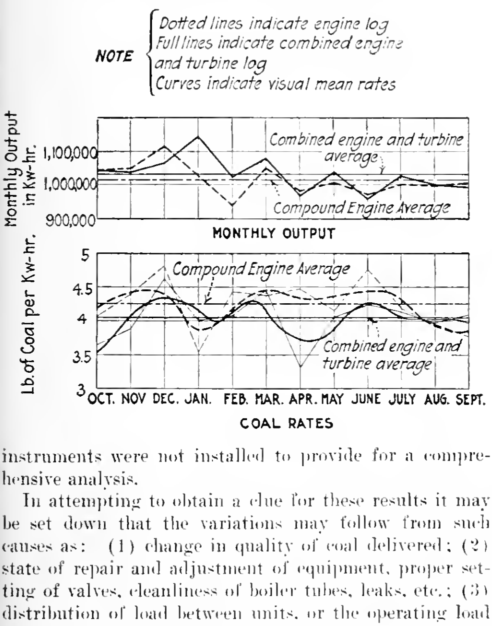
First, the low-pressure turbine is dependent upon a favorable vacuum being maintained, and secondly, a good load must be carried upon the unit. Otherwise the potential economy is sacrificed.

The accompanying curves, taken from the records of such a low-pressure turbine plant exemplify this phase of power-plant engineering and operation. The average saving in coal consumption throughout the year was somewhat less than 4 per cent., representing a reduction from 4.25 lb. to about 4.1 lb. per kilowatt. Under favorable conditions, the low-pressure turbine should effect an improvement of over 25 per cent. and lower the coal rate to 3 lb. or better. An analysis shows that the load is a widely swinging one and the fluctuating condensing-water conditions preclude high vacuum being regularly maintained. Furthermore, the power consumption of the condenser auxiliaries is abnormal on account of the rise and fall of the water-supply level, and as the station furnishes only a direct-current output and the turbine is coupled to an alternator, converting machinery with its attendant losses is required. So the operation of the low-pressure turbine is prejudiced, and it would be an unfortunate commentary upon this type of prime mover if all of these controlling factors were not made clear.

As will be observed, the load on the plant did not vary sufficiently to have any appreciable bearing. The difference in coal rate from month to month is partly explained by the irregularity with which coal is received.

The curves show twelve months preceding and twelve months succeeding the installation of the low-pressure turbine. Some theories may be advanced as to the reason for the apparent irregularities. The high coal rates obtain at about the same time as the heavy load. As a station's economy should ordinarily improve with an increase in output, the cause for the variation may be due to engines pulling loads at long and uneconomical points of cutoff, or the hand-fired boilers may have been forced to a point where their efficiency fell off rapidly.

Sometimes the winter coal rate will increase on account of the greater radiation losses and the introduction of colder air into the furnaces, if the condensing equipment is not capable of operating on a low-terminal temperature difference, and therefore does not utilize the benefit of the low circulating-water temperatures. But apparently, these circumstances do not exert much bearing in this case. Sufficient measuring and indicating instruments were not installed to provide for a comprehensive analysis.



In attempting to obtain a clue for these results it may be set down that the variations may follow from such causes as: (1) change in quality of coal delivered; (2) state of repair and adjustment of equipment, proper setting of valves, cleanliness of boiler tubes, leaks, etc.; (3) distribution of load between units, or the operating load factor of the different units; (4) the efficiency of the operators during the periods under comparison.

Visual mean curves have been drawn so as to counterbalance the irregularities in billing the coal and other charges from month to month. The coal rates when running with and without the low-pressure turbine approach each other closely except in April, when a happy set of conditions seems to have been hit upon in the operation of the low-pressure turbine. As compared with the noncondensing engine, the economy of the low-pressure approaches the proper point, taking the maximum dip of the solid line, while in the month of August the comparison is somewhat startling. The station is subject to a rapid swinging of the load over 15 per cent. either side of the mean, and this no doubt has an important effect upon the coal consumption.

The way in which the load divides between the engines and the turbine may account for a good part of the discrepancy, particularly as the entire output of the low-pressure turbine, which is direct-coupled to an alternating-current generator, must flow through a motor-generator set, with a loss of 20 per cent. or more, depending upon the load carried.

Oil and scale on the blades of the turbine would noticeably affect the ultimate economy, but during the period under discussion the turbine was in good condition.

The unit under consideration is of 1000-kw. capacity; steam pressure carried, 150 lb. gage; and vacuum sought, 28 in. (30 in. bar.), though it ranges around 27 in. and less.

In view of this development, which might have been foreseen had these conditions been reckoned with, the natural inquiry is what would have been the most appropriate machine to have installed? The plant was equipped with single-cylinder Corliss engines. Undoubtedly, a straight condensing turbine would have best satisfied the requirements and provided a unit *per se* modern, and would have obviated the perpetuating of the use of the reciprocating engine, as has become necessary with the installation of the low-pressure turbine. Besides, floor space might have been economized, and it would also have made it simple to carry out further extensions both in consistency of type and arrangement.

One thing that should lead to careful consideration in engineering work is that any failure to fully regard all governing conditions will probably be cast up later as a display of lack of ability, and consequently the installation becomes a conspicuous error.

Redesigned Barton Expansion Steam Trap

This thermostatic trap was described in the April 25, 1911, issue of POWER, and was then manufactured by John W. Barton, Cleveland, Ohio. It has been slightly redesigned, and is now manufactured by the Automatic Steam Trap & Specialty Co., Detroit, Mich. The former trap consisted of an inner and an outer expansion tube and a casing holding the two heads. The redesigned trap has but one inner brass tube, an outside steel tube and a valve. A short extension screwed onto the brass tube seats against a flat disk, which is adjustable for different temperatures of steam. In other respects the trap is the same as the original one. The brass tube is free to expand and as its length increases more rapidly than that of the steel tube, when heat is applied it will seat against the disk. Reinforcing rings around the brass tube tend to prevent buckling.

When the trap is first installed the disk is adjusted so that the valve will close when the brass tube is full of steam. When this steam cools into water the brass tube shortens, pulls away from the valve disk and allows the condensation to escape. Steam following the water again expands the tube and closes the valve. This operation is repeated, and the system to which the trap is attached is kept free of water.

Anthracite—When the first two tons of anthracite coal were brought into Philadelphia in 1803 the good people of that city, so the records state, "tried to burn the stuff, but at length, disgusted, they broke it up and made a walk of it." Fourteen years later Col. George Shoemaker sold eight or ten wagon loads of it in the same city, but warrants were soon issued for his arrest for taking money under false pretenses.

Suggestions on Overhauling a Refrigeration Plant

By Thomas G. Thurston

SYNOPSIS—An article alive with practical suggestions for finding the weak and the leak spots in a refrigeration system, and putting the plant in good condition for the next season's run.

The time is here when the demand on the refrigerating system is lowest. Preparations should be made for the time when part or all of the system can be shut down for repairs to put it in good condition for next season's run.

Notes should be made of the defects and troubles that have been contended with during the season and steps taken to remedy them. Joints that cannot be kept tight with reasonable tension on the bolts should be marked for attention when the system is shut down. Leaky valves should receive the same treatment. If the ammonia charge is loaded with oil and impurities, pump it out and have it purified.

The Ammonia End of the Compressor

Open and go over every part of the compressor: Examine the cylinder for shoulders and score marks; see that it is round and of uniform diameter throughout its length. Examine the piston and rings and see that the former is a snug fit in the cylinder and that the rings fit in the piston grooves. See that the rings have sufficient tension; if they have not they can be peened out a little with a hammer, although this is a makeshift. Examine the connection of the piston to the rod and make sure it is firm. Caliper the piston rod and if it is worn or scored have it turned or replaced with a new one.

If the old rod is turned, be sure and make a junk ring for the bottom of the stuffing-box to keep the packing from squeezing out between the smaller rod and the bottom of the box. If the rod is much smaller than the original the stuffing-box gland should be babbitted to about one-sixteenth inch larger than the rod.

If the machine has false heads inspect them and the seats for score marks and signs of ammonia blowing through. Grind them in with emery or powdered glass and oil, or, if they are too bad, they will have to be faced first.

Go over the valves, seats and cages thoroughly. If the valves and seats are not much worn they can be ground in; otherwise, get new ones. See that the valves fit snugly on the guides and that the springs have the proper tension. The correct spring tension can best be determined by the indicator. Any other way is merely guesswork.

In most designs of valves there should be a small hole in the valve or guide to let the latter act freely. If this opening is neglected the gas in the valve or guide will compress or form a vacuum, depending on which way the valve is moving, and interfere with its free action.

Examine the check valve in the discharge; see that it seats properly; grind the valve in or rebabbitt the disk if necessary; be sure that it does not fit too loosely on the guide, for if it does it may hammer and will not seat properly. Clean, oil and grind in the relief valve and see that it works freely. If the suction line has an automatic check valve in it, this should be cleaned and oiled and the valve and seat examined.

Some plants have an elaborate system of piping for oiling the stuffing-boxes and for relieving gas from them. These should be cleaned, as they generally accumulate packing and dirt. Clean out the oil separator; if it cannot be opened it can be fairly well cleaned by blowing it out with a steam hose. Clean, oil and test all the gages. Test all the thermometers if any are used.

The Steam End of the Compressor

The engine cylinder, piston and rod should receive the same attention as similar parts of the compressor. Examine the valves and valve gear thoroughly. Caliper the crosshead guides, and if they are much more worn in the center than at the ends, have them bored or planed. If the crosshead shoes are badly worn they should be babbitted. Caliper the crosshead pins, and if they are not round, have them turned. They may be dressed with a file. See that they fit tightly in the hole in the crosshead. While the machine is dismantled run a line through the cylinders and see how the cylinder guides and main bearings align.

Take the main bearings apart, clean them and see that the oil grooves are open and sufficiently deep. Examine the cranks to determine if they are loose on the crankshaft, or if the crankpins are loose in the disk. When the crankshaft is placed in the bearings be sure to adjust the quarterboxes so that the shaft will line up with the cylinder. After the engine is assembled, adjust the clearance on both the compressor and engine. On an engine and a double-acting compressor this is practically fixed; on a single-acting machine the clearance is adjustable and should be set as close as possible consistent with safety. Some operators have run the piston clearance as low as $^1/_{64}$ in., where the machine is equipped with false heads. The writer believes it should never be less than $\frac{1}{16}$ in.

The Condenser

The condenser should be examined before it is shut down, and all joints that have caused trouble by leaking should be marked. This applies to the joints that may be tight, but have been drawn up with more than a reasonable tension on the bolts to keep them tight. Leaky valves should also be marked. Open a few of the coils, and if there is much oil or foreign matter present they should be cleaned.

Make a steam connection to the gas header, shut off all the gas valves, open the ends of the liquid header or disconnect the coils altogether. Then blow out the coils one at a time by turning steam on the header and opening the gas valves in succession until the oil and foreign matter are blown out. When this is done disconnect the steam connection and pump about 100 lb. of air pressure on the header and blow the coils as before.

Clean the scale and mud from the outside of the pipes with a wire brush if it is an atmospheric condenser. If it is of the double-pipe type remove the return bends and clean the inside of the pipes with a tube scraper or a turbine cleaner. Open the water headers and clean out the sand and scale that have accumulated in them.

Remove the bonnets from the valves on the gas liquid line and pump out headers. Examine the seats and disks and if they are scored or show signs of blowing through or the babbitt is squeezed out, they must be ground in or rebabbitted. Renew the gaskets on all the bonnets. If it is important to keep the machine running continuously during the season, renew the gaskets between the valves and headers unless certain that the gaskets are in good condition and will not blow out if they start to leak, but may be drawn up without undue strain on the bolts.

The gaskets between the valves and the individual stands are not so important, as a blowout on this side of the valve puts only one coil out of service. For this reason the gaskets between the valves and headers should receive particular attention. If a gasket blows out between the stand and valve or any place in the stand, it is only necessary to shut off the gas and liquid valves, pump out the coil and repair the blowout, when convenient to do so. In the meantime the rest of the condenser may be kept in operation. For this reason it is also important that the valves be tight. The gaskets in the headers should also receive the same attention.

Renew the packing on all the valve stems, also the gaskets in all the leaky joints. Draw up all bolts and if any are rusted so they cannot be turned with reasonable effort, replace them with new ones. Inspect the pipes and headers thoroughly for pitting and corrosion, especially at the water and ammonia joints. If any of them are badly eaten away put in new ones.

Testing for Leaks after Repairing

After everything has been thoroughly examined and repaired, pump an air pressure on the condenser a little higher than the maximum head-pressure carried. This will show bad leaks or joints that have not been tightened. Make thick soapsuds and apply with a brush to all the joints under pressure. Leaks will be indicated by the formation of soap bubbles. After all the leaks that have been found are taken up, pump the pressure up again, shut the discharge valve on the machine and see that the bypass valves are tight, also the blowoff valve on the oil trap and other connections to the discharge line. If there are no leaks and all the valves are tight, the pressure should hold for a long time. If the pressure falls rapidly there is a valve open somewhere or a bad leak, and this must be found.

If the pressure falls gradually, a few pounds an hour, it is generally caused by small leaks that will take up after the condenser is in operation or can be found with a sulphur stick after the ammonia is turned into the condenser.

After the high-pressure test, let the air out of the condenser and pump a vacuum on the latter and let it stand for several hours to see if it will hold; sometimes a line or coil that will stand a high-pressure test will not hold a vacuum for even a short time. About the only way to locate these leaks is to hold a lighted candle to the suspected joint; if it leaks the flame will be drawn in. If the vacuum test is satisfactory, pump all the air possible out of the condenser, and turn the ammonia into it immediately (to keep air from leaking in), until the pressure comes up to five or ten pounds. Now go over every joint with a sulphur stick.

Leaky Water Pipes in Condenser

Tests must now be made for leaky water pipes if it is a double-pipe condenser. The return bends must be off and the sulphur stick held in front and at both ends of each pipe in succession. Corroded pipes must be replaced by new ones.

When the leaks have all been attended to, pump full pressure on the condenser and test it again. If this test is satisfactory put on the return bends and test these and the water headers with water pressure.

Expansion Coils

Unless one is certain that there is no oil present in the expansion coils, it is better to open a few of them and investigate. If there is oil it should be blown out. Make a steam connection to the coils, disconnect all the coils in the case of a brine tank, and first blow each out with steam. If it is desired to remove every trace of oil, pump a solution of caustic soda through the coils after blowing them. In either case they must finally be thoroughly blown out with air.

Renew the gaskets on all the joints opened and tighten the rest. Go over the suction and expansion valves and repair those that may require it. If brine tanks are used, clean them out thoroughly. Pipe hangers and supports around a brine tank deteriorate rapidly and should be looked after. Any of the headers on the liquid or suction sides of the tank that have caused trouble by leaking should be attended to. After the coils have been cleaned, test them as the condenser was tested, although it is not necessary to use as high pressure.

Lines and Auxiliaries

Joints in the lines that have caused trouble during the season should have the gaskets renewed. Remove the bonnets from the stop valves and examine the seats and disks. Note the position of the valves in the line. Nearly all ammonia valves are of the globe or angle type and should be placed in the line so that the flow will lift the disks off their seats in case they come loose from their stems. If the valve is placed in the line in the reverse position and the disk comes loose from the stem, it will act the same as a check valve and stop the flow. This is dangerous, especially in a discharge line. Inspect the lines for pitting and corrosion. If any are rusted badly they should be renewed; if any of the liquid or suction lines are uninsulated they should be covered; if the liquid receiver is in the engine room it also should be covered.

Inspect the brine pump closely for pitting and honeycombing in the surfaces exposed to the action of the brine. The writer remembers one case where the wall between two valve chambers became so weakened from this cause that a large piece blew out and disabled the pump.

A High Boiler Pressure is to be carried on the battleship "Nevada," now nearing completion—295-lb. gage. Oil-fired Yarrow-type boilers will be used.

Retubing Tubular and Water-Tube Boilers

By J. C. Hawkins

SYNOPSIS—Simple and thorough directions for taking out and putting in tubes in various kinds of boilers. What troubles to expect when expanding and beading tubes. How to get a bagged tube through the tube sheet. The use of tools to do this kind of work.

Renewing Tubes in Horizontal Tubular Boilers

The location of the tube to be renewed will govern to some extent the procedure in getting it out. If the tube can be taken out at the lower manhole it can be cut off at both ends inside the heads with a bent chisel or with an inside tube-cutter, Fig. 2. The bead on the outside of the sheet is then cut off with a chisel and the tube ripped through the seat. The ripper, with dimensions, is shown in Fig. 1. In ripping the tubes the workmen should be careful not to cut the tube seat. After the cut is made the ends are closed, Fig. 3, and the piece knocked out. If the tube cannot be taken out at the manhole it must come out through the tube hole.

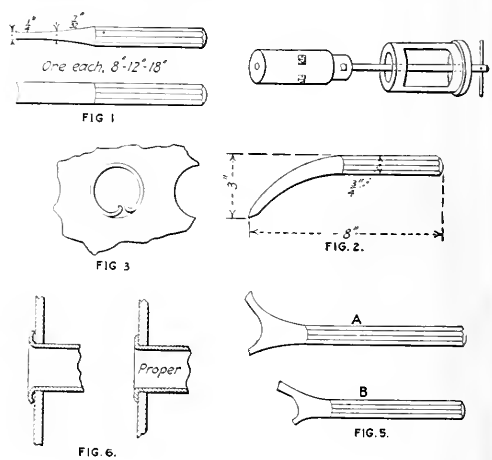
Tubes are usually covered with hard scale and are sometimes bagged or blistered, so it may save time to run the tube-cleaner through the tubes to be taken out. When a tube is to come through the tube hole it is not cut inside, but the ends are ripped and closed up and the tube forced out through the hole.

This may be done in many different ways and the one to be chosen will depend chiefly on the condition of the tube. It may be forced out a few feet with a sledge-hammer and a block of hard wood on the back end, but there is but little room at the back chamber to insert a long block or bar to drive it out. It may be possible to get a flat bar down between the tubes by getting on top of them and swinging the bar against the end of the tube. A chain hoist or block-and-fall hitched to the projecting end of the tube and to the wall will help. If the tube is badly scaled, striking it with a hammer close to the head will help to knock off the scale. Sometimes, turning the tube with a pipe wrench or chain tongs will screw it out of the sheet, especially if a chain hoist is attached to the end to pull it along. After it has been forced part of the way out the projecting end can be cut off with a pipe cutter and a new hitch taken on the remaining part.

As the back end will be battered up in driving the tube out it will not come through the hole without being closed up; this can be done from the outside with a hammer and chisel. Often, more damage is done to the tube hole in getting an old tube out than by working the boiler several years. After the old tube is out the seat is cleaned and the new tube slipped in. Some engineers recommend that the ends of new tubes be annealed in a charcoal fire before putting them in, to make them more homogeneous and prevent them from cracking while being expanded. This is not necessary if precautions are taken to put the tube in properly so that it will not be stretched excessively in expanding.

In some fire-tube boilers copper ferrules are used to fill the space between the tube and the sheet. This is not necessary unless the tube hole has been stretched by repeated expanding. Strips of copper or copper ferrules should be used to fill the space. Whatever the material, it should be softer than the head to prevent stretching the tube sheet. Copper gives the best results. The tubes in a fire-tube boiler should project through the head about one-quarter inch on each end to allow for beading after the tube is expanded. If it extends more than this, the tube is likely to be cracked in beading over. The ends should be expanded tight before beading. Before starting to expand the tube, see that both ends extend through the proper distance, then have a helper hold the front end tight with a bar to prevent it from slipping while the other end is being expanded. In placing the expander in the tube care should be taken to have the rolls extend an equal distance at the sides of the sheet and that the tube expands gradually all around to prevent splitting.

There are two types of expanders—the prosser and the roller, or dudgeon, Fig. 4. The former does its work by a turned taper wedge being driven into the center of a block made up of a number of wedge-shaped sections. The roller expander, which gives the best results and is generally used, consists of a frame carrying three steel



Tools for Cutting and Beading Boiler Tubes

rolls forced out against the tube by a taper plug. The plug is tapped lightly to set the rolls out against the tube and is turned to roll the tube against the seat. If the tube hole is not round the tube will be expanded tight into all the cavities by the roller.

One difficulty sometimes encountered by an inexperienced man in using the roller expander is that when the tube is a loose fit the plug is driven in snug at the start. This will tend to stretch the tube at three points, and when turning the plug the rolls will not move out of these spots. If this occurs the rolls will have to be loosened, set in a different place and the tube gradually rolled until these spots are worked out. Sometimes this causes much trouble, but if the plug is tightened gradually as it should be, no trouble will be given.

Sometimes the workman is at a loss to know when to stop rolling. As soon as the tube is rolled out tight the rolls will seem to be turning on a smooth surface and the plug will be tight when tapped with a hammer. It is best to stop at that time and examine the joint. If there appears to be spots that are not rolled out tight the expander should be used again. Afer the tube is expanded the ends should be beaded over flat against the head. This can be done best with a beading tool, Fig. 5. The bit of these tools should be about 3/8 or 1/2 in. wide. Tool *A* is used first to draw the edges over, striking lightly to prevent splitting, and *B* is used to draw it down flat against the tube sheet. Fig. 6 shows proper and improper beading.

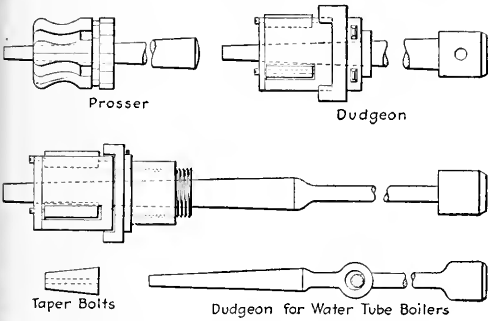


FIG. 4.

TUBE-EXPANDING TOOLS

Replacing Tubes in Water-Tube Boilers

Water-tube boilers are built in so many different shapes that no rule applies to all boilers. In the Babcock & Wilcox, Heine and some others of similar design, all the tubes except those in the bottom and top rows will have to come out through the tube hole. Those in the bottom row usually have to be replaced much more often than the others.

The easiest way to get out a bottom tube is to cut it at both ends with the ripper, Fig. 1, made long to extend through the water leg and close the ends up. The tube may then be cut in pieces and easily taken out by cutting it in the furnace near the bridge-wall and again back of the bridge-wall. If the boiler has horizontal baffles on the lower tubes it need not be cut. The most convenient way of cutting a tube is with the five-wheel pipe cutter, Fig. 7, but it may be done with a plain three-wheel cutter by turning the tube with chain tongs. Tubes above the bottom row must come out through the tube hole.

It is a hard job to get bagged tubes through the tube holes. If the enlarged part can be reached with a long chisel between the tubes it may be split and closed up to go through the header. After being driven as far as possible from the back end it will have to be treated in the same way as in fire-tube boilers. It has been necessary, where the tube was badly bagged, to put a clamp on and use a jackscrew on each side to get it out.

Tubes in water-tube boilers are not beaded as in fire-tube boilers, but are "belled" or flared out; that is, expanded to greater than the original diameter outside the header. This is done by first expanding the tube in its seat, then pulling the rolls out so that the end projecting beyond the header, which may be from 1/4 to 3/4 in., will be expanded to a diameter about 1/4 in. larger than the tube. In putting in the new tube care should be taken to replace the baffle brick, which may fall out when the old tube is removed. The best expander for water-tube boilers is made as shown in Fig. 1. This is similar to the plain dudgeon, but the end which carries the adjusting collar enables the collar to be set at any distance from the rolls. The advantage of this is that the center of the rolls may be set over the tube seat irrespective of the distance the tube projects through the header. The plug used in this expander is made long enough to extend through the header to give plenty of room for operation.

The tubes in the vertical boilers of the Wickes and Cahall type are removed through handholes in the head of the steam drum and the new tubes are put in in the same manner as in horizontal water-tube boilers except that the tube must be blocked up in place in the mud drum while the upper end is being expanded and belled.

In Stirling boilers the tubes are so spaced (except in some of the older types) that any tube may be taken out without disturbing any other tube. A Stirling boiler of given horsepower may be high and narrow or low and wide. As the tubes are not all the same shape or length, it is necessary to order them from the makers, stating the type and size of the boiler and for which row they are wanted. The rows are numbered from back to front, No. 1 tube being the one nearest the back wall between the back drum and the mud drum, No. 2 is next toward the grates, etc. They are numbered in the opposite direction to the flow of gases.

To get these tubes out, rip the ends about six or eight inches at the lower end and four inches at the top end. Close up the end and push it down into the mud drum until the top end comes out. Swing it around and pull it out, then twist it around until it will slip out between the other tubes and through the door in the setting. This is sometimes quite a puzzle, but unless the tube is badly warped it will come out easily. The new tubes are marked "Top" on the end that goes into the steam drum and can be put in only one way. Each is also marked with the number of the row in which it belongs. Roll them in as mentioned. They must be blocked up in place and the top end rolled, first being particular to get the bend in line with the others. If this is not done trouble will be experienced in taking out the tube next to it. The first two or three rows next the fire are most likely to give trouble and are generally badly warped. These tubes should be belled in expanding, not beaded.

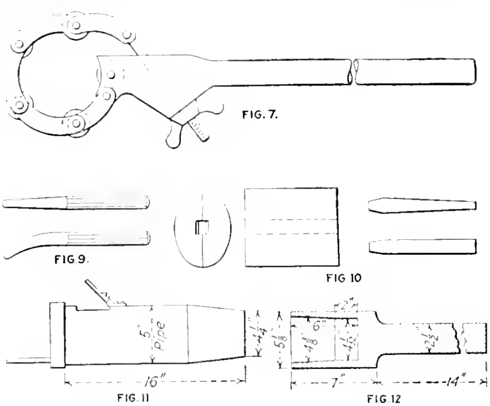
In any boiler where the seat is in good condition and the tube properly expanded there is small chance of leakage, but as a precaution the boiler should be given a hydrostatic pressure test at one and one-half times the working pressure.

Calking and Riveting

Each time the boiler is out of service the tube ends and joints should be examined for leakage, which usually shows as a grayish-white substance on the fire side of the plate. If the seams appear to have been leaking, they should be calked with a round-nose tool, Fig. 9. The calking should be done while the pressure is off or very low. If on testing after calking it is found that the leak cannot be stopped, some of the rivets may have to be replaced. If it is a lap-riveted, longitudinal seam the leak may be caused by a lap crack and the inspector should be called in to examine it. Although reriveting may be done by the engineer, it is best to call in a boiler maker. Should the shell over the fire become bagged and require a patch, the job should be turned over to a boiler maker. If the bag is not bad enough to need a patch, it may be driven up by heating it with a blow-torch, beginning at the outer edge and gradually driving it up. Have a template made of the radius of the outside of the shell as a gage.

Replacing Headers in Water-Tube Boilers

At the first glance this appears to be a hard proposition. Renewing a header in a Babcock and Wilcox boiler is no worse than renewing several tubes when they have to come out through the tube holes. These headers are cast steel and must be ordered from the factory, stat-



Tools for Removing Boiler Tubes

ing the number of tube holes and whether the header is for the front or back end. Sometimes the front headers become cracked at the lower end by the brick below the header falling out, exposing the end to the heat of the furnace, and as the pockets below the lower tube usually contain some scale, the header becomes overheated. A header may be ruined by having a piece cut out of the tube seat in ripping out an old tube.

In one instance five headers were cracked on the front end and two on the back end, when the blowoff pipe pulled out of the flange fitting, draining the boiler and causing the tubes to overheat. The feed water was on at the time and as this came in contact with the overheated headers they cracked.

To replace these headers an assortment of special tools is required. As the tubes are usually in good condition, except possibly the bottom one, the header is split off the tubes. This is done by a block made to fit the tube cap-hole and split in half, having a taper slot and wedge as shown in Fig. 10. The tube cap-hole is nicked with a chisel at the top and bottom and will usually split from one hole to the next. This leaves the tubes in good order but with the ends expanded. The nipple connecting the top end of the header to the steam drum is then split with the ripper, closed up and then pulled out.

After the old header is removed the ends of the tubes are swedged down to the original size. They are heated in a charcoal furnace, Fig. 11, made of a short piece of 5-in. pipe having one end drawn down to $4\frac{1}{4}$ in. and the other capped. In the lower side of the cap is connected a 1-in. pipe 3 ft. long to act as a handle and to which the air pipe is connected. A hole in the top of the 5-in. pipe with a hinged cover admits fresh fuel. The air supply is taken from the air-compressor line or other source. A piece of firebrick is placed in the tube about a foot from the end and the heater slipped over the end of the tube. It will only take a few minutes to heat the tube to a bright red.

The swedge used to draw the end down should be made as shown in Fig. 12. This is turned out of a solid piece of machinery steel. The bore is tapered from $4\frac{3}{8}$ in. at the mouth to 4 in. at the end of the taper, and straight from there to the bottom. This is driven on the hot tube with a sledge and if driven quickly only one heat will be necessary. To prevent the rear end from being loosened while swedging, block it by bracing to the wall or a solid part of the boiler. After the tube ends are drawn down, all the tube and nipple holes are cleaned out in the new header and it is slipped onto the ends of the tubes, which will have to be raised up and entered with a bar. Two pieces of wood 2x4 in. and about three feet long are made with holes bored to slip over the stud of the tube-hole caps, one in the new header and one on each of the old ones on each side, top and bottom. This brings the header up to place and square with the tubes. Care must be taken to get the header exactly in line, because if this is not done, much trouble may be given in putting in new tubes at any future time; they will bind on the adjacent tubes and will not go through the baffle-walls if the header is crooked.

After the header is in place and properly squared up with the tubes, the nipple holes should be lined up with the throat piece, and also with the mud-drum end if it is a rear header. Sometimes, with these holes in line, the tubes do not sufficiently extend through the holes to allow them to be belled. The cause may be that the header on the opposite end has been pushed out in swedging the tubes and can be sprung back. If this cannot be done, it will be necessary to push the header on farther and roll the nipples in at a slight angle. Cut the nipples from a piece of new tube and expand them in place with the adjustable expander, using the jointed plug shown in Fig. 4. The top end should be expanded first. The bottom end of the top nipple may be rolled through the top tube-cap hole with the jointed plug. In rolling the mud-drum end of the bottom nipples with the loose collar of the adjustable expander reversed to increase the distance between the collar and the rolls, taper rolls are used instead of straight ones. The plug is entered through the lower tube-cap hole. This will bell the projecting end of the nipple. Before expanding the nipple in the header make sure that it is square with the tubes, especially if it is on the front end.

After the work is completed a hydrostatic test of one and one-half times the working pressure should be given. Some of the joints on the opposite end from the new header may show signs of leakage and will have to be re-expanded. This work of replacing headers may be done under the supervision of the engineer

New Traveling Screens at Delray

By C. F. Hirshfeld*

SYNOPSIS—Endless screens specially designed to simplify the washing operation. If desired they may be washed continuously while in operation.

An interesting installation of traveling screens for screening the circulating water has just been completed at the Delray plant of the Edison Illuminating Co., of Detroit. This plant contains eight vertical-type Curtis turbines with an aggregate rated capacity of around 93,000 kw. The circulating pumps which serve the condensers of these units have an aggregate capacity of about 173,000 gal. per min.

This large quantity of water is drawn from the Detroit River, on the bank of which the plant is built. After flowing through the condensers it is returned to the river at a point farther down stream. At all times of the year the water is apt to contain large quantities of floating and submerged débris of one sort or another, and in the fall of the year it generally carries large quantities of grass and other marine growths which have broken loose from the flats at the lower end of Lake St. Clair and at the entrance to the river. At certain periods large quantities of fish of various sizes also appear at the plant.

To prevent the clogging of pump runners and of condenser tubes, it is therefore necessary to screen the water thoroughly before it is circulated through the plant. Before the installation of the traveling screens this was done by passing the water first through gratings or trash racks and then through vertical screens. A so called screen house is located at the plant end of the intake canal. The water flows through arches under one wall of this house and then through the gratings, which give it a rough screening. These gratings are about 6 ft. in width and

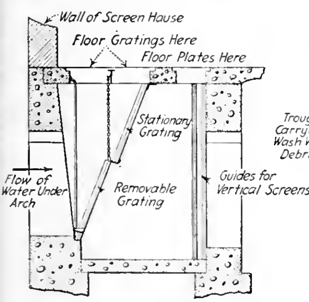


Fig. 1. Arrangement of Screens

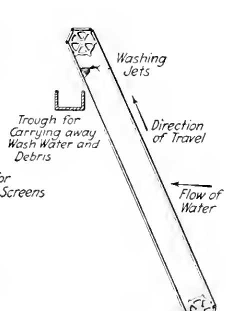

Fig. 2. Endless-Belt Screen

a little over 7 ft. in length. They are made of 3/8x3-in. flat iron bolted together with broad sides adjacent and with 3/4-in. spaces between neighboring bars. They are set with the edges of the bars toward the current and at an angle as shown in Fig. 1, two gratings being joined end to end to give a total length, or height on the incline, of about 14 1/2 ft. There are twelve of these units arranged along the length of the screen house. Removable gratings in the floor above facilitate inspection and cleaning.

After passing through the gratings the water strikes the vertical screens. These consist of copper-wire screen fastened upon a rectangular frame made of channel and angle irons. The frames are about 9 ft. wide by about 12 ft. high and are divided into four rectangular panels

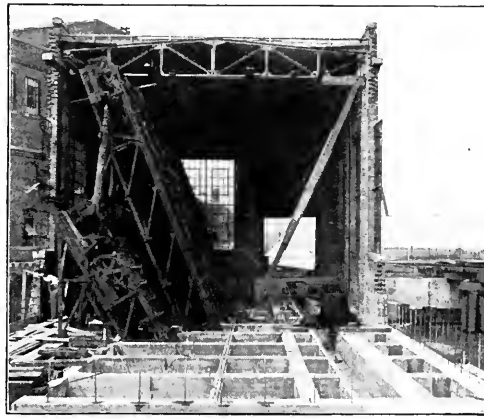

Fig. 3. Screen House Partly Completed

by horizontal and vertical cross-members. Each panel is braced by two diagonals. This construction affords a stiff frame and does not give large unsupported areas of screen. The wire screen is so woven that the mesh is rectangular and the openings measure approximately 1/4 in. in each direction.

These screens are arranged in units of two each. The back of one screen of a unit is placed adjacent to the face of the other screen of that unit, thus making the water flow through the two in series. The two screens of a unit are dropped into vertical channels which serve as guides and support them in a vertical position with their lower edges resting on the bottom of the water way. This arrangement makes possible the raising of one screen of a unit for washing without entailing the closing of gates or the passing of unscreened water. There are six of these units distributed along the length of the screen house on a line parallel to that of the gratings already described.

In ordinary operation all of the screens were washed three times per day, but when the water contained large quantities of marine growths it was often necessary to wash screens continuously, and even then the water in the rear of the screens frequently fell to an alarming extent.

When a screen is to be washed, the checkered iron floor-plates above it are first raised and moved out of the way by a small hand-operated winch carried on a car rolling on a track laid in the screen-house floor. One screen is then raised by means of a traveling crane and placed in

*Research engineer of the Edison Illuminating Co. of Detroit.

a wash box, which is mounted on wheels and travels along the rails just mentioned. This box is open on the side opposite the rear of the screen when in position, and the screen is washed by means of a fire hose and nozzle which plays the water against the rear of the screen, thus driving out all débris which has been caught in the mesh and forcing all accumulations off of the face or front side of the screen. The wash water, with its burden of trash, flows to waste through a spout fastened to the bottom of the wash box.

The new screens were designed to simplify the washing operation. They can be washed continuously while in operation, if desired. Each unit consists of an endless belt carried over sprocket wheels at the top and bottom of a frame, as shown in Fig. 2. The belts are made of panels formed of a light frame and wire screen similar to that used on the older screens.

The belt can be moved by means of a geared motor in the direction indicated in Fig. 2, the speed being 12 ft. per min. The débris collected on the face of the belt can thus be carried up over the top and down the back and washed off into a trough, as shown in the drawing.

For ordinary water conditions, the screens stand stationary most of the time, each screen being moved and washed once in four or five hours. In case of very bad water, it is, however, possible to wash all screens continuously, thus precluding the possibility of getting low water in the plant because of fouled screens.

Seven of these screens have been installed in a new screen house located over an enlargement in the old intake canal, and there is room for the installation of three more. Each frame with its motor and screen belt forms a unit and is located in a separate compartment or canal between concrete walls. These walls carry inclined guides on which the frame of the unit is supported and on which it can be slid upward and out of the water for inspection, painting or repairs. The passing of unscreened water when a unit is raised is prevented by closing a gate at the entrance to the canal or passage in which that unit is housed.

The screen house is shown partly completed in Fig. 3, with one screen lowered into place and the rest raised in the position they would occupy when being inspected or repaired. The circulating water flows from under the trestle at the right, through the screens, and into the old screen house, which can be seen to the left. The interior of the completed screen house is shown in Fig. 4, with seven screens in operating position.

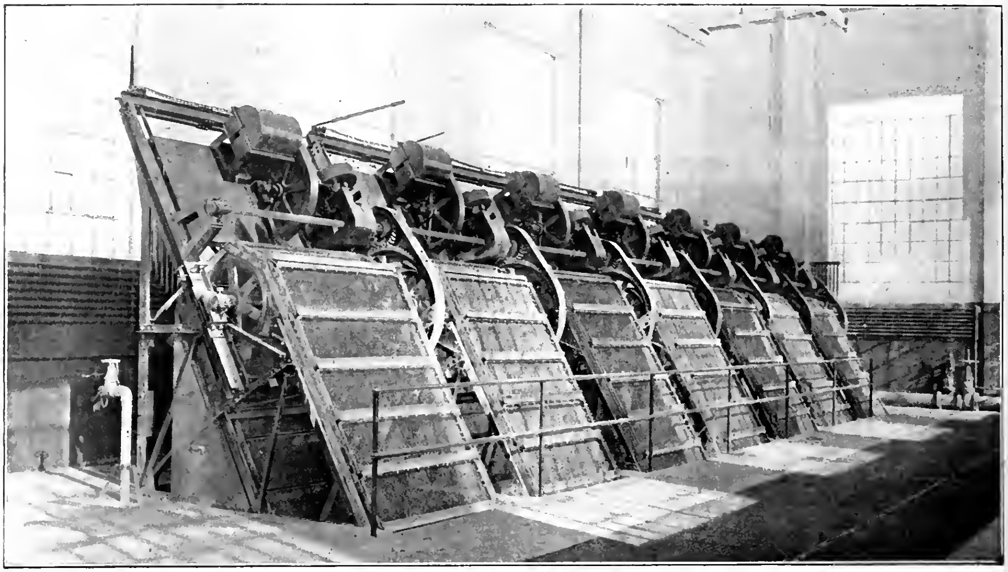

Fig. 4. Several Units in Operating Position

Gripwell Pulley Covering

Gripwell pulley covering is a cement to be used on the face of pulleys to prevent the slipping of the belt and to permit of running it loose. It is applied to the pulley, which has been cleaned with a strong solution of sal soda dissolved in water to remove all grease, etc., in a thin coat with a brush and is then allowed to stand until hard and dry.

In the case of large belts a covering of canvas ¼ in. narrower than the face of the pulley is applied to the latter about twelve inches at a time, and rubbed down hard with the cement until the pulley is covered.

It is claimed for this covering that it prolongs the life of the belt, the bearings and the machinery, that it eliminates the taking up of belts and is waterproof.

This pulley covering is manufactured by the Gripwell Pulley Covering Co., Hollis, L. I., N. Y.

Tantalum is much harder than diamond, as is shown by the fact that the only effect produced by a diamond drill, worked day and night for three days on a sheet of metal 1/25 in. thick, with a speed of 5000 r.p.m., was a slight dent in the sheet and the wearing out of the diamond. When red hot, tantalum can be easily drawn into wire or rolled into sheets.

Direct-Current Armature Winding Principles

By Jacob Gintz, Jr.

SYNOPSIS—Directions for the proper spacing and connecting of coils in both series and parallel windings.

The principle of armature winding is nothing more than placing a number of coils, properly spaced and connected to the commutator, so that they accumulate the induced electromotive force produced in the various coils which are connected in series between the brushes.

There are two types of direct-current windings—lap, or parallel, and series, or wave, windings. These are again divided into classes according to the number of winding elements per slot; that is, if a winding has one element per slot it is called a "one-layer winding," and if it has two elements per slot it is called a "two-layer winding." Two winding elements form one complete coil, and the distance that these two elements are apart depends upon the number of coils and poles and is expressed in the number of winding spaces.

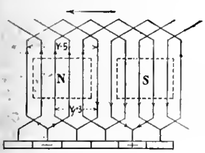

Fig. 1. Front Pitch Less than Back Pitch

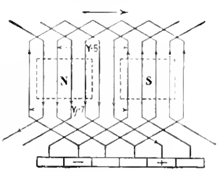

Fig. 2. Front Pitch Greater than Back Pitch

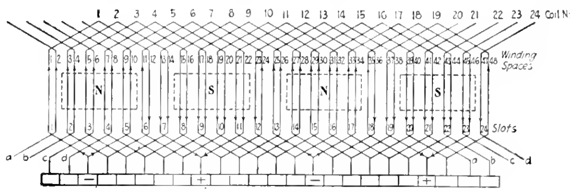

Fig. 3. Winding Laid Out in Accordance with Data in Table 1

When an armature is being prepared for winding, the first step is to insulate the slots, the ends of the core, the shaft and any other parts of the metal with which the winding may come in contact. The materials used for this purpose are fiber paper, shellacked canvas or muslin on the smaller armatures, and on the larger ones, micanite, press-board, empire cloth and various other materials. The coil must be so placed that both its elements do not come under the influence of the same field polarity at the same time, that is, while one side of the coil is influenced by a north pole the other side must be influenced by a south pole. The distance between opposite sides of the same coil is called the pitch, or spread, and is found by the formula

$$\frac{C \pm A}{P} = Y$$

in which C is the number of coils to be placed on the armature, A the number of times the current divides at the negative brushes (once at each negative brush), P the pairs of poles and Y the spread of the coil, expressed in the number of winding spaces. The value of Y must be an odd number. Should it result in an even number, it must be made odd by adding one. If it results in a mixed number, drop the fraction, and if the remaining whole number is odd the value of Y will be the same, even if it is made odd as explained above. This applies to lap, or parallel, windings only.

When the spread of a coil has been found, the distance from the end of one coil to the beginning of another is

$$Y \pm 2 = Y_f$$

where Y is the spread of the coil, counted across the back end of the armature (the end away from the commutator) and Y_f the front pitch, also expressed in the number of winding spaces, but counted across the front end of the armature. The pitch Y_f, however, is not a winding pitch, but merely the distance from the end of one coil to the beginning of the next. In many cases it has been found that instead of considering the pitch Y_f, it is easier for the winder to know that the winding is to be placed from right to left or from left to right and that the beginning of the second coil is to be two winding spaces from the first.

There is an advantage when using —2, in that the ends of a coil do not cross one another in connecting to the commutator, thus obviating the danger of short-circuit. When +2 is used the leads will cross as shown in Fig. 2.

In Fig. 1, $Y = 5$ and $Y_f = 3$

In Fig. 2, $Y = 5$ and $Y_f = 7$

If the connections in Figs. 1 and 2 are applied to two armatures and both are run in the same frame, that in Fig. 1 will run in one direction and that in Fig. 2 in the opposite direction.

In lap, or parallel, windings there will be as many brushes set around the commutator as there are poles in the machine. If such a winding is run with less brushes than poles the entire winding will not be active, and in the case of small machines sparking at the brushes would strongly interfere with operation.

For a practical example of a lap, or parallel, winding consider an armature having 24 slots and 24 coils to be placed in a four-pole machine.

In the winding where there is a like number of coils and slots (each coil being represented by two winding elements) there will be two winding elements per slot, and it will be termed a two-layer winding. There will also be 24 commutator bars, since there must be as many bars as active coils. In a four-pole machine the coils must spread at least one-quarter of the circumference, or 180 electrical degrees. Now find the spread or pitch expressed in the number of winding spaces, with $C = 24$ and $A = 2$. In lap- or parallel-wound armatures there are as many brushes as poles; then two brushes will be negative and two positive, and as the current will divide once at each negative brush, there will be two divisions of current. Also $P = 2$, since there are 4 poles (one north and one south pole make one pair). Applying the formula;

$$\frac{C + A}{P} = Y, \text{ or } \frac{24 \pm 2}{2} = \frac{26 \text{ or } 22}{2} = 13 \text{ or } 11$$

While it is possible to use either 13 or 11 winding spaces, one spacing having no electrical advantage over the other, it is better to use the smaller value, because it requires less wire to wind the armature, saving material and cost of manufacture.

Having chosen 11 winding spaces for the spread of the coil, then the first coil will be placed in winding spaces Nos. 1 and 12 (11 spaces between). This being a two-layer winding, space No. 1 will be in slot No. 1 and space No. 12 will be in slot No. 6. To locate the beginning of coil No. 2, apply the formula, $Y \pm 2 = Yf$. This will give the number of winding spaces to be counted back from the end of coil No. 1 to the beginning of coil No. 2. Remembering the advantage and disadvantage of the minus and plus values of 2 in this formula, then, $Y \pm 2 = Yf$, or $11 \pm 2 = 13$ or 9. Taking the minus value of Y_f, which is 9, and counting 9 winding spaces back from No. 12 will bring the beginning of coil No. 2 in winding space No. 3, in slot No. 2. Then, spreading the second coil 11 winding spaces between Nos. 3 and 14 will bring it in slots Nos. 2 and 7. Table 1 indicates the number of the winding space and the number of the slot between which the coils are wound.

7	13 and 20	7 and 10	15	29 and 6	15 and 3
8	15 and 22	8 and 11			

By following this table Fig. 3 is constructed. The spacing of brushes, expressed in the number of commutator bars from the toe of one brush to the toe of the next of opposite polarity, is determined by dividing the number of commutator bars by the number of poles. In Fig. 3, 24 bars ÷ 4 poles = 6 bars from one brush to the other.

In connecting the windings to the commutator one should know how the brushes will be set in relation to the polepieces. If they are to be set as in Fig. 4, the beginning of each coil should be connected straight out from the slot to the commutator bar, or if they are set as in Fig. 5, the beginning of each coil will be connected a certain number of commutator bars to the right (in parallel windings only), this number of bars, known as the "lead pitch," being determined by dividing the number of commutator bars by twice the number of poles. If this results in a mixed number it should be increased to the next whole number. The reason for these connections is that when the coils are under commutation they should be in neutral position.

When coil AB, Fig. 4, has moved to the position $A'B'$, its conductors are moving parallel with and are not cutting the lines of force; hence, they will not produce an electromotive force. At the same time the commutator bars, to which the coil leads are connected, are under the brushes C. If the coils were connected as in Fig. 5 with the brushes set as in Fig. 4, it would be impossible to operate the machine, because there would then be a dead short-circuit of the coil whose bars were under the brushes.

In some types of armatures there are two or three times as many commutator bars as there are slots in the armature core, the coils being wound with two or three wires in hand, which is the same as winding so many individual coils and connecting them together as one. There are two methods of connecting the coils to the commutator, namely, in parallel or individually. When two or more coils are connected in parallel it is to do away with the handling of large conductors and to make it easier to wind and shape the coils; in this case there

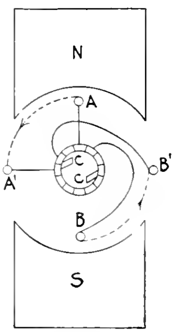

Fig. 4

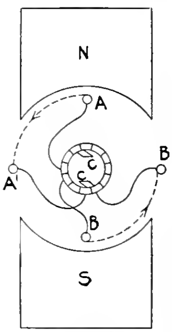

Fig. 5

Winding Dependent on Setting of Brushes

will be as many commutator bars as there are slots. When there are two or three times as many commutator bars all the coils will be connected separately. This is done to keep the potential between the bars down to a minimum; that is, about 5 volts between bars of machines not exceeding 110 volts, 10 volts between bars of machines not exceeding 220 volts, 15 volts between bars of machines not exceeding 550 volts, etc. These differences in potential apply to both series- and parallel-wound armatures.

The series-wound armature is little different from the parallel-wound armature except in the connections between the coils and the commutator bars.

A wave, or series, winding is sometimes called a two-circuit winding, because it requires but two brushes (one pair) and, as previously explained, there is but one division of current for each negative brush, which is equal to two paths, or circuits. To find the spread, or pitch, of a coil in a series winding, apply the same rule as in the parallel winding, but the value of Y can be any number —odd, even, or a mixed number. Series windings are divided into two classes, namely, single- and average-step windings, depending on the value of Y. If Y is an odd number the winding will be single-step, in which case Y will equal the commutator pitch (the distance between opposite ends of the same coil expressed in the number of commutator bars). When Y is even it must be made odd by adding one, but the commutator pitch can have two values, that is, it can have the original value of Y or it can equal the coil pitch, which was made an odd number, as explained; this is termed average-step winding. The two values of the commutator pitch are called the "long" and the "short" pitch. The short pitch is preferable because it results in fewer crossings of leads from the coils to the commutator. Fig. 6 illustrates the use of the short pitch in a four-pole series winding, showing two coils in series between adjacent commutator bars from right to left, and Fig. 7 shows the long pitch with two coils in series between adjacent bars from left to right.

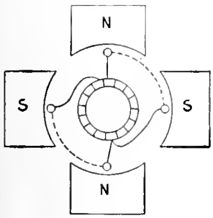

FIG. 6. ILLUSTRATING THE SHORT PITCH

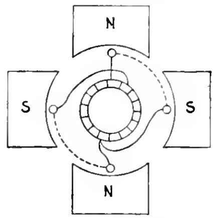

FIG. 7. ILLUSTRATING THE LONG PITCH

If a series-wound armature has been connected according to the short pitch and is reconnected with the long pitch, it will reverse the direction of rotation of the armature.

If the value of Y should result in a mixed number the fraction is dropped. In a four-pole winding this can only be ½; in a six-pole winding ⅓, etc. By dropping the fraction there will be an inactive coil, that is, one which will not be connected to the commutator. This, however, will occur only in the older types of armatures, for in the modern designs this has been eliminated, there being an odd number of coils in the winding. In any two-circuit winding it is impossible to connect an even number of coils.

For a practical example of a wave-, or series-wound armature, consider one having 15 slots and 15 coils to be placed in a four-pole machine. This will be a two-layer winding, since there are as many coils as slots, and 15 commutator bars will be required. Then $C = 15$, $P = 2$, and $A = 1$, since only one pair of brushes is required and there will be but one division of current.
Then

$$\frac{C \pm A}{2} = Y, \text{ or } \frac{15 \pm 1}{2} = 8 \text{ or } 7$$

Using the minus value of A, as previously explained (in parallel windings), $Y = 7$. Referring to Fig. 8, this will spread coil No. 1 between winding spaces 1 and 8 (which is seven spaces from No. 1) and it will be located in slots 1 and 4. To find the position of coil No. 2, apply the formula $Y \pm 2 = Yf$. Using the minus value of 2, as explained for parallel windings, $Yf = 5$. Counting 5 winding spaces back from No. 8 will bring the beginning of coil No. 2 in winding space 3 in slot No. 2. Then spread coil No. 2 from space 3 to 10 in slots 2 and 5. Table 2 indicates the number of the winding space and the slots between which the coils will be wound.

The connections between the coils and the commutator are made according to the commutator pitch, which in this problem can be either 7 or 8, as previously explained.

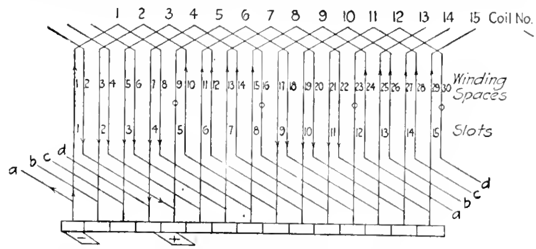

FIG. 8. WAVE WINDING BASED UPON DATA IN TABLE 2

Using the short pitch 7, the coils will be connected as indicated in Table 3.

The spacing of the brushes in Fig. 8 is found by dividing the number of commutator bars by the number of poles; that is, 15 ÷ 4 = 3¾ bars. By placing a negative brush on bar 1 and a positive brush 3¾ bars away, which will be between bars 4 and 5, the direction of current through the winding will be as indicated by the arrows. If the windings in Fig. 8 were connected according to the long pitch, the connections would be made as indicated in Table 4.

The brushes being set in the same position, the current will be reversed, which would also reverse the direction of rotation of the armature.

If the brushes were set as in Fig. 4, in relation to the poles, the beginning of each coil would be connected straight out from the slot to the commutator bar, and if they were set as in Fig. 5, the beginning of each coil would be swung a certain number of bars to the left (in series windings only), this number being found by dividing the number of commutator bars by twice the number of poles.

In Fig. 8 the positive brushes are set across bars 4 and 5, and as there are as many coils in series between adjacent bars as there are pairs of poles, there will be two coils in series. Therefore, there will be two coils short-circuited—Nos. 5 and 12, which are marked with small circles.

The formulas employed in this article are somewhat different from those found in textbooks, but they arrive at the same results. A winder will always remember that the winding step Y must be an odd number, and that the difference between any two adjacent coils must be two winding spaces; also, before connecting the winding to the commutator he will find out in which position the brushes are going to be set. This will apply to both series and parallel windings.

Test of Booster Pumps

At the Roseland Pumping Station, Chicago, two booster pumps were recently installed to raise the pressure of 50 to 60 lb., normally carried in the water main, to a maximum of 87 lb. (200 ft.) for the Washington Heights section.

Each unit, as shown in Fig. 1, consists of a 14-in. Worthington horizontal centrifugal pump direct-connected to a 115-hp. Kerr turbine running at 2750 r.p.m., a 325-sq.ft. Worthington cylindrical shell waterworks type surface condenser located in the suction next to the pump, a 5x12x10-in. single vertical flywheel-type air pump with attached hotwell pump, and a 4-in. automatic atmospheric-exhaust valve. The main pumps are of the single-stage, double-suction, screw impeller type with volute casings, and the turbines are each controlled by two governors—a speed-regulating governor and a pressure-regulating governor. The former is of the oil-relay type and the latter of the Fisher type, designed to maintain a constant pressure in the mains regardless of any fluctuations in either the capacity or the suction pressure.

Some of the principal dimensions are as follows: Suction inlet of pump, 13 in. square; discharge outlet, 14 in. diameter (corresponding to a velocity of $7\frac{1}{4}$ ft. per sec.); steam inlet to turbine, $2\frac{1}{2}$ in.; exhaust outlet, 12 in.; condenser water outlet, 13 in. square, and water inlet, 20 in. diameter. A steam pressure of 170 lb. gage is carried. The manufacturers guaranteed that each pumping unit would develop a duty of not less than 67,000,000 ft.-lb. per thousand pounds of steam at the pressure stated, and not less than 98 per cent. quality when delivering at the rate of 5,000,000 gal. of water per 24 hr. against a head of 85 ft. (not including friction through the pump nor through the suction and discharge piping as measured between the suction- and discharge-pressure gages).

The acceptance tests were conducted by a board of three engineers—one representing the City of Chicago, one the contractor, and the third selected by the first two. In order to vary the capacity and maintain the same constant during each run, the discharge piping system was isolated from the Washington Heights high-pressure system and the water returned to the low-pressure system through cross-over valves controlling the rate of flow. A pitometer was installed about one mile west of the station at a point convenient to the valves mentioned, which were manipulated as necessary to get the desired rate of flow as indicated by the pitometer. This method of regulation permitted constant rates of flow to be maintained, and the temporary isolation of the discharge from the service lines gave the desired freedom from surges which would otherwise have been present in the mains.

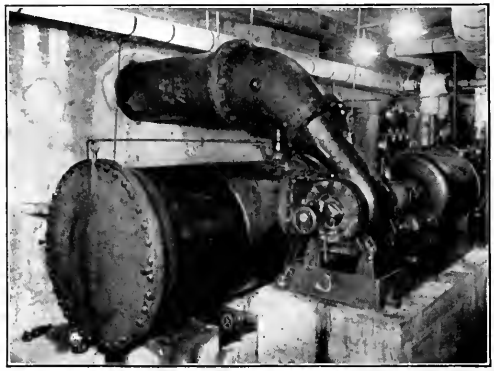

FIG. 1. ONE OF THE BOOSTER UNITS

In accordance with the specifications, the quantity of water pumped during the tests was measured by a 30-in. venturi meter, which is a part of the permanent equipment of the pumping station. The air pump was operated condensing, and the condensate from it was weighed along with the condensate from the main turbine.

The curves in Fig. 2 show the relation between head, capacity and duty through the range covered by the tests, the dotted lines showing the probable performance beyond this range.

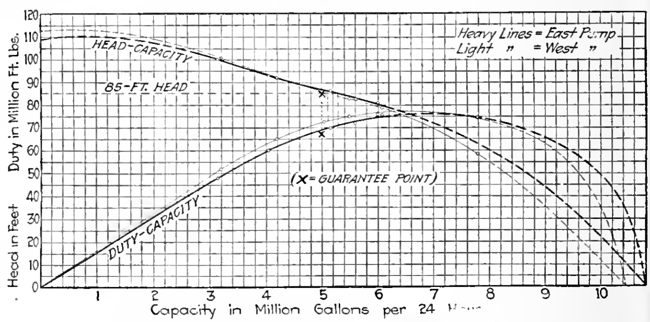

FIG. 2. CURVES SHOWING PERFORMANCE OF PUMPS

The west pump showed a duty of 73,000,000 ft.-lb. per 1000 lb. of steam, corrected to an initial pressure of 170 lb. gage and 98 per cent. dry, and a capacity of 5,120,000 gal. per 24 hr., thereby exceeding the guaranteed performance by 8.95 per cent. in duty and 2.4 per cent. in capacity.

The tests of the east pump, when operating against the specified head at 85 ft., showed an initial duty of 71,000,000 ft.-lb. per 1000 lb. of steam, corrected to the initial conditions, and a capacity of 5,280,000 per 24 hr., thereby exceeding the guaranteed performance by 5.97 per cent. in duty and 5.6 per cent. in capacity.

Research and Equipment Engineering

Few engineers are privileged to keep in touch with the progress of laboratory and mathematical investigations in different parts of the world, which affect power-plant development and operation in indirect ways. The reasons are that intense absorption in "practical" problems takes so much time and that research work is conducted for long periods with little publicity because the follower of pure science hesitates to give out results not well established. It is a great mistake, however, to look upon research as a subject of mainly speculative interest, for out of experiments and studies often far removed from matters of routine operation sometimes come developments of immense engineering value.

In a lecture given recently at the Worcester (Mass.) Polytechnic Institute, Professor Albert Kingsbury, inventor of the thrust bearing associated with his name, outlined the steps in lubrication research, extending over many years, which led to the final development of this interesting equipment. Without recounting the sequence of events, it is of interest to note that the most delicate resources of the physical laboratory were drawn upon in measuring the axial eccentricity of a revolving piston fitting closely in a cylinder in which the only lubrication was provided by a film of air about one-thousandth of an inch thick; in studying the wedge effect of rotation upon the lubricant, and in comparing experimental observations with the predictions of Reynolds, whose remarkable mathematical studies of bearing friction, published in the "Transactions of the Philosophical Society of Great Britain" as far back as 1886, threw a flood of light upon many phenomena of obscure explanation noted in the subsequent tests.

The dependence of bearing friction upon speed rather than upon load under these conditions, the practicability of measuring pressure distribution at different points on bearings by multiple gages of the mercury type, the checking of piston displacement by a telephone receiver, setscrew, battery and contact method, taking advantage of the excellent insulation provided by the minute skin of air between the piston and the cylinder, and the study of tool-point lubrication by microscopic observation of cuts in a running lathe, all had a bearing upon the investigation which need not be detailed here, but they serve to point out that it is rash to limit the possibilities of scientific method or to take it for granted that because a phenomenon in friction, thermodynamics or electricity is obscure, it is beyond the reach of modern laboratory apparatus. Few of us need to master the detailed calculations of Reynolds, Lord Kelvin and other savants in the field of mechanical friction, but it is singular and interesting that the experimental results of Kingsbury were so accurately forecasted by mathematical research, which, however, in the case of Reynolds, made the mistake of supposing that the minute quantities involved could not be experimentally measured.

Each type of investigation thus supplemented the other, and the two together ultimately brought forth a useful form of equipment for commercial service, in which the principles determined in investigations which might seem largely theoretical were turned to account in the design and construction of apparatus for power-plant applications. In a broad sense, the final research was a byproduct of a study of the friction of screws—a point worth bearing in mind in observing and recording collateral phenomena in connection with any technical investigation.

A Suggested Activity for the Engineering Foundation

Few realize the prodigious rate at which additions are being made to available engineering information. In the first place, there are constantly appearing new branches and ramifications to engineering. A half-century has developed electricity into a great industry with an extensive literature, abstract and applied. In a quarter of a century the internal-combustion engine has grown from a driver of coffee mills to one of rolling mills. A couple of decades has seen the evolution of the steam turbine with all the consequent changes in power-plant apparatus and design.

These in our own field; in other fields as great or greater developments have taken place. And with all this, in addition to the fund of knowledge which we have acquired and are still acquiring about the old things, come voluminous contributions to current knowledge about the new. Research laboratories are discovering; committees are investigating and reporting; professors and postgraduates are studying; inventors and developers and manufacturers and users are finding out; professional societies are hunting all who have special information and inducing them to add it to the general fund. The technical press has, for its reason for being, the production and recording of such information. The specialist who a few years ago could get all the available information about his subject in a few standard volumes, the proceedings of a single society, and perhaps a monthly magazine, could now keep so busy reading about it that he would have no time to practice.

In the mass of engineering literature produced, transient as may be the interest of much, subject to criticism and refutation as may be a great deal, duplicative and even contradictory as may be some, there are recorded the accumulated knowledge of and thought upon the subject. If out of this, the material of permanent interest could be put upon record in an orderly fashion, so that the seeker for knowledge upon a particular phase of any engineering subject could find it all together, what effort and time and money would be saved to the delver for facts already known and the traveler upon paths which have been already demonstrated to lead into a dead end.

To what worthier purpose could the trustees of the Engineering Foundation so generously established by Ambrose Swasey devote their initial activities than to the development of some method of analyzing, classifying and filing engineering information? With sufficient time and talent, a system could be evolved under which the periodicals could print against the titles of articles of reference value or even against individual paragraphs, numbers, of the Dewey-decimal or other system, which would automatically lead these articles or card-index references to them into the right file. The principal reason that this has not been already done is the want of a standard filing system for engineering information.

This is the one engineering purpose in sight which is broad enough to warrant the use of a fund designed "for the advancement of engineering art and sciences in all their branches, to the greatest good of the engineering profession and to the benefit of mankind." And the motion by Henry Hess, in his discussion of the paper by Edwin J. Prindle, dealing with the classifying and indexing of the records of the American Society of Mechanical Engineers, to the effect that it be suggested as an object of their interest and activity, should have been sustained.

One might as well not have a thing as to have it and not know that he has it.

What better use could the means available be put to than in taking stock of current engineering knowledge, classifying and arranging it for ready reference, and organizing a system whereby new information would flow to its appointed place as it develops?

Analyzing Station Design

The study of generating plant and substation designs is instructive to any engineer. Even if an operating man never expects to lay out a plant it pays him to scrutinize the arrangement and composition of other installations than his own, for it gives him a broader outlook upon local problems and a sense of proportion which is a valuable asset. The more plants one visits, or studies through carefully prepared descriptions in the technical press and in the transactions of engineering societies, the more apparent it becomes that standardization in design is a long way off, and fortunately so. Nearly every installation has some peculiar feature of note, and it is always interesting to weigh and compare the merits of different ones.

A plant recently examined illustrates these points. Situated in a deep valley above a small town, the station is close to the edge of a cliff and utilizes a head of one-hundred feet, with a maximum development of about thirteen thousand horsepower in three direct-connected generating units of modern design supplied with water by a pair of large penstocks leading to the wheels from a dam a short distance above the station. The plant represents a gradual development which has been carried on by its owners with great skill in view of the local difficulties encountered. No criticism of these men is intended in the following comments upon the layout in relation to the latest ideas in hydro-electric development, which are simply advanced to show the importance of viewing installations from the standpoint of trying to see wherein they might be more efficiently arranged were the opportunity to build anew afforded. In other words, it is important to try to determine for oneself whether each installation visited measures up to the most advanced practice known to the visitor, and if not, to quietly study wherein it appears to fall short. This does not mean any failure to appreciate the good points of any layout or to condemn a plant for a few apparent defects for which its present owners and even its original designers may not be responsible, for the art of station design advances as do other affairs, and the best of today soon becomes eclipsed by the practice of tomorrow.

In the case selected, there are industrial plants on the river in the town which utilize eighty feet of additional fall in scattered wheels with both mechanical and electric drives. If the development were to be made today, the existing hydro-electric plant would not be built, but instead, a tunnel would be driven through the hill on one side of the town to the river over one hundred and eighty feet below on the other side of the barrier, and the entire development would be on the basis of utilizing maximum head in concentrated generating units. This would be bold compared with the ideas of the builders of the existing station, but this is the day of bold conceptions in engineering.

Close scrutiny of the present plant indicates the desirability of building a straight operating room free from angles, so that the switchboard can be seen from all points; of bringing the water into the wheels in penstocks which do not obstruct the view in the operating room and the movement of a high-powered traveling crane from end to end; of placing the switchboard where the shortest possible cable runs from the generators will be required that are consistent with good visual control of main units; of providing ample space for oil switches in outgoing lines and straightway runs for high-tension wiring; of placing the chief engineer's office in a commanding position in relation to the operating room instead of in a distant wing of the building without visual connection to the latter; and of avoiding unnecessary complications in high-tension bus and switching arrangements for the sake of a flexibility in operation seldom required in actual service.

Bearing in mind that the design of any station upon which good engineering is expended is more or less of a compromise, it is none the less true that critical examination of such installations pays well for the time and trouble put upon the work, provided at every point effort is made to formulate constructive and not merely captious criticisms.

That our insistence upon the danger of the breathing head is warranted is again attested by another failure of this sort, this time of a bumped head on a Stirling boiler in New Bedford. Fortunately, the defect was discovered before an explosion or serious damage occurred.

At the recent investigation of the Public Service Commission of New York for the First District, Travis H. Whitney, secretary of the commission, testified that in the electric-light cases against the New York Edison Co., which have lasted over three years, fifty-two hearings have been held and over one thousand eight hundred pages of testimony taken. The case, he said, has been reopened, not at the instance of the complainant nor the company, but on the application of the Merchants' Association. The company, however, made no objection.

Which is very funny, inasmuch as the application of the Merchants' Association has all the earmarks of having been inspired by the company itself.

Correspondence

Using Graphite in Boilers*

Mr. Weaver's letter in the Jan. 26 issue on the use of graphite reminded me of my experience with it in two or three plants. One plant had three 100-hp. locomotive-type boilers which were heavily scaled. After washing, I put 10 lb. of graphite into each boiler and then fed ½ lb. every twenty-four hours. In three months our boilers were free from scale, and in less than eight months from the date of beginning the use of graphite we had saved about $80 on the coal bill.

It seems to me that engineers expect graphite to act too quickly. It should be remembered that the graphite must get between the scale and the boiler shell and work the scale off by mechanical means. By feeding the graphite in the manner mentioned, a total of 160 lb. of hard scale was removed from a boiler in less than 70 days.

G. A. Bennett.

Denver, Colo.

Mr. Weaver's experience with graphite as a scale remover coincides with mine. I find that graphite and a good mechanical tube cleaner go together. The graphite will soften and loosen the scale and make it easier for the mechanical cleaner to bring it down in either a water-tube or fire-tube boiler. If a boiler is badly scaled it is slow and hard work to get the scale off even after the graphite has loosened it, but the cleaner will break it up and quicken the process of removal.

A. A. Blanchard.

Oxford, N. J.

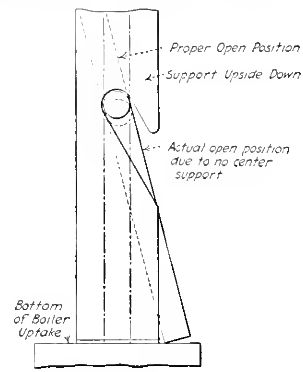
Dampers Would Not Close

The municipal water-works here has four vertical water-tube boilers of 450 hp. each. While the load seldom requires the operation of more than one boiler at a time, two are always under steam in order to provide service in case anything should happen to either boiler. This precaution is necessary, as the pumping engines operate on the Holly system without reservoirs.

During night loads it is advisable to bank one of the boilers. This had been tried on one pair of boilers with fair success. The other pair, however, could not be properly banked. Examination showed that the dampers stuck on the bottom while at the tops they were open as much as four inches. Each boiler has three damper paddles operated on one stem. At one time a strip had been cut from the bottom of a paddle to increase the clearance. This merely aggravated the trouble. Later the center paddle had been tied to the outer ones by straps which slightly bettered conditions.

As this failed to give satisfaction, further examination showed that the stem was bearing at the ends only, the center supports being over the notch for taking out the dampers, and apparently in upside down. The weight of the moving parts caused the damper to settle, strike the bottom first and prevent the top from closing. The more that was chipped off the bottom, the lower the damper sank. The result was inefficient operation when this bank of boilers was in use and a poorer draft when the other bank was on duty, as both are attached to the same stack.

The trouble was remedied by placing a small support under each of the centers between the paddles, thus keeping the bottoms free. The stack now has a much better chance to operate at full efficiency. How much coal went



Arrangement of the Damper

up the chimney since the boilers were installed is problematical. What we do know is that since April, when the station was taken over, the coal consumption has decreased 30 per cent. and the pumps run much slower, in spite of the fact that our meters are reporting more water consumed.

Dayton, Ohio.

A Satisfactory Average Vacuum

In reviewing the many references to the effect of high vacuum on reciprocating engines which have appeared in a long series of volumes of Power, I have been impressed with the omission of consideration of the changeable temperature of condensing water throughout the year. Again and again the disadvantage of larger condensing apparatus, with its resulting high cost, is set down against the gain due to high vacuum, when any such gain is acknowledged at all. I have yet to see a single instance where the question is considered as to whether during the winter time (when high vacuum is available, inasmuch as cool entrance circulating water or injection water makes it so) it is desirable to have air-pumping apparatus of the requisite design and in a requisite state of maintenance, to make the potentially available high vacuum actually existent.

It is, of course, only in recent years that any serious opposition has appeared to the old view that 25 in. or

*See "Power," Jan. 6, Mar. 3 and 31, and Apr. 7, 1914.

slightly more represented the most economical vacuum for reciprocating-engine service—an argument apparently based on the widest experience in the days when it was customary for the hotwell water to be used as feed water without subsequent heating with the exhaust steam from independently driven auxiliaries. When this long accepted conclusion began to be questioned there remained a strange absence of any consideration of the possible desirability of keeping the condensing apparatus of moderate size, so that during summer weather only moderate vacuum could possibly be attained, but utilizing steadily increasing vacuum as condensing water becomes colder from summer to winter.

Utilization of this scheme necessitates air-removing apparatus of the best possible operating characteristics. But such apparatus is relatively inexpensive when it represents dry-vacuum pumps used with surface condensers and still less expensive when it represents mere modernized design of jet condensers of the barometric or equivalent form. Why has it not become recognized that a condensing-engine equipment is not installed, and should not be thought of as installed, to maintain some definite and constant vacuum throughout the year, whether it be 26 or 28 in. or more, but as installed is capable of maintaining a certain vacuum in summer and a much higher vacuum in winter, and is to be so operated throughout the year as to maintain as nearly as possible a constant vacuum efficiency referred to the changing vacuum available?

A Puzzling Ground

Several years ago, while operating a substation, I had a peculiar experience with a large booster set used for charging a storage battery and boosting one of the long feeders. The system was Edison three-wire with the neutral grounded; 230 volts across the outside wires and 115 volts to the neutral.

The switches on the high-tension side of the system were remote-controlled, and to operate these, as well as the protective devices on the different units a separate operating busbar was connected across the positive main busbar and the neutral. Fig. 1 shows the connections of the booster and operating busbar.

The first indications of trouble occurred one Sunday, when one of the attendants received a shock while cleaning the booster. Everything on the switchboard was apparently as it should be, so I touched the machine rather gingerly in several places, to see if I could repeat the performance, but without results. With a test lamp I then tested every conceivable place and finally went over the machine with the portable voltmeter, without finding anything wrong.

Everything went along all right for a couple of weeks, when, on Sunday, while making an insulation test the chief found the operating busbar grounded and told me to locate the trouble. To my surprise the operating busbar tested clear, whereupon I decided that the chief had been mistaken and told him so the next day. He maintained, however, that the busbar was grounded when he tested it.

Two days later the chief received a jolt from the commutator of the booster. He was too busy at the time to investigate, but instructed me to do so. Again everything tested clear, only to be followed by the night man receiving a shock from the same machine.

This was getting to be a joke, so I connected a lamp between the frame of the machine and a water pipe to make a ground and placed the lamp directly above the desk so that anyone would be sure to see it in case it should light, for the instant the machine became grounded on either side, the current would flow through the lamp to ground and back to neutral.

One evening, while I was sitting at the desk the light suddenly flashed in my face. I grabbed the test lamp and tested from the positive booster-generator to the frame, but without results. When I applied the test lamp to the negative booster-generator and the frame the lamp lighted up brilliantly. I disconnected the machine from every possible source of potential, even from the operating busbar connections to the speed-limit device, but the lamp burned as brightly as ever. I finally gave up in disgust and sat down to think it over, when suddenly the light went out.

Nobody was near the machine at the time, but the assistant was just switching off the lights over the booster

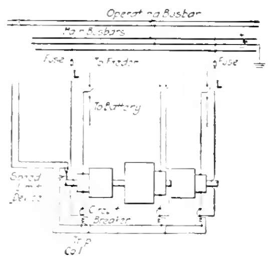

Fig. 1. Booster Connections

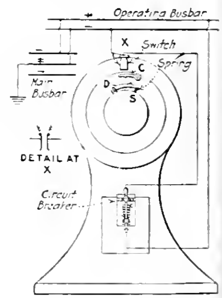

Fig. 2. Speed-Limit Device

set. There was a light over each of the four bearings. These were run in conduits up alongside of each bearing pedestal and clamped to it. I had the lights switched on and, sure enough, the lamp over the desk lighted up again.

One of the light sockets was broken, so this was replaced and the light over the desk stayed out with the machine lights on. I decided that the trouble had been located, concluding that, due to the broken socket, the lighting circuit had been grounded intermittently on the machine.

Two days later, while cleaning the commutator on the negative generator I received a jolt that made me jump. One hand was on the frame at the time, and the other happened to touch one of the brush-holders. The lamp was connected again and lighted up as before. The lights over the machine were out at the time, so it was concluded that they could not be the cause.

A few nights later the night operator again received a jolt from the machine, and at the same time the signal lamp indicated; but he was unable to find anything wrong.

One Sunday, shortly after this, I was sitting at the desk when the light suddenly flashed. The assistant was around the machine at the time and at that particular instant was wiping the end of the bearing and the inside of the hood over the speed-limit device. I had him go over it again and the signal lamp went out. Evidently the trouble was in the speed-limit device.

Fig. 2 illustrates the construction of this device, in which X represents the contact points or clips of the switch, C is the switch blade hinged on a pin screwed into the main bearing, and D is a weight hinged on a pin fastened to the shaft and revolving with it. Centrifugal force tends to throw this out when the shaft rotates, until at the predetermined speed it strikes the switch blade C, closing the circuit and tripping the circuit-breaker. The tripping speed is regulated by adjusting the tension of the small spring S. It was the switch C that caused all the trouble, for it was not insulated from the pin on which it was hinged; consequently, when the switch closed it grounded the machine.

To complicate matters the switch worked rather stiffly and made contact with one clip before touching the other. In wiping the machine the operator moved the blade C just enough to make it touch one clip without closing the switch, which would have tripped the circuit-breaker. This grounded the machine. Sometimes, due to the jarring of the machine, C would drop down again, or it would stay up until the next time the operator wiped it or sometimes for several days. With the signal lamp connected from the machine to ground, this also grounded the operating busbar.

What made the matter still more puzzling was the fact that the lighting circuit was grounded on the machine at the same time. To remedy the trouble we bored out the hole in C and put in a fiber bushing.

THOMAS G. THURSTON.

Chicago, Ill.

Fixing the Horsepower

A circular issued by the Bureau of Standards points out that at present there is no accepted authoritative definition of horsepower and, therefore, different equivalents of this unit in watts are given by various books. They state that inasmuch as the horsepower is a gravitational unit of power, it varies with latitude and altitude, being 552 ft.-lb. per sec. at the Equator and 549 ft.-lb. per sec. at the North Pole. They recommend the adoption of the horsepower as 550 ft.-lb. per sec. at 50 latitude (approximately that of London) and sea level and that the equivalent in watts be taken as 746.

There are too many engineering quantities for which there are no exact definitions, and it is to be hoped that the engineering societies will adopt standard values. The engineering congress to be held at San Francisco this fall would afford a fine opportunity to settle this and several other values, such as the British thermal unit.

While the writer believes in exact definitions for engineering quantities, he is of the opinion that the Bureau of Standards has over-estimated the commercial importance of the variation of the horsepower with latitude and altitude. It claims that this variation is enough to be of commercial importance and should be taken account of in engineering tests. The greatest error that could occur due to a variation in latitude and altitude is 1/3 of 1 per cent. Practically the only tests made at the present time are to determine the water rate either per indicated horsepower or per brake horsepower.

In the first case the error of the indicator is easily 1 per cent. and the personal error in working up the card can hardly be less than 1 per cent. Other variables, such as weighing the water, etc., will affect the result, so that any engine test can hardly be guaranteed to within 2 to 3 per cent. This would also be true when measuring brake horsepower. It would hardly seem worth while to take into account a variation of less than 1/3 of 1 per cent., when the known error is four to six times as much. This is on a par with boiler tests published from time to time, in which the results are carried out to the fourth and fifth places.

Another quantity which has even more effect on the water rate per horsepower with different altitudes than gravity is the pressure of the atmosphere. Yet the writer thinks that the decrease in back pressure with increase in altitude is not considered of sufficient commercial importance to be taken account of.

W. L. DURAND.

Brooklyn, N. Y.

Home-Made Feed-Water Heater

The criticism by E. H. Pearce in the issue of Dec. 8, 1914, on page 816, of the total result obtained from a feed-water heater which I described on page 502, Oct. 6, 1914, is entirely just. What I neglected to say was that the first heater gave such satisfactory results that five more were made, some of which were larger than the one described. I regret the blunder very much.

SAMUEL L. ROBINSON.

Providence, R. I.

Probable Cause of Boiler Explosions

Referring to the tabulated list in your issue of Jan. 26 of boiler explosions which occurred during the first half of 1914 and your editorial comment thereon that "these statements (of the probable cause) are not always as full and satisfactory as might be desired" is very true.

Tube failures and other conditions found after the explosions are not the true causes thereof, but are rather the results of conditions for which the tubes should not be held responsible, such as the nature of the feed water—too hard, containing mineral salts and other scale-forming constituents, suspended insoluble matter, or oil which was not filtered out. In the last case, boilers tubes of all kinds are apt to suffer, no matter how excellent they may have been when first put into the boiler.

It has been stated by Messrs. Stromeyer and Barron in a paper before the Society of Naval Engineers of Great Britain, that 1/8 in. of scale will raise the temperature of a boiler plate 300 deg. F., whereas less than 0.001 in. of oil will produce a far worse effect. They also state that the effect of oil is intensified where scale is present, therefore no effort should be spared to keep it out of boilers, not only when slight quantities are found floating on the surface of the feed water, but particularly when the oil is in the so called emulsified condition, as indicated by a cloudy appearance of the water.

There are many and adequate systems now in use to render hard and scale-forming water practically harmless, and also processes which remove every trace of oil from feed water, so that there is no good reason why boilers should be fed with poor water, which is the source of most boiler troubles and serious accidents.

It is to be hoped that state or Federal control will be made more strict in regard to the details gathered relating to boiler explosions, so that no particulars which might throw light upon the true causes of such disasters can be withheld from publicity.

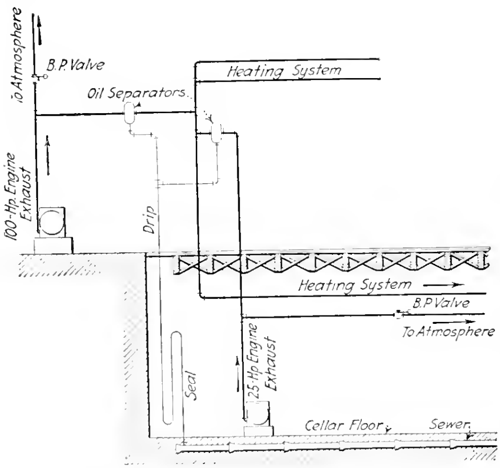
Trouble with Oil Separator

Referring to Mr. Goodwin's trouble with the oil separator described on page 207 of the Feb. 9 issue, as I have experienced similar trouble and overcame it successfully, I offer him a solution as per the following sketch.

He states that he carries eight inches of vacuum on his heating system. This will sustain a column of water about eight feet high in the pipes leading from his oil



Remedy Suggested for Trouble with Oil Separator

separators, and he should have at least that amount of fall from the bottom of his separator to the top of any seal that he uses. He does not state whether he ever has any pressure above atmosphere, and I take it for granted that he has, so he will need some seal to prevent steam blowing to the atmosphere when such is the case. His sketch shows only sixteen inches of head in one case and practically none in the other.

If he can get no more fall than he shows, it will be better to remove the seals entirely and run a line direct to the sewer with a swing check valve on as low down as possible, opening toward the atmosphere. This will give a head of water over the check to open it against atmospheric pressure, and the check will prevent entrance of air into the system. If he carries a pressure above atmosphere the addition of a steam trap of large capacity will prevent the loss of steam.

His basement separator cannot be given that much fall, but the one on the first floor can be arranged with the seal in the cellar instead of as located, and then it will work. Then he should take the exhaust from the engine in the basement and put it into the heating line at a point near where the other separator enters, moving the basement separator up there, so as to get enough fall to take care of it with a seal in the cellar. I have shown this in a sketch, using only one seal of larger capacity. Perhaps a separate seal for each would be more satisfactory, especially if the separators should be of different patterns or if the piping areas are restricted.

W. F. Meinzer.

Brooklyn, N. Y.

Referring to Mr. Goodwin's inquiry in the Feb. 9 issue regarding trouble with oil separators, the heating system is carrying eight inches of vacuum, which means that a head equivalent to eight inches of mercury, or about eight feet of water, must be carried on the separator side of the seal before the oily drips will overflow the seal.

From the sketch it is evident that the seals are set too close to the separators. My advice would be to run both drips together into a ½-in. lifting trap of the tilting type. When the trap dumps it will cut off the inlet and, consequently, the vacuum of the heating system, allowing the trap to discharge by gravity.

W. L. Durand.

Brooklyn, N. Y.

Referring to H. G. Goodwin's letter in the Feb. 9 issue concerning "Trouble with Oil Separators," it is suggested that the drip loop in connection with the larger separator should be dropped at least 4 ft. so as to give sufficient head in case of vacuum in the exhaust system, and a ½-in. vent inserted in the top of the last leg of this loop, and a check valve placed at the discharge end near the connection to the waste line. In reference to the smaller separator, it is suggested that the seal loop be replaced with some form of "grease trap" with a check on the discharge side.

Charles A. Nelson.

Chicago, Ill.

Chain Oiler Stopped

The oil chain in the outboard bearing on a new gas engine gave much trouble when the engine was first put in service, by stopping and allowing the bearing to get warm unless it was noticed in time and started again before the bearing was dry.

The cap was removed and the chain run around by hand. One joint between two links was rather stiff, but aside from this, there was apparently nothing wrong. The joint was limbered up, the cap replaced, and the engine started again, but before the week was out it was as bad as ever.

Upon a closer examination, the chain was found to be dragging on the bottom of the oil well. Three or four links were taken out, making the chain just long enough to clear the bottom nicely, which entirely eliminated the trouble.

Earl Pagett.

Coffeyville, Kan.

Safety Devices for Elevator Doors

Now that New York City has a law making it compulsory after a few months to have elevators provided with safety devices on gates or doors, discussion in POWER as to the working of these would be welcome. Several buildings in New York have such devices.

In the building where I am employed there is an electro-mechanical gate lock which has worked well for the last four years. The elevator cannot be started unless all gates in the shaft are closed tightly. When a gate is open a magnet placed over the operating valve (hydraulic car) is energized and, through an arm connected to the lever of the valve, prevents the latter from being moved by reason of the lever being held rigid. To bring out the relative merits of different devices for this service I hope discussion will be forthcoming.

W. T. OSBORN.

Newark, N. J.

[New York City has no such law. A proposed ordinance making the use of such devices compulsory and calling for the inspection of all elevators in the city was presented before the aldermen some time ago, but that body has not yet acted on it.—EDITOR.]

Starting Small Motors

W. S. Grimscom's diagnosis of the trouble experienced in starting a small shunt motor without a starting box when changed from driving a bottle-washing machine to driving a jig saw, referred to in his letter in the Jan. 12 issue, is quite correct, although he might have overcome the difficulty by shifting the brushes. The decrease in the starting torque was caused by the excessive current in the armature which set up a very strong magnetizing force from the neutral points of the armature across the polepieces.

The current in the armature of a direct-current machine produces magnetic poles at the neutral points which cross-magnetize the main poles, weakening the pole tip back of the neutral point and strengthening the one in front, the degree to which the polepieces are weakened and strengthened depending upon the position of the brushes. If the brushes are set slightly in front of the neutral point one is about equal to the other, but if set back of the neutral point the pole tip back of the neutral will be weakened faster than the one in front is strengthened, resulting in a decrease in the field strength. This accounts for the increase in speed of a motor by shifting the position of the brushes backward around the commutator against the direction of rotation. This shifting of the brushes, however, is limited by the sparking at the commutator.

The brushes may be set far enough back of the neutral point to cause no ill effects under normal working conditions, but when subject to an extreme overload current, as in Mr. Griscom's case, the distorting effect may be great enough to weaken the motor or even cause the armature to develop a backward torque.

Mr. Griscom could have remedied his trouble by giving the brushes a forward lead, thus causing the armature current to strengthen the polepieces instead of weakening them. He could also have improved his lamp starting device by short-circuiting it with a single-pole switch after the motor had been accelerated. Furthermore, a starting box could have been secured for this purpose for approximately the cost of the lamps and fittings, not to mention the more satisfactory operation of the driven machine when running under the proper conditions. For a temporary starting device a water rheostat could be used, and this could be made to give as satisfactory results, as far as starting is concerned, as a starting box.

The practice of starting shunt motors by connecting them directly across the line is not to be encouraged except in the case of small, slow-speed machines up to about ¼ hp. running at a speed not exceeding 750 r.p.m. and starting under very light load. If there is liability of the load stalling the motor while starting, a starting box should be used, even under these conditions. In a great many cases where trouble is experienced in the operation of small motors it is from no other cause than improper starting. In small series and compound motors the above rule need not be so rigidly followed, for the series field winding helps choke down the starting current, and as the current increases in the armature it also increases in the series field winding, causing a much greater increase in the starting torque than in the shunt machine, which will accelerate the load more rapidly than is possible with a shunt motor.

Selecting a Pump

In reading the article, "Selecting a Pump for General Service," by Charles L. Hubbard, in the Feb. 9 issue, I was disappointed at not finding more helpful information or suggestions, and more so in discovering a real lack of accurate knowledge and a tendency to erroneous statement.

It is stated that direct-acting steam pumps, engine- and turbine-driven plunger pumps and centrifugal pumps are adapted to conditions where the friction head in the suction pipe plus the elevation does not exceed fifteen to eighteen feet. Should it not be mentioned that a centrifugal pump is not as well adapted where there is a suction head, for it must be "primed" before it will pump water? Sometimes this is a comparatively easy operation, but often it is not. The various methods of "priming" a centrifugal pump might be stated, for certainly the availability of some method of priming might be a deciding factor in the selection of a centrifugal pump.

If the water supply of a power house must be pumped, the distance between the pump and the power house is hardly the only consideration when choosing the type of pump or determining whether to convey steam from the boiler house to the pump or "to drive the pump by an electric motor or gasoline engine" or "to install and care for a special boiler."

In pumping water from artesian wells the air lift is often desirable, but not "to increase the flow." The normal flow of a well cannot be materially increased by any method of pumping, and the air lift is not the type of pump which will always give a maximum delivery from a given-sized hole.

Mr. Hubbard says that "deep-well pumps have an efficiency of 40 to 50 per cent. and a slippage of 10 to 15 per cent." I have used several double-acting deep-well pumps which showed an efficiency of over 80 per cent. and had no slip whatever. Moreover, these pumps delivered much more water from the well than we could possibly obtain with an air-lift pump.

The statements regarding centrifugal pumps show a surprising lack of knowledge concerning this type, which is so widely used. Their efficiency is given as from 60 to 80 per cent. for the better types, working under the conditions for which they were designed. But, he says, "it is not possible to obtain as high an efficiency as with the best design of piston pumps when the latter are kept in first-class condition." The efficiency of direct-acting piston pumps is given as from 65 to 75 per cent. and of triplex pumps as from 60 to 80 per cent. According to the figures given, the efficiencies of all three types are remarkably similar.

The statement that "turbine pumps are designed for high lifts and are usually compounded in order to reduce the peripheral velocity and thus reduce the friction" is beyond my comprehension. Evidently, the design which characterizes volute and turbine pumps is not clear to Mr. Hubbard, nor is the reason for compounding, as he calls it. High heads require multi-stage pumps, and compounding does not necessarily decrease friction.

Brewster, N. Y.

Vacuum Heating without Thermostats

In an article on "Vacuum Heating without Thermostats," by E. F. Henry, in Power of Oct. 20, 1914, the author states that "provision is always made for injecting water into the return pipe, so that the pump will not attempt to pump steam." This is a rather broad statement, and in this connection the writer wishes to say that if the traps on the radiators leak steam, then it is necessary to have jet water at the vacuum pump. However, if a properly constructed thermostatic trap is used—and there are such to be had—the necessity for jet water is obviated.

In the article referred to it appears as if the author has the idea that thermostatic traps are altogether impractical. The writer can cite a vacuum installation where the radiators are twenty-odd feet below the vacuum pump, yet the condensation from these radiators is lifted to the pump without the use of jet water. Attention is called to the fact that a twenty-foot lift, including friction in the piping, would correspond to a vacuum of approximately 18 in. At this pressure, water boils at 170 deg. F., approximately. This should reveal the fact that, in case any leakage occurred, the lifting of the condensation would be impossible, since the vacuum line would be quickly filled with steam. The writer can refer to many vacuum systems of heating where no jet water is being used, and where the vacuum pump is quite able to produce a vacuum of from 8 to 15 in.

Mr. Henry is quite right in saying that in some cases a thermostat has been removed without materially affecting the operation of the system. However, in such instances the radiator from whose trap the thermostat has been removed must be located at quite a distance from the vacuum pump, or at a point where the vacuum is low and the discharge from the radiator has ample opportunity to cool before coming to a portion of the return line where a higher vacuum is carried, and even then, trouble is likely to occur.

Theoretically speaking, the substitution of globe valves for the thermostatic trap at the return end of the radiator might work very well, but from a practical standpoint it will be almost impossible to throttle the return from each radiator so that it will allow only the condensation to pass, especially since there is no means of telling just the amount of openings that would be obtained by turning valve handles each a certain distance, because different valves would give different openings. Besides the uncertainty of valve opening it must be remembered that condensation in a radiator may be increased at times as much as 100 per cent. or on the other hand may be so much reduced as to allow steam to blow through. The use of jet water at the pump may prevent the pump from pumping steam, but in such a case the steam is in the return line, up to the point where the jet water enters. In such cases one of the main advantages of a vacuum system is curtailed, to say nothing of the complications usually brought about by the use of jet water, which destroys steam, and it is generally also the case that surplus water has to be discharged from the system.

D. N. Crosthwait, Jr.

Marshalltown, Iowa.

We are given to understand by E. F. Henry's statements under "Vacuum Heating Without Thermostats" that he refers to all types of vacuum return valves, although it should be borne in mind that the term "thermostatic" would be more proper, and then strictly correct only when applied to those valves which operate by the expansion of a volatile liquid inside a disk, as distinguished from the float type of valves. His reference to the virtue of the vacuum system as means of abstracting more heat from the steam "before it is thrown away" must be intended to apply only to the use of exhaust steam.

The scheme Mr. Henry proposes has been employed satisfactorily on gravity systems with the return open to the atmosphere and no pump. This is similar to the so called vapor system. With this system, however, a special valve is used that can be shut off and so set, that when it is wide open only the right quantity of steam is admitted to the radiator. This scheme could also be used with a vacuum pump on the return line, provided the difference between the supply and return were always the same—a condition that would be impossible to maintain in practice and would immediately be upset by the least change in either the steam pressure or the vacuum in the return.

With hot-blast heaters, where the rate of condensation changes with every variation of the outside temperature, the scheme would be impractical.

If globe valves are used on the radiators, as suggested, another disadvantage would be that the heating units could never be shut off unless two valves were used.

Taking all points into consideration, I would not advise any engineer to install a heating system and put a vacuum pump on the return line and use no vacuum valves; neither would I advise changing over an existing system with the sole idea of a large saving in operating cost, for there will be none.

W. L. Durand.

Brooklyn, N. Y.

Electric-Light Rates

When electric plants first came into use they furnished current for lighting purposes only, and their total cost of doing business was, therefore, charged up to the current sold for this purpose. It did not take long to learn that if the same equipment which was installed to provide for light customers could be operating in the daytime, they could afford to sell current cheaper during the day than at night, provided they could continue to charge the cost of doing business up to the light customers. This led to the conception and final birth of the present rate-making "theories."

What citizen or court would permit a street railway to charge a passenger riding on a car during rush hours a fare several times larger than that charged at other times of the day? Can you justly ask a street-car company to charge less for a ride in an owl car just because the load in the power plant at that time is in the valley of the load curve, and because they ought to be glad to have "even a little revenue during that time"?

The electric-light companies seek to show that they are the one exception and that they should be allowed to charge up a greater proportion of their cost of doing business to the small consumer who cannot "kick back," and a lesser proportion to the larger customer who can.

F. F. CHANDLER.

Indianapolis, Ind.

Vibration Due to Missing Blades

We have in our plant a 100-hp. impulse single-stage turbine running 12,000 r.p.m. The wheel is 24 in. diameter and mounted on a shaft whose diameter is 7/8 in. There are 196 blades on the wheel and the peripheral velocity is, as usual, quite high, being 1256 ft. per second.

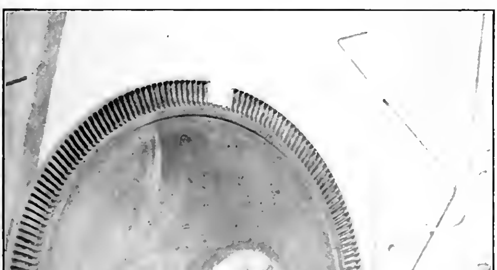

FIG. 1. TURBINE WHEEL, SINGLE-STAGE, UNBALANCED BY LOSS OF FOUR BLADES

An examination of the turbine to discover the cause of excessive vibrations of the shaft showed a gap in the rim where four blades had broken off (Fig. 1). Wheels running at this high speed must be perfectly balanced. The loss of a single blade will cause noticeable shaft vibrations.

The blades of these single-stage turbines are made with bulb-shaped shanks which fit into slots in the rim of the disk. The outer ends of the blades are flanged to

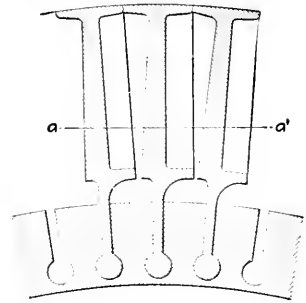

FIG. 2. SECTION OF BLADING

form a continuous rim of metal (Fig. 2). No special apparatus is needed in replacing the blades. In this case the wheel and shaft were removed from their bearings, the shanks of the broken blades punched out and new blades inserted by driving in from the side. The flanges were then filed true.

Moisture in the steam, small particles of scale, etc., are probably responsible for the breakage. There is no separator in the steam line, though one should be put there.

R. S. HAWLEY.

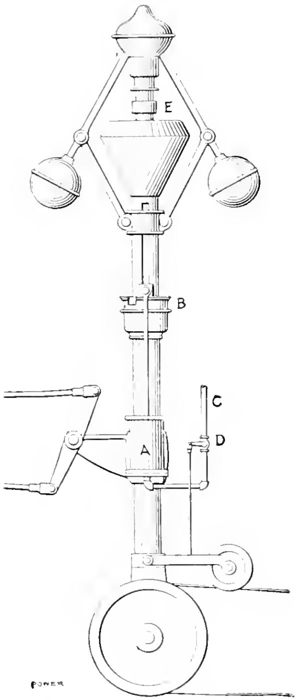
Golden, Colo.

Blocking up the Governor

The direful consequences of blocking up a Corliss engine governor have been so often impressed upon our minds that, with many of us, the faculty of reasoning whether the practice is always hazardous has either never been allowed to awaken or has been quickly inhibited at its inception. The opinion is prevalent that no argument, however reasonable, can justify this practice, and that even to discuss it on the negative side is in itself criminal. Yet there is scarcely any danger—I do not say peril—that cannot be risked with impunity at some opportune time, and certainly there exist conditions under which the governors may be blocked up with comparative if not complete safety. In case of large engines operating under fluctuating loads it is a decided advantage in economy.

Engineers employed in street-railway plants know that, during certain periods of the day, when the peak loads are reached, it is sometimes necessary to prevent the governor weights from dropping below the point of maximum cutoff by fastening up the starting pin. Judging from many an attendant's apprehension at that particular time, however, few seemingly understand that the breaking of a governor belt on one out of two or more engines driving generators connected to the same set of busbars will be attended with little if any evil consequences. Even in industrial plants, in which two or more engines are connected mechanically by means of the factory shafting, the danger is slight provided (and here is where reason and common sense enter) the load is, while the pin is up, at all times equal to, or greater than, the full-load capacity of the largest engine then in operation.

The case is similar to two horses drawing a loaded wagon. One of them may be fresh and impatient, smarting under the restraint of its harness. It prances, jerks and endeavors to run away with the load, but finds it beyond its strength to do so and therefore it is forced to follow the gait of its more conservative brother. Suppose



Common Flyball Governor

two engines operating under similar conditions of heavy load, and suppose that the governor belt on one breaks when the starting pin is up. What will happen? Simply this, the other engine will obligingly give the unrestrained one all the load it can take and the latter is immediately forced to adopt the speed of the other engine. It really does not matter whether the governor revolves when the load is so heavy as to bring the weights down on the starting pin.

To sum up, my point is that under conditions as stated an engineer may attend to his ordinary duties with as little concern about his engines as at any other period of the day, and my only justification for so elaborately enunciating it is that we all have enough trouble without borrowing more.

The great danger lies in the neglect to release the starting pin when the load becomes light, and—but this introduces another matter—carelessness, which is not the subject of this writing.

Regarding the one-engine plant, I can only repeat the frequently iterated admonition never to block up the governor unless an independent speed-limiting device is part of the engine's equipment or the ingenuity of the chief engineer has removed, or at least diminished, the certain risk attendant upon the practice. Where necessity spurs, it really is not a difficult matter to devise some scheme to lessen the danger, as the many creditable efforts that have been described and illustrated in power-plant papers prove.

In one plant I was shown an ingenious device which I mention because of its surprising simplicity. The type of governor and the essential details are shown in the illustration. *A* is the oil dashpot, in the bottom of which is inserted a loose piston of a thickness equal to the depth of the step in the movable rest-collar *B*. Leading from below the throttle is the ⅜-in. pipe *C*, which communicates with the bottom of the dashpot and has the cock *D*, whose handle connects with the arm of the idler, as a shutoff.

It is apparent that the arrangement is such that when the governor belt breaks, the idler will fall and open the cock, which, by supplying steam below the loose piston, should force the governor weights to their highest position against the collar *E*. If one will remember that the piston is always lubricated by the oil contained in the dashpot, and that the steam-cock *D* is also prevented from sticking by the same oil seeping past the loose piston into the pipe, I think it will be agreed that its success is probable if the diameter of the dashpot allows of sufficient area. In no way does it lessen the utility of the dashpot.

R. O. Richards.

Framingham, Mass.

Meter and Pump Trouble

In a steam plant using water from the city main the water meter got out of order, the readings being less than they ought to be. The cause was located in the layout of the triplex power boiler-feed pump, which had a bypass from the discharge pipe to the suction.

There had been a light load for a couple of months and the temperature of the feed water entering the boilers was higher than at normal load. The bypass was slightly open most of the time, as that was the only way to reduce the water-supply and to get a steady feed. This constant circulation of hot water back to the suction pipe caused considerable heat to get to the meter, which was located near the pump, and put it out of order.

When a new meter was installed two horizontal check valves were placed between the meter and the heater. Later, there was a complaint of a pulsation in the mains of about 12 lb. I connected in the suction line an air chamber made of 4-in. pipe capped on both ends. The lower cap was tapped and made up with a 1½-in. nipple a valve and another nipple screwed into a tee on the suction line. The body of this air chamber was drilled and tapped at the top and bottom for ⅛-in. pet-cocks, and these with the valve kept the chamber clear of water and recharged with air. Since then there has been no pulsation or water-hammer.

John Powers.

New Bedford, Mass.

Inquiries of General Interest

Calking of Butt and Double-Strap Joint—Where is the calking done on a butt and double-strap boiler joint?

R. G. M.

On the outside along the edge of the narrower strap, where the rivets are close enough together to obtain a good calking pitch.

Steam Lap of Slide Valve—What determines the amount of lap that should be given to the steam side of a D-slide valve?

J. D. P.

The travel of the valve and the angular position of the crank at the time of cutoff.

Delivery in Duty Trials of Pumping Engines—In making duty trials of pumping engines what is the usual method of determining the quantity of water delivered?

A. E. W.

The delivery is usually determined from plunger displacement, after making due allowance for slippage and leakage, which should be ascertained by actual test.

Units of Compression—What is meant by the term "units of compression" as applied to the operation of a reciprocating engine?

S. C. N.

The expression has been used in designating the number of clearance volumes displaced by the piston during its compression of the exhaust. If, for instance, compression of the exhaust begins at the completion of 75 per cent. of the return stroke, then if the clearance is 5 per cent. there will be $(100 - 75) \div 5 = 5$ units of compression.

Cleaning Heating Coils of Grease Deposits—How can steam-heating coils be cleaned of grease that has been deposited by the use of exhaust steam?

W. C. C.

The grease can be removed by filling the coils with a solution of caustic soda made in proportions of about 20 lb. of soda to a barrel of water. The coils should be filled with a warm solution, and after having them filled for about 24 hr. the solution should be drained off and replaced with clean warm water, which should be blown out of one coil at a time with high-pressure steam.

Setting Boilers with Same Height of Tubes—When two horizontal return-tubular boilers, respectively 72 in. and 60 in. in diameter, are set together, should the upper rows of tubes of the boilers be at the same level, so that there will be the same height of safe water level in each boiler?

S. L. G.

There will be no advantage setting the boilers with their upper rows of tubes at the same level, for dependence cannot be placed on maintaining the same water level by connecting the boilers together below water line, as the proper water level must be maintained by regulation of the feed through a feed stop valve for each boiler.

Relative Economy of Engine with Increase of Speed—If the main receiving pulley on a jack shaft is increased in diameter from 72 in. to 84 in., requiring the engine to make nine more revolutions per minute to drive the shaft at the same speed, will not more steam be required by the engine for driving the same power?

E. H.

There will be $^{72}/_{84}$, or $^{6}/_{7}$, as much work required of the engine per stroke and less steam will be required per stroke, and for the same economy the consumption of steam would need to be only $^{6}/_{7}$ as much per stroke, but whether more or less steam would be required per hour for developing the same power would depend upon relative points of cutting off and other conditions affecting economy.

Connecting Two Engines to the Same Receiving Shaft—For obtaining the power of both engines would it be practical to connect a Corliss and an automatic engine to the same receiving shaft?

J. W. D.

For good regulation it would not be practical, as the governors would not synchronize. An approach to ordinary regulation, though only for gradual loading and unloading, could be obtained by adjusting the governor of the automatic engine for carrying the load up to a point where its speed would become reduced to the working speed of the Corliss governor. Then, with the automatic governor blocked against admission of a greater amount of steam, the Corliss engine could pick up any additional load with a reduced speed. But any sudden change of load would give rise to spasmodic variations of speed of unusual extent and duration. Besides the uncertainties of speed regulation there is an additional objection to connecting the engines as proposed, especially when they are widely separated, arising out of the danger of starting up one engine and sustaining a water smash in the cylinder of the other.

Running Shunt Motor as a Dynamo—At what speed will a 30-hp., 115-volt, 120-r.p.m. shunt motor have to be run when used as a dynamo?

H. G. C.

It will have to be run faster as a dynamo than as a motor to deliver the same voltage to the line, because of the drop in the armature circuit. In the motor the speed will be great enough to produce a counter-electromotive force equal to the difference between the impressed voltage and the armature (IR) drop. In the dynamo the speed must be such as to generate an electromotive force which, minus the IR drop, will equal the line voltage.

To solve the problem accurately it will be necessary to know the armature resistance. Assuming this to be 0.08 ohm, then as a motor rated at 30 hp. and 115 volts will have a full-load current of about 165 amp., the armature drop would be approximately

$$165 \times 0.08 = 13 \text{ volts.}$$

The counter-electromotive force would be

$$115 - 13 = 102 \text{ volts}$$

generated at 120 r.p.m. Run as a dynamo, the armature would have to generate

$$115 + 13 = 128 \text{ volts.}$$

Therefore, as a dynamo, the speed would be

$$120 \times 128 \div 102 = 150 \text{ r.p.m.}$$

Changing Speed of Induction Motor—How can the speed of an induction motor be changed?

F. H.

There are five ways in which this may be accomplished, namely: (1) Changing the applied voltage, (2) changing the rotor resistance, (3) varying the number of poles, (4) operating in cascade, and (5) varying the frequency.

The usual means under the first method is the use of a compensator, or autotransformer. This method does not give very satisfactory speed regulation; the efficiency and power factor decrease with the speed.

In varying the resistance of the rotor winding a constant speed is not obtained over the torque range of the machine, but changes with the torque. As in the first case, the efficiency decreases with the speed.

The third method is applicable when only two speeds are desired; as the number of speeds increases, the necessary wiring becomes cumbersome and complicated. The power factor is not appreciably affected in this case, but as it is necessary to open and close the supply circuit in making the change, variation in primary current and fluctuations in voltage are apt to result.

In cascade operation two motors are necessary, the rotors being connected together mechanically. The stator of the first is connected to the supply and its rotor (which is of the slip-ring type) feeds the stator of the second motor; the rotor of the latter is usually connected to an adjustable resistance. This method is frequently used where the speed changes are frequently made, and the horsepower relatively high, such as in electric locomotives. The power factor and efficiency of two motors in cascade are less than a single machine of the same capacity.

The fifth method mentioned, namely, varying the frequency, is usually impracticable. ?

Just for Fun

[More stories of stupidity and ignorance competing with "Some Original Ideas," as printed Jan. 19, 1915.]

While I was employed in a large plant, it became necessary to remove the bonnet of a 36-in. valve. The assistant engineer, the happy owner of License No. 1, was put on the job. The valve bonnet had been unmolested for many years. After he had worked for about one hour, I discovered that he had twisted off 31 of the stud bolts. Two men had to work twelve hours drilling out the studs with a ratchet and "old man" to repair the damage. *Answer*—Always cut the nuts with a chisel. Nuts are plentiful and split easily with the grain of the metal.—*James Browning, Joliet, Ill.*

A few years ago, while I was running a lighting plant in a small country town, a high-school professor visited the plant one night with his class in physics, and asked my permission to explain the electrical apparatus to the boys and girls. I gave my consent after cautioning him to be careful not to let anyone get hurt. Then I prepared to listen to the discourse myself, thinking this would be a good chance to add to my small store of electrical knowledge.

After lining his class up in front of the switchboard, he said, "Now, first we will have a little demonstration in magnetism," and taking a large jackknife from his pocket, before I realized what he was doing he placed it squarely across the main switch. The report and flash that instantly followed were appalling. The professor's hand was badly burned, and the switch had two large scallops melted out where the knife had touched it, and the back springs, handle, and blades of the knife were fused together. The professor explained that he thought the switch would attract the knife.—*C. M. Knowland, Louisville, Ky.*

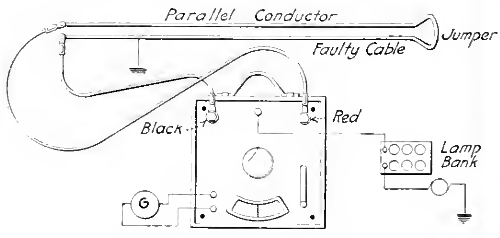
In an artillery electrical plant an officious artillery engineer annoyed the electrician sergeant very much by aimlessly playing with the apparatus. The sergeant, therefore, got some electric primers and concealed them in a cable conduit and connected them to the dead side of several switches, and then found important business elsewhere when the officer appeared again. Of course, the officious one started his usual performance, but very soon heard an explosion, and continuing his monkey business, the noise was soon repeated. He couldn't seem to locate any trouble, and it "got his goat." He hunted up the sergeant and breathlessly said: "I say, sergeant, you'd better go down there and see what the trouble is, for every time I close a switch there is an explosion." And, of course, the sergeant hurried away to make an investigation.

Some years ago a central station in this vicinity was operating several old Thomson-Houston arc machines. A policeman on that beat frequently stepped in for a few minutes. One night he came in looking kind of glum and remarked that he wasn't feeling very chipper—kind of stiff and rheumatic. When no one was looking he took hold of both brushes of one of the arc machines. He said afterward it was pretty harsh treatment, and one dose was enough, but maintained it knocked the rheumatism out of him.—*H. L. Strong, Yarmouthville, Maine.*

Portable Fault Localizer

A portable fault localizer, for quickly locating a ground on an electric cable has been developed by the Westinghouse Electric & Manufacturing Co. The position of a ground is read directly from the dial in per cent. of length of the defective cable. It is an application of the wheatstone bridge, with all the necessary apparatus contained in one portable case wired for connection to the circuit to be tested. Its use assumes that the cable is grounded at only one point and that a parallel conductor of the same length and resistance is available.

After proper connections are made, a dial on the instrument is revolved by means of a knob in the middle of the localizer until the galvanometer shows no deflection when the key is closed. The reading of the meter then gives the percentage of length of the feeder from the point where the test is being made to the location of the ground, assuming the total length of the feeder to be 100



OUTFIT FOR LOCATING FAULTS

per cent.; the red scale indicating that the ground is on the conductor connected to the binding post marked red, and the black scale indicating to the binding post marked black. Direct current only is used in these tests.

The variable-resistance arms consist of two loops of low-resistance wire attached to the side of a revolving disk, upon which the dial is attached, so that contact is easily made from two brushes attached to the case and connected to the galvanometer terminals. As the disk is revolved the point of contact between the brushes and the resistance loops is thus varied, as in the slide-wire bridge. The dial is calibrated in percentage of the length of the conductor tested, so that the reading is direct.

Rules for Thickness and Weight of Lead Pipes

The thickness of lead pipe required to withstand a given pressure may be calculated by the following formula:

$$T = \frac{0.433 \times H \times R}{2745}$$

in which

T = Thickness of pipe in fractions of an inch;
H = Head of pressure in feet;
R = Radius of pipe in inches;

from which we get

$$T = 0.0001578 \times H \times R$$

For lead a factor of safety of 10 is required, hence the last rule becomes $T = 0.001578 \times H \times R$

or, if we take D = the diameter of pipe in inches, instead of radius R, we get

$$T = 0.000789 \times H + R$$

The formula for the weight of lead pipes is

$$W = 3.86 \ (D^2 - d^2); \text{ or } 3.86 \ (D + d) \times (D - d)$$

in which

W = Weight of pipe per lineal foot in pounds;
D = External diameter of pipe in inches;
d = Internal diameter of pipe in inches;
3.86 = A constant.

Oil Engine for Off-Peak Load

By L. H. Morris

SYNOPSIS—Saving effected in a small municipal plant where an oil engine was installed to handle the load between midnight and 7 p.m., the steam plant handling the evening load.

At present much attention is being given to the oil engine in the West and Southwest, where plants of small and medium size are to be installed. However, it is not alone in new plants that the oil engine finds application, but also in existing steam plants where additional power is necessary, or where a more economical engine is found desirable to handle the off-peak load. This is especially true as regards the small electric-light plants of capacities up to three or four hundred kilowatts, where the load from midnight until morning consists of the street lights and a few residence lights, and where the day load consists of a few motors of small power. In such cases a steam plant of a size to carry the maximum evening load must operate at a low load factor during fifteen to eighteen hours a day, and the resulting cost per kilowatt-hour is often too high to show a fair profit on the investment.

A situation along these lines arose in a municipal light plant with which the writer is connected. This plant, including the pole lines, etc., was purchased from a private company some years ago at a total cost of $35,000. The power house contained a 125-hp. noncondensing Corliss engine belted to a 75-kv.-a. alternator, a 75-hp., high-speed engine belted to a 40-kv.-a. alternator, two 72-in. by 18-ft. and one 54-in. by 16-ft. tubular boilers, together with the usual switchboard, piping, pumps and heaters. A fair estimate of the replacement cost of the plant, including the building, would not exceed $12,000, leaving the outside system to carry the remaining $23,000, less the franchise value; although the entire plant and system could be replaced for less than $20,000.

The load consisted of the lights for the entire town, a few small motors, and a 15-hp. motor driving the city water-works pump. The amount of water pumped was approximately 72,000 gal. per day, the bulk of this being used by the railroads and mill. This pump was thrown onto the line whenever the engineer found the water in the standpipe getting low.

The plant has been under municipal control for about four years, and at no time have the earnings been as large as was expected. This, of course, led to much dissatisfaction and caused the resignation of several plant operators. Finally, there came into office a new set of city officials who were committed to a policy of running the plant on a profitable basis, or of turning it over to a private company.

This ultimately led to an investigation of the oil engine, especially the high-compression type. It was generally understood that the plant required a 150- and a 75-hp. engine. The investigation readily proved that this type of engine would have a high maintenance charge and would require higher-grade engineers than the town could afford to employ, even though the fuel cost be exceedingly low. The medium-compression or semi-Diesel was finally decided upon, but the entire scheme was abandoned upon learning the cost of the two units.

Finally, a new superintendent was employed, who decided to approach the matter in a more systematic way and, therefore, ran a test on the plant with the idea of learning the exact load and the total amount of fuel used per hour.

Curve No. 1, Fig. 1, shows the hourly load for the twenty-four hours. It will be noted that the output is below 40 kw. from midnight until 6 p.m., while from 6 p.m. until 11 p.m. the load is considerable. Furthermore, the crosses marked 1, 2, 3, etc., indicate the hours during which the pump motor was in operation, from which may be judged the load at these hours with the pump motor eliminated (this motor required 13 kw.). Curve No. 2 shows the fuel cost per hour, while curve No. 3 covers the total fuel and labor cost per hour.

An examination of these curves shows that the coal used per hour was out of all proportion to the kilowatt output. It is readily admitted that the excessive fuel charge is open to criticism, and it is self-evident that

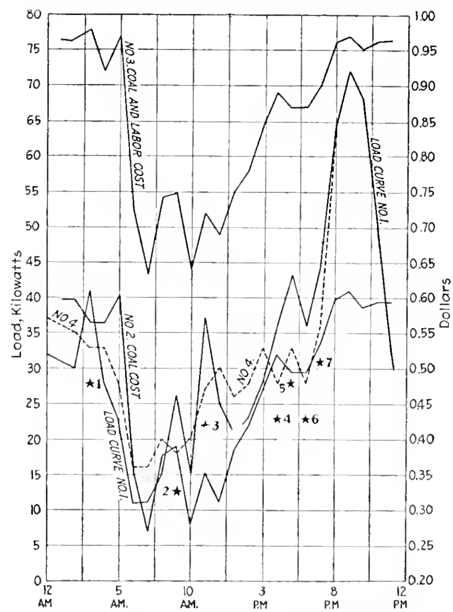


Fig. 1. Hourly Load of Steam Plant

either the engines were in bad condition or the firing was bad. A test on the high-speed engine showed that it used 59 lb. of steam per kilowatt-hour at full load, which, while high, is not excessively so, in view of the belt loss. Furthermore, a casual investigation of the firing method in vogue during the hours of light load indicated that the greater part of the loss was in the boiler room. However, even if the firing conditions had been improved, the fuel cost would still have been high, because of the varying load.

As already mentioned, the original idea of purchasing two oil engines had been abandoned on account of the cost; therefore, a plan was adopted whereby the plant could use both a small oil engine and one of the steam engines.

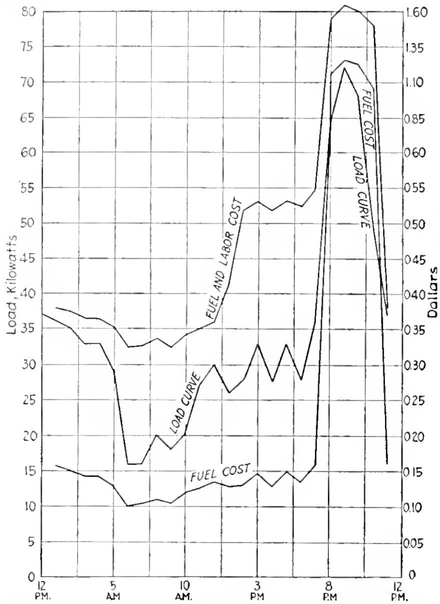

Fig. 2. Hourly Load of Steam- and Oil-Engine Plant

As a means of evening up the load a 4x6-in. duplex power pump was installed to handle the city water, this being driven by a 5-hp. motor operating twenty hours a day, while retaining the centrifugal pump and motor for additional fire protection. This would cause the load to take the form of curve No. 4, Fig. 1. In this way the load would not exceed 40 kw. during nineteen hours of the day; and as the load each day was almost uniform, it could be assumed with safety that this value would not be exceeded for some time to come.

A 60-hp. medium-compression oil engine was purchased at a total installed price of $3800. This engine was of the single-cylinder horizontal type with a guaranteed fuel consumption of 0.067 gal. of desulphurized fuel or crude oil per horsepower-hour, and furthermore was to have a 25 per cent. overload capacity. This was belted to the 40-kv.-a. alternator already installed.

The setting of one of the 72-in. by 18-ft. boilers was altered so that oil could be used as fuel. This involved but slight expense, as the alterations consisted of building a checkerwork of firebrick on the bridge-wall and of covering the grates with a layer of cinders and firebrick. This type of furnace is not ideal for the use of oil, but is one quite generally used where there is a possibility of changing back to coal. Some time in the past the plant had used oil as fuel when it could be obtained at 70 to 80c. per barrel, and consequently it was not necessary to purchase a burner, pumping outfit or storage tank.

The plan of operation was to run the oil engine from midnight until 7 p.m. and then cut in with the steam engine, it being easy to raise steam in about thirty minutes. The oil cost 3c. per gallon delivered. Very little oil was actually used under the boiler from 11 p.m. to 12 p.m., as the steam was allowed to go as low as 50 lb. during this hour, so that the oil saved here made up for the oil used in steaming up between 6 p.m. and 7 p.m. This saved about 1000 lb. of coal that would have been used in banking fires and steaming up.

With this method of operation it was possible to dispense with one man and to raise the salaries of the two engineers. The night engineer worked from 7 p.m. to 7 a.m., the day engineer from 7 a.m. to 7 p.m., while the fireman's hours were from 12 noon to 12 midnight. This allowed two men to be on duty during the heavy load when the steam plant was in operation, and also gave the day engineer time to do repair work each afternoon.

As regards the total saving; it was impossible, of course, in ordinary operation to find any one day's load which corresponded exactly with the day's run plotted in Fig. 1. Consequently, arrangements were made to run a twenty-four-hour test on a Sunday, wherein each hour's load was made the same as on the first test with the exception of the waterworks load, which was distributed over twenty hours instead of seven.

Accordingly, on Saturday night the standpipe was filled, a water rheostat was arranged for manipulating the load and at midnight and each hour thereafter the load was kept to the proper value. It was thought best not to run the pump motor, as it was necessary to take care of the commercial load, which might be slightly larger than during the former test.

Fig. 2 shows the results of the test plotted as to load, fuel cost and total cost. The oil engine, while handled by the city employees, did not come up to the guarantee, but the ease of operation and apparent reliability more than offset the increased fuel consumption. The steam plant used a large amount of oil per kilowatt-hour, causing the fuel cost to be much higher during the peak hours than it was during the corresponding hours of the first test. However, all banking of fires was avoided, with a resultant saving of fuel, and all things considered, the oil proved more satisfactory.

For comparison, the costs per day under both conditions are given below, showing a net saving of $2209.70 per year, which represents a return of 57½ per cent. on the cost of the oil engine and the alterations to the boiler. As soon as the city can raise more funds, a larger oil engine will undoubtedly be installed.

	Steam Plant	Steam and Oil
Fuel: coal at $1.80 per ton, oil at $0.03 per gal.	$11.60	$7.29
Labor: 2 engineers at $72 per month, 2 firemen at $60	8.80	
2 engineers at $80, 1 fireman at $60		7.33
Total cost per day	$20.40	$14.62
Net saving per day		$5.78
Net saving per year		2209.70
Cost of engine and alterations		4200.00
Cost less value of old steam engine		3850.00
Saving on investment		57½ per cent.

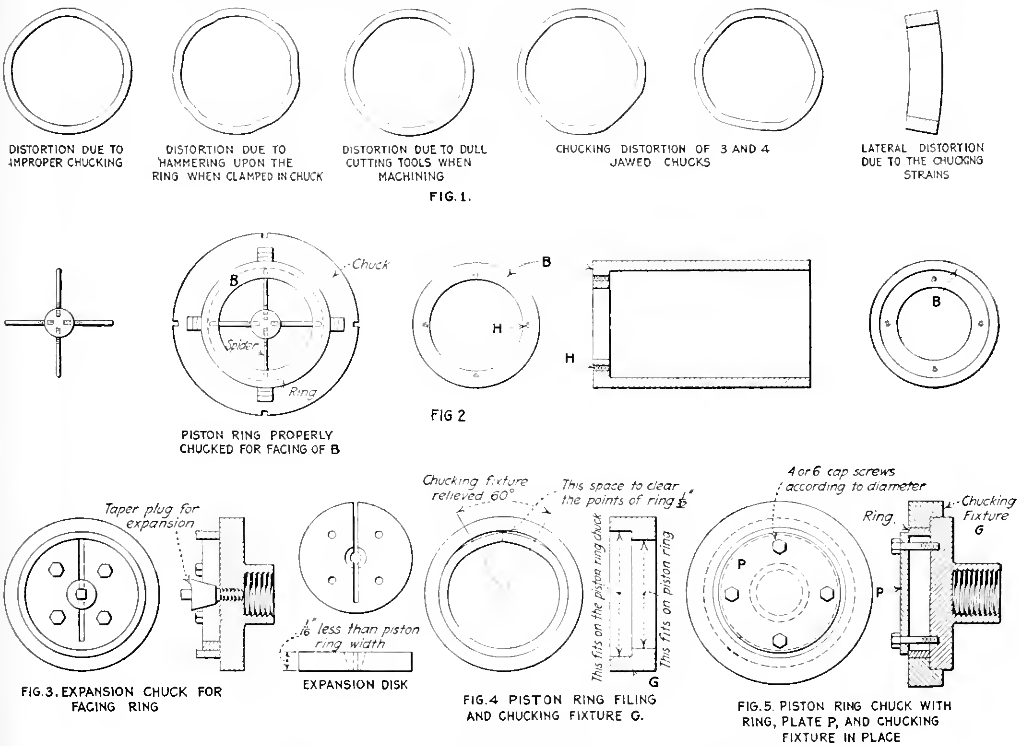
The amount of lubricating oil was practically the same on each test owing to the bad condition of the high-speed engine.

Machining a Piston Ring

By G. Strom

A piston ring with a plain surface will wear to its bearing in four or five hours if properly made and fitted. The real cause of leakage is distortion of the ring in manufacture. Fig. 1 shows some of the effects of such distortion.

To produce a properly fitting piston ring, a casting of the required dimension is secured. A spider with the same number of screws as there are jaws in the chuck is then inserted and the screws tightened slightly, Fig. 2; this is to prevent springing the casting when chucking.



Process of Machining Piston Rings and Some Distortions

The casting is then placed in a lathe, chucked upon the spider screws and end *B* faced true. Holes *H* are drilled for bolts or tapped for capscrews for bolting to the faceplate. This must be faced true. The casting is machined to the required dimensions, allowing $\frac{1}{32}$-in. thickness and width for re-turning. In both machining and cutting-off operations the tools must be kept sharp, otherwise the ring will have a wind impossible to remove.

The ring is then placed on an expansion chuck, Fig. 3, to have its sides faced as follows: Place the ring, which should be a sliding fit, on the expansion disk, loosen the four capscrews slightly, press the ring against the chuck plate with a board, tighten the taper plug and the capscrews and then all is ready for facing. Three light cuts are required on each face, using $^1/_{100}$-in. feed.

After both sides of the ring are finished it is split diagonally, using a hacksaw or milling cutter, and fitted into a chucking fixture *G*, Fig. 4, which is $\frac{1}{16}$ in. larger in diameter than the finished ring and is relieved $\frac{1}{8}$ in. for one-sixth of the circumference opposite which the cut in the ring is placed. This is to allow the points to spring slightly outward and when turned off will prevent the points from "digging" into the cylinder.

The fixture with the ring inside is put on the special faceplate *P* and tightened. The chucking fixture is then removed and the face of the ring turned. Only one ring at a time should be chucked; if several are placed together they will buckle and be spoiled. A diamond-pointed tool should be used with a $^1/_{100}$-in. feed per revolution. Three cuts should be taken across the ring with a sharp tool, allowing $^6/_{1000}$ for the finishing cut. The finished ring should be the diameter of the cylinder plus $^1/_{1000}$ for wearing in, and no filing is necessary. The piston should have dowel pins to keep the ring from rotating. In slipping the ring on the piston and into the groove a tin shield should be used instead of wire nails, and the like, as is sometimes done.

In fitting new rings no allowance need be made for circular expansion. This will leave the joints tight when the ring has worn to a bearing and there will be no blowing or leakage.

It might be argued that so tight a ring would score and cut itself and the cylinder. This is not true. A tight piston will quickly score its cylinder, but a tight ring will not. The foregoing is for rings ranging from 3-in. to 18-

in. diameter and $\frac{1}{8}$ to $\frac{7}{16}$ in. thick and from $\frac{3}{16}$ to 1 in. wide. The following table gives the dimensions of several sizes of rings and the allowance for tension.

PISTON RING DIMENSIONS

Diam. of Finished Ring, In.	Width of Finished Ring, In.	Thickness of Finished Ring, In.	Diam. of Ring before Splitting, In.	Allowance for Tension on Ring, In.
18	1	$\frac{7}{16}$	$18\frac{5}{16}$	$\frac{5}{16}$
17	1	$\frac{7}{16}$	$17\frac{5}{16}$	$\frac{5}{16}$
16	1	$\frac{7}{16}$	$16\frac{5}{16}$	$\frac{5}{16}$
15	$\frac{7}{8}$	$\frac{13}{32}$	$15\frac{5}{16}$	$\frac{5}{16}$
14	$\frac{7}{8}$	$\frac{13}{32}$	$14\frac{5}{16}$	$\frac{5}{16}$
13	$\frac{7}{8}$	$\frac{13}{32}$	$13\frac{1}{4}$	$\frac{1}{4}$
12	$\frac{3}{4}$	$\frac{3}{8}$	$12\frac{1}{4}$	$\frac{1}{4}$
11	$\frac{3}{4}$	$\frac{3}{8}$	$11\frac{1}{4}$	$\frac{1}{4}$
10	$\frac{5}{8}$	$\frac{11}{32}$	$10\frac{3}{16}$	$\frac{3}{16}$
9	$\frac{5}{8}$	$\frac{11}{32}$	$9\frac{3}{16}$	$\frac{3}{16}$
8	$\frac{9}{16}$	$\frac{5}{16}$	$8\frac{3}{16}$	$\frac{3}{16}$
7	$\frac{9}{16}$	$\frac{5}{16}$	$7\frac{5}{32}$	$\frac{5}{32}$
6	$\frac{3}{8}$	$\frac{9}{32}$	$6\frac{5}{32}$	$\frac{5}{32}$
$5\frac{3}{4}$	$\frac{5}{16}$	$\frac{3}{16}$	$5\frac{29}{32}$	$\frac{5}{32}$
$5\frac{1}{2}$	$\frac{1}{4}$	$\frac{5}{32}$	$5\frac{21}{32}$	$\frac{5}{32}$
$4\frac{3}{4}$	$\frac{1}{4}$	$\frac{5}{32}$	$4\frac{29}{32}$	$\frac{5}{32}$
4	$\frac{1}{4}$	$\frac{5}{32}$	$4\frac{1}{8}$	$\frac{1}{8}$
3	$\frac{3}{16}$	$\frac{1}{8}$	$3\frac{1}{8}$	$\frac{1}{8}$

Extension of the Dunston Station

The much discussed Dunston Station at Newcastle-upon-Tyne has been undergoing extensions, although completed only four years ago. An agreement was entered into with the Teams Byproducts Co., Ltd., to purchase the surplus gas from a large battery of Otto-Hilgenstock coke ovens about 1½ miles from the Dunston Station. Gas is carried to the station in 16-in. welded steel pipes and is burned under water-tube boilers. The station was originally laid out for four 6000-kw. units, only three of which were installed. The new installation consists of a 12,000-kw. turbo-alternator of the impulse reaction type, built by Richardsons, Westgarth & Co., Ltd., and Brown Boveri—the turbo and alternator, respectively. Merz & McClellan, of Newcastle-upon-Tyne and Westminster, are the consulting engineers.

Decision for Municipal Light Plant

Columbus, Ohio, has a municipal light plant which has been in operation for several years, and in the past few years has been selling some of its day output to private parties. A citizen, James M. Butler, sought from the courts an injunction against the city to prevent this practice, the case being outlined in the Jan. 20, 1914, issue of "Power." Since then the newly elected city solicitor, Henry L. Scarlett, has defended the city.

There were two main contentions made in support of the petition and amendment by plaintiff's counsel: (1) That the City of Columbus, by reason of the sale of current from its electric light plant to private consumers at less than cost is operating its plant at a loss, which loss must be paid by the taxpayers; and (2) that in the sale of such current there is no uniformity or classification of prices among customers. The operation of the plant by the city officials under these conditions was claimed to be such a gross and manifest abuse of their discretionary powers and such a disregard of the rights of the taxpayers as to amount to fraud upon them, entitling plaintiff as a taxpayer to an injunction..

The city solicitor argued in reply that an electric-light plant, such as is owned by the City of Columbus, is operated by the city acting in its proprietary capacity as distinguished from its governmental capacity. Thus the plant would be run as a business concern and, as such, might have pr..its and might have losses. The sale of electricity for private purposes so far has been incidental, in order to dispose of a portion of the day load, which otherwise was a waste product. The principal use of the plant being for lighting the streets and other public places, it is apparent that when the night load and a very small part of the day load are utilized on city properties the entire operation and maintenance cost, including interest and depreciation on the investment, is a burden upon the public. If the sale of the extra available day load to private consumers pays the extra operating cost incurred by its generation and a proper depreciation and interest charge on the extra equipment necessary for its generation and distribution, and contributes anything, however small, to the fixed charges, then the day load is sold at a benefit to the city and not at a loss.

Municipalities and their officers have the legal power, and it is their duty to apply the surplus power and use of all public utilities under their control for the benefit of their cities and citizens, provided always that such application does not materially impair the use of these facilities for the purpose for which they were primarily created.

As to its rates for private service, the city plant was in competition with a privately owned plant, and had to meet that competition as any business concern would. It did not have enough power to supply the whole city, and therefore furnished electricity to such customers as might use a sufficient quantity, in the judgment of the officers, to net the best returns. The contracts were entered into voluntarily by the private parties, and the rates made were agreed to and were satisfactory. No intimation was raised by the plaintiff that a higher price would have been secured, and so no foundation is laid for charge of fraud. No private consumer had sought court relief on the basis of unequal rates.

Judge Rodgers ruled against the plaintiff and in favor of the defendant, the city, and denied the injunction sought. Some quotations from his ruling are of wide interest, and are as follows:

I am unable to reach the conclusion that the pleadings make a case for injunctive relief, either on the ground of misapplication ot corporate funds, or abuse of corporate powers, or the execution or performance of contracts in contravention of the laws governing the city, or through fraudulent or corrupt procurement. The right of the city to furnish electric current to private consumers is conferred by statute wherein it grants the power to establish, maintain and operate municipal lighting, power and heating plants, and to furnish the municipality and the inhabitants thereof with light, power and heat, and to procure everything necessary therefor. And in the exercise of this power the city is exercising an administrative function. It is fundamental that, in the exercise of such duty, courts will not interfere unless the discretion of the officials is so grossly and manifestly abused as to amount to a fraud upon the taxpayers and a disregard of their rights.

Apparently, the theory of plaintiff's counsel is that, whatever service the city renders to one of its private citizens, it must be remunerative at least to an amount equal to the cost of the service. In other words, the service must be self-sustaining; otherwise it cannot be rendered by the city to the individual.

I do not understand that this is the theory upon which the various public utilities of a municipality are operated by it, such as the water-works, lighting and power plants, gas plants, garbage- and refuse-disposal plants, the removal of ashes and other refuse from the residences of its citizens and the like.

The statute granting authority to cities to furnish light and power to its inhabitants does not confer power on the city to sell electric light or power to the inhabitants, but confers power to furnish such light and power. Whether such light and power may be furnished above, at or below cost or even free to the inhabitants, does not appear by the express language of the statute. . . . The city is given power to furnish its citizens electric light and power, and it is left with the city to fix the terms upon which such light and power may be furnished. If the city sees fit to furnish light and power to its inhabitants at less than cost, I see nothing in the statute to prohibit the city, through its officials, from exercising its discretion to that end. If plantiff's contention were correct, that in the sale of electric current to the inhabitants there must be no loss to the city, and that the sale price must at least equal the entire cost of production, a municipal plant might never be able to furnish its citizens with electric light or power. Of necessity, every municipal plant of this character must start with a few customers; yet as a matter of economy must make preparation in the way of lands, buildings, installation of machinery, wiring, poles, and the like, for probable future increase of business. On the other hand, if the power conferred by the statute upon the city to furnish electric light and power to its inhabitants is construed to mean authority to sell at such prices as the city may determine, the city in the exercise of its proprietary functions is put in a position to operate the plant as business men would engage in a like enterprise. As a matter of economy business men would probably build their plant, not alone to supply present needs, but in anticipation of probable future demands, with the view that the future returns on the investment on account of increasing business would make up for any present losses.

The statutory authority of cities to furnish electric light and power to the inhabitants is found in the general enumeration of powers recited in the statutes, and these powers include the power to maintain police and fire departments, to provide for a supply of water, to establish, maintain and regulate free public band concerts and free public libraries, to provide for the renting of free public hospitals, to provide for the collection and disposal of sewage, garbage, ashes and animal and vegetable refuse, etc. For the use and benefit of its citizens the city charges them for some of the benefits above mentioned which the city has power to furnish, and for others it makes no charge whatever, as for example, the removal of garbage, ashes and refuse matter and the extinguishing of fires.

As it appears to me, so far as the city has the power to and is furnishing a part of its inhabitants electric current, who are willing to pay the price therefor, it is not within the province of the court to interfere with the prices at which the city is disposing of its electric current, merely on the ground that the city thereby is losing money.

A further contention is that the prices charged for the electric current are not uniform under the same or like conditions and are discriminatory among the city's customers. I am inclined to the opinion that the pleadings show a wrong in this respect that is in need of a remedy. That a city through its officials cannot discriminate in furnishing service of any kind to its citizens, but must act impartially in furnishing such service, appears to be fundamental. However, is the plaintiff a proper party to make complaint? The discrimination in rates charged and paid for the electric current in no wise appears to affect the plaintiff as a taxpayer. In other words, it is not shown that his taxes would be less if there were no discrimination in rates, or in fact would be affected either way; nor does it appear that he has sought to have the city furnish him service at a reasonable rate, and it has been refused, although the city is furnishing like service to others on more favorable terms. In this view of the case I am of the opinion that the plaintiff does not allege sufficient facts in the respect just mentioned to entitle him to injunctive relief.

Rate Publicity Ordered

One of the most far-reaching orders that the upstate Public Service Commission of New York has issued in years went into effect Feb. 15, requiring the rate schedules of all gas and electric corporations and all municipalities subject to the regulation of the commission to be filed in the commission's office, and to be kept in convenient form for the inspection of customers at all offices of such corporations and municipalities where contracts for service are made or payment for services received.

This order follows out the plan of the commission in regulating other corporations under its control, and requiring the fullest publicity of all rate schedules in order to prevent discrimination. The order specifies that the rate schedules are to be uniformly printed and that when asked for by a customer the person having charge of them in the corporation's office shall give all necessary assistance in gaining information therefrom. The schedules include not only rates, present or proposed, but regulations for service and privileges and facilities under each rate.

The Corrosion of Condenser Tubes

We have received from E. Bates, White Bay Power House, Sydney, N. S. W., a copy of a paper on the corrosion of condenser tubes, read by him before the Electrical Association of New South Wales in 1913. In this paper Mr. Bates states that the exceedingly serious corrosion of condenser tubes experienced at the Ultimo power station of the Sydney Tramways had been completely checked by the simple procedure of painting the whole of the interior of the cast-iron water boxes with an anticorrosive paint. Following the success at Ultimo, the same procedure was adopted with equally good results at the power station of the Adelaide Tramways, where much trouble had been experienced from condenser-tube corrosion. Attempts to check this by improving the contact between tubes and tube-plate and by suspending zinc plates in the water boxes had all failed, but on learning of the results achieved by Mr. Bates at Sydney, it was decided to try the same plan at Adelaide. In the first instance, the interior of the water boxes, covers and pipes of one condenser were painted with three coats of biturine solution. The result was that the corrosion did not recommence until the paint was washed off. Subsequently an anticorrosive paint was used, and was found to last three times as long as the biturine solution.

As is well known, many engineers have made claims to success in stopping condenser-tube corrosion, but in many cases an extended trial has proved these pretensions to be illusory. An example brought forward at the discussion on Mr. Bates' paper was one presented at the Ithaca meeting of the American Association for the Advancement of Science in 1906, by W. W. Churchill, who declared that tube corrosion at the Bay Ridge station of the Brooklyn Edison Co. had been traced to stray currents and that the trouble had been completely checked by installing a booster to provide a counter electromotive force. One of the speakers on Mr. Bates' paper related, however, that he had visited New York subsequently and learned that the plan in question had proved a complete failure, and that the booster sets providing the counter electromotive force had been thrown out of service. It is therefore interesting to learn from Mr. Bates that his system is still in use at the Sydney power stations, and with excellent results.

The trouble originally arose with the condensers of certain 5000-kw. turbo-generators. Electrolytic methods of protection were tried on the installation of a new unit, and for eight months this condenser gave no trouble and electrolytic protection was deemed a success. Then, however, the tubes began to fail rapidly. It was therefore decided to try Mr. Bates' plan on two of the older condensers, and when it proved successful with them, the same process was adopted in the case of the new condenser, the electrolytic protection being dispensed with. During the succeeding nine months not a tube failed in this condenser.

Mr. Bates' method is based on the hypothesis that the corrosion, being of the pit-hole type and practically confined to the bottom of the tubes, must be due to the deposit of electro-negative material, and this material must, he concluded, have been derived from the corrosion of the cast-iron water boxes. He states that once a pit hole is started by the deposit of such material, the corrosion will proceed even if the initiating cause be washed away subsequently, since when local corrosion has commenced the "balance" of the alloy is upset. The ordinary condenser tube has, he says, a composition giving a minimum waste by corrosion in normal conditions. If the constitution is altered locally by selective dissolution following the deposit of electro-negative matter, then, even when the latter is removed, the corrosion will continue, owing to the "balance" of the alloy having been disturbed.

During the 15 months which have elapsed since Mr. Bates' paper was read the number of tubes removed from the two older 5000-kw. condensers has, he informs us, not exceeded three per month, while before the Bates method of protection was adopted it was not uncommon to lose 150 tubes from one condenser in a single week.—"Engineering."

Recent Court Decisions

Digested by A. L. H. STREET

Damages Caused By Power Dam—A hydro-electric power company is liable to a suit in a county into which its dam backs water to the injury of inhabitants of that county, although its principal place of business and its plant may be in other counties, according to the decision of the Georgia Supreme Court in the case of Central Georgia Power Co. vs. Stubbs, 80 "Southeastern Reporter" 636. The court decided these further propositions: The Georgia statute, which permits suit to be brought in the county where the cause of action arose, is not unconstitutional. If water is so impounded by the dam as to create a nuisance, to the injury of an adjoining landowner, he may recover damages, including those brought about by sickness of himself and family caused by the nuisance, but, the conditions complained of being permanent, he must recover all of his damages in one suit, not being entitled to prosecute successive actions for continuing injury. The power company is not liable for loss of trade at his mill resulting from people moving away on account of the nuisance.

Insurance of Boilers—A peculiar case involving the liability of a fire-insurance company on an ordinary fire-insurance policy for injury to a stationary boiler was recently passed upon by the Kansas Supreme Court. It appears that at the close of a business day the boiler was left more than half full of water, with the gas which furnished the fuel turned off. The next morning it was found that someone had entered the building and caused the fire to be restarted and kept up long enough after the water was exhausted in steam or by draining to injure the boiler. The next morning the gas was found turned off. On these facts the Supreme Court decided (McGraw vs. Home Insurance Co., 144 "Pacific Reporter," 821) that the evidence was insufficient to warrant the inference that someone not connected with the plant had maliciously caused the injury, so as to render the insurance company liable for the loss. The court holds that proof of the facts stated was not inconsistent with the injury having been caused by someone connected with the plant, in which case the insurance company could not be held on the policy.

Responsibility for Boiler Explosion—In lately affirming judgment against the defendant in the case of Eberts vs. Mount Clemens Sugar Co. (148 "Northwestern Reporter," 810) for injuries sustained by the plaintiff, an employee of the defendant, in a boiler explosion, the Michigan Supreme Court held that an employer's duty to make proper inspection of boilers to promote the safety of employees cannot be discharged by merely entrusting it to a certain employee. In other words, an employer is liable for injury directly attributable to the negligent omission to discover any defective condition of a boiler, although the immediate act of carelessness may have been that of a co-employee of the injured worker to whom the duty of inspection was entrusted. In this case it was the plaintiff's theory that the rear stay-plate of the boiler became bulged or corrugated by overheating, that this was a dangerous condition likely to result in a failure or explosion, and that an inspection, which was negligently omitted, would have disclosed such condition. On the other hand, the defendant claimed that the condition could not have been discovered by a reasonable inspection before the accident and that the initial rupture occurred not in the stay-plate, but in the combustion chamber.

OBITUARY

H. WARD LEONARD

H. Ward Leonard, the well known electrical engineer, died suddenly at the Hotel Astor, New York, on Feb. 18, while attending the annual banquet of the American Institute of Electrical Engineers. He was born in Cincinnati, Feb. 8, 1861, was graduated from the Massachusetts Institute of Technology at the age of 22, and a year later became associated with Mr. Edison in the introduction of the central-station business. After three years in this line he was with the Western Electric Light Co. for a short period, and later became part of the firm of Leonard & Izard. This concern was finally absorbed by the Edison company, and Mr. Leonard became general manager of the combined Edison interests.

In connection with the Ward Leonard Electric Co., which he founded, his later life was identified with a large number of important inventions, among which are the Ward Leonard system of motor control, used generally by the U. S. Navy; the well known multiple-voltage system which bears his name, a lighting system for trains and automobiles, and an electric gear shift, besides other inventions relating to mine hoists, electrically driven reversible rolling mills, locomotives, elevators and gasoline-electric trucks. In 1903 he was awarded the John Scott medal by the Franklin Institute, and also received medals at both the Paris and the St. Louis Expositions. He was a life member of the American Institute of Electrical Engineers. A widow survives him.

ENGINEERING AFFAIRS

The Irish-American Association of Stationary Engineers is the newest organization in this craft. It meets at K. of C. Hall, 81 Hanson Pl., Brooklyn. Harry F. Burns, at the same address, is president.

National District Heating Association—The next annual convention will be held in Chicago, June 1, 2 and 3, 1915, with headquarters at the Hotel Sherman. The papers will be: "Commercial End of the Heating Business," by C. F. Oehlman, of the Denver Gas & Electric Co., Denver, Colo.; "Typical Hot Water Heating Plant," by W. G. Carlton, New York City; "A Pressure Study Survey," by C. C. Wilcox, of Commonwealth Power Co., Jackson, Mich.; "Exhaust Steam vs. Live Steam for Heating," G. W. Martin, New York City; and a paper, the title of which is not yet announced, by E. F. Tweedy, of the New York Edison Co. Reports will be made by the committees on rates, underground construction, public policy, education, meters, station operating and station records. In addition, there will be three addresses by men of national reputation. Altogether, the next convention promises to exceed in attendance and interest any that the association has ever held.

NEW PUBLICATIONS

PRACTICAL IRRIGATION AND PUMPING. By Burton P. Fleming. Published by John Wiley & Sons, New York, 1915. Size 6x9 inches; 260 pages; cloth. Price, $2.

According to the author, the farmer is now looking toward the vast areas on the higher ranges, or mesas, where the latent agricultural possibilities of the soil are enormous. To irrigate this land means the pumping of surface and subsurface water, and it is the purpose of this book to treat chiefly of the subject of pumping. The author considers the matter of wells and well sinking, pumps, pumping machinery, selection of prime movers for pumps, and irrigation by windmill-operated pumps. The chapter on pumping costs should prove interesting to those interested in irrigation. Contractors and engineers, who are called on in their professional capacity to solve the pumping difficulties of irrigation jobs, should find the book of value.

HANDBOOK OF FORMULAS AND TABLES FOR ENGINEERS. By Clarence A. Pierce, instructor in power engineering in Sibley College, Cornell University. With mathematical sections by Walter B. Carver, assistant professor of mathematics, Cornell University. Published by the McGraw-Hill Book Co., New York. Flexible leather; 168 pages; thin paper; tables and diagrams. Price, $1.50.

This book is a compendium of tables and formulas frequently used by students and practicing engineers in making calculations in higher mathematics, mechanics and machine design, and should be found of great convenience to those who may have forgotten or are doubtful of some of the applications of higher mathematics in the solution of engineering problems.

The work is divided into 10 principal sections, covering the subjects of algebra, geometry and trigonometry, analytical geometry, calculus, measurements, physical and chemical properties of substances, mechanics, strength of materials, standard gages, fastenings and flanges, and mathematical tables. It also gives a Mollier entropy chart of the thermal properties of steam. The book affords in convenient form a collection of tables and formulas most commonly used by engineers and for which they have usually been dependent upon reference to a number of handbooks and textbooks.

BUSINESS ITEMS

The Lea-Courtenay Co., 90 West St., New York, due to increased business, has opened its own Chicago branch in the Conway Building, with Mr. Maher, formerly of the Maher & Byrne Co., as manager.

The Whitlock Coil Pipe Co., Hartford, Conn., has just published Bulletin No. 22, Series No. 3, dealing with the subject of heating surfaces in steam actuated water heaters. Copies are mailed on request.

The Schaeffer & Budenberg Mfg. Co., in order to take care of its increasing business, has moved its offices and plant to the splendid new building at South Fifth and Berry St., Williamsburg, Brooklyn, N. Y.

"Central Power Station Economy" is the title of a very interesting booklet published by the Wm. B. Scaife & Sons Co., Pittsburgh, Penn. It is a treatise on water purification for all purposes. Copies are mailed for the asking.

The Combustion Engineering Corporation, 11 Broadway, New York, has just issued a new booklet descriptive of the type "E" stoker. It is a 20-page booklet, well illustrated, giving a complete description of the stoker, construction and operation and showing several installations. Copies are mailed on request.

William B. Merrill & Co., 3368 Washington St., Boston, Mass., has received order to furnish "Tripp" metallic packing for all piston rods and valve stems of the new steamer now being built for the New York & Porto Rico Steamship Line. The company has also received during the past month orders for 234 sets of "Tripp" metallic packing from Ingersoll-Rand Co.

CONTRACTS TO BE LET

Bids received until Mar. 12, 1915.

Five Pumping Engines

MAYFAIR PUMPING STATION.

Department of Public Works.

Chicago, February 17, 1915.

Sealed Proposals will be received by the City of Chicago until 11 A.M. Friday, March 12th, 1915, at Room 406 City Hall, and then publicly opened, for furnishing and erecting five pumping engines at the Mayfair pumping station, Chicago, as follows:

Three pumping engines, capacity 25 million gallons per day, normal head 140 ft.

Two pumping engines, capacity 17½ million gallons per day, normal head 200 ft.

The contract includes discharge piping and suction connections for seven engines, according to Plans and Specifications on file in the office of the Department of Public Works of said City, Room 406 City Hall.

Proposals must be made out upon blanks furnished at said office, and be addressed to said Department, indorsed "Proposals for Five Pumping Engines, Mayfair Pumping Station," and be accompanied with Twenty-five Thousand Dollars in money or a certified check for the same amount on some responsible Bank located and doing business in the City of Chicago and made payable to the order of the Commissioner of Public Works.

The Commissioner of Public Works reserves the right to reject any or all bids.

A deposit of three hundred dollars ($300.00) will be required to insure return of plans and specifications.

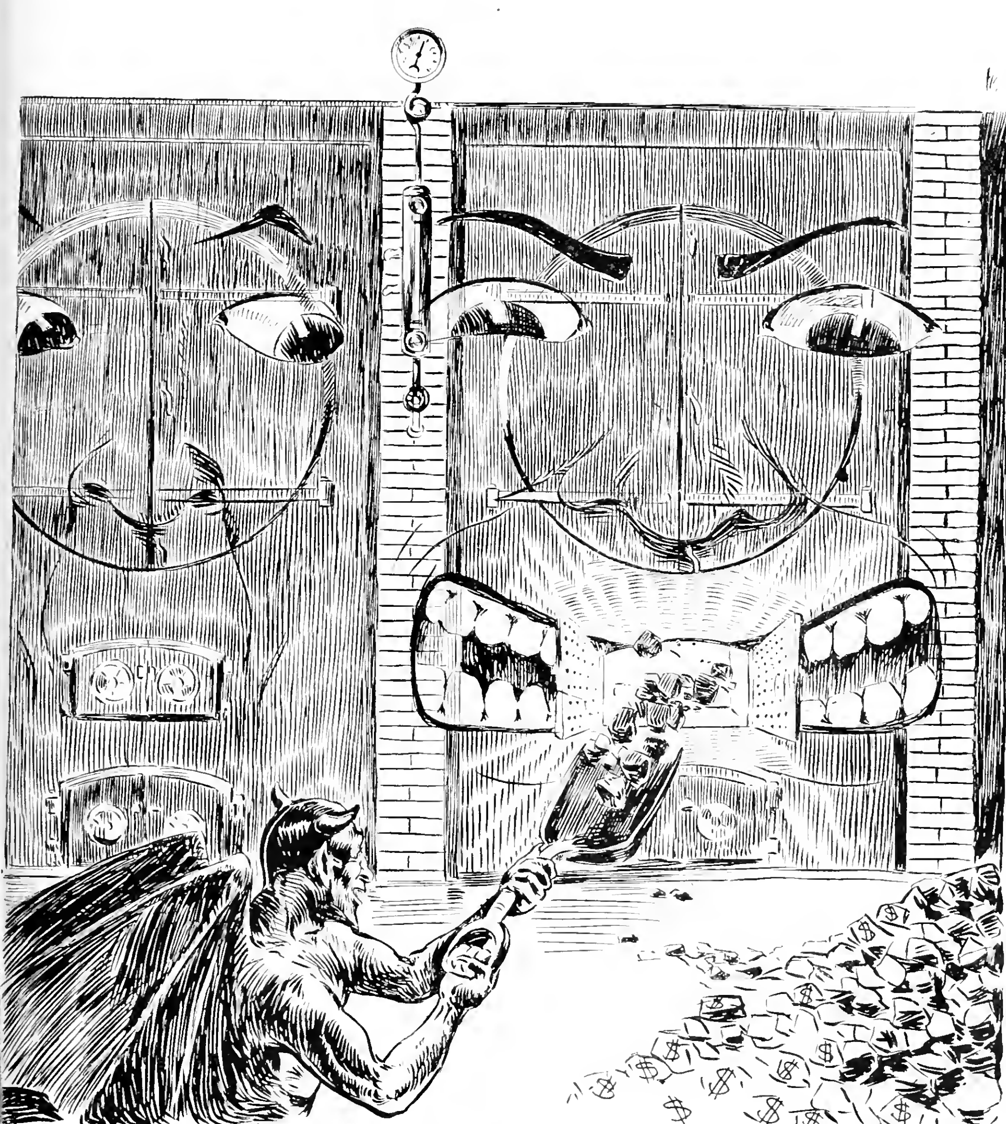
No proposal will be considered unless the party offering it shall furnish evidence satisfactory to the Commissioner of Public Works of his ability, and that he has the necessary facilities together with sufficient pecuniary resources to fulfill the conditions of the Contract and Specifications, provided such Contract should be awarded to him.

Companies or firms bidding will give the individual names as well as the name of the firm with their address.

L. E. McGANN,
Commissioner of Public Works.

POWER

Vol. 41 | NEW YORK, MARCH 16, 1915 | No. 11



How the Employer Thinks of the Fireman

Extension of the Cos Cob Plant

By Warren O. Rogers

SYNOPSIS—The chief features of the station equipment are water-tube boilers having superheating coils, and eight steam turbines consisting of three 3750-kv.-a., four 5000-kv.-a. and one 4250-kv.-a. units; a combined forced- and natural-draft system is operated with the new boilers, the forced-draft fans being turbine driven and the first to operate with a reducing gear between the fan and turbine.

It is doubtful if any steam-power plant in this country operates with so much depending on continuity of service as the one at Cos Cob, Conn., which supplies electrical energy to the New York, New Haven & Hartford R.R.

When the Cos Cob plant was first built and the New Haven system was electrified as far as Stamford, Conn., 11,000 volts, single-phase, was the working voltage of the generators and on the lines. The voltage was supplied from the generator terminals to the contact wires without the aid of transformers. As this was a departure from existing practice, new problems and difficulties, naturally, were introduced, but the system was developed and the difficulties were overcome with two exceptions. One was that of electro-magnetic disturbances in neighboring telegraph and telephone circuits paralleling the railroad tracks. This disturbance had been corrected in a measure, but with the necessity of using larger currents as traffic increased, the adding of neutralizing transformers and other corrective apparatus did not appear satisfactory.

The other need was in relation to transmission voltages, and as it was planned to extend the electrification of the New Haven lines to New Haven, a distance of 45 miles, as well as to take on the Harlem River branch and freight yards, it was necessary to add to the original plant the turbines and boilers required to carry the increased load. There were difficulties in the way of raising the transmission voltage, because about 350 miles of overhead-contact wire insulation, together with rolling stock and other apparatus, would require replacing.

Under the old system all of the current flowing in either the overhead wire, the rails or ground return was in the same direction for the greater part of the trackage involved. With the new arrangement the generators at the power house do not directly feed the contact wire, but are connected to 22,000-volt auto-transformers at the power house, which have their centers grounded to the rails; the terminal voltage of the generators is, as formerly, 11,000 volts. One terminal of the transformer is carried to the contact wire and the other to feeder wires.

Turbine Plant

Two views of the turbine room are shown in Fig. 1, in which there are eight horizontal steam turbines with a total rated capacity of 35,500 kv.-a.; single-phase, 25-cycle current is used for railroad electrification, but three-phase for the other transmission.

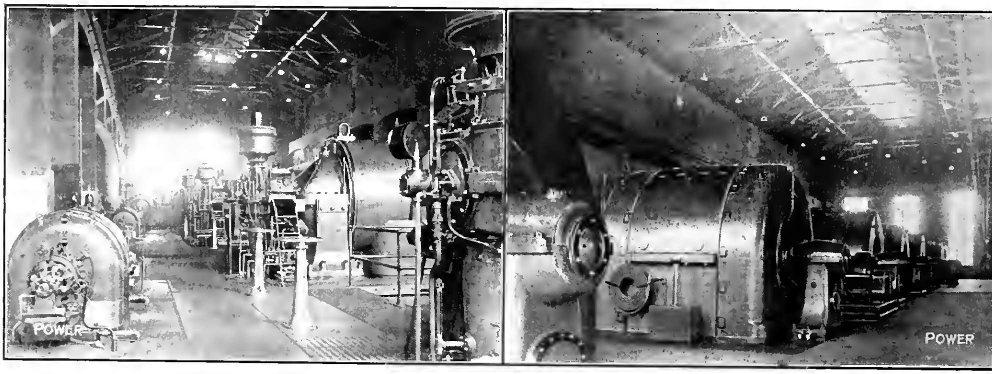


Fig. 1. Two Views of the Cos Cob Turbine Room

The turbines of the old station are connected to surface condensers having engine-driven circulating and independent air pumps. The four new turbines exhaust into jet condensers. Fig. 2 shows an elevation of the piping and arrangement of the condensers in the basement. Fig. 3 is a side elevation of the new boiler room.

Exciter current is furnished for the generators in the old plant by two 12 and 22 by 13-in. compound-vertical engines, each directly driving a 125-kw., 125-volt, direct-current generator. For the new units there are two turbine-driven, 125-kw., 125-volt generators driven through a reducing gear from one turbine. There is also one 125-kw., 125-volt generator driven by a 190-hp., 440-volt induction motor at 480 r.p.m. and one 175-kw., 125-volt generator driven by a 260-hp., 440-volt induction motor at 480 r.p.m.

Along one side of the turbine room are two turbo-generators of 130-kw. capacity, each delivering 2300-volt, single-phase, 60-cycle alternating current at 3600 r.p.m. The electrical energy developed by these units and from a motor-driven set consisting of a 500-hp., 440-volt induction motor and a 450-kv.-a., 2300-volt alternating current, three-phase, 60-cycle generator at 720 r.p.m., is for operating railway signals. The plan view, Fig. 4, shows the location of the various units in the new half of the plant. There is a noticeable absence of piping in the

fan placed above the boilers and between the economizers and the stack. The furnace gases from eight boilers pass through two economizers and those of the other six pass through but one before going to the fan and stack.

In the boiler-room addition there are 14 water-tube

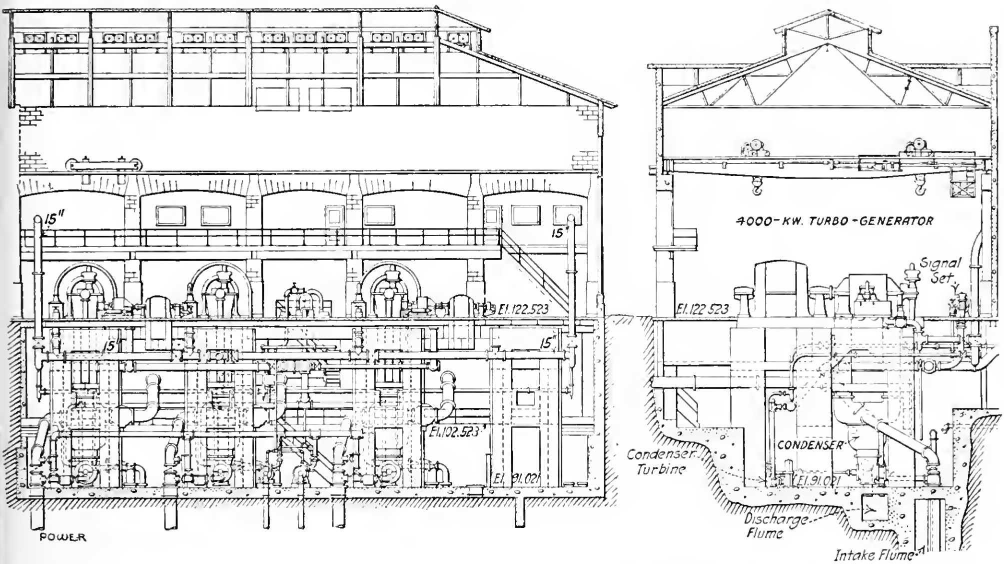

FIG. 2. SIDE AND END ELEVATION OF TURBINE AND CONDENSER ROOMS

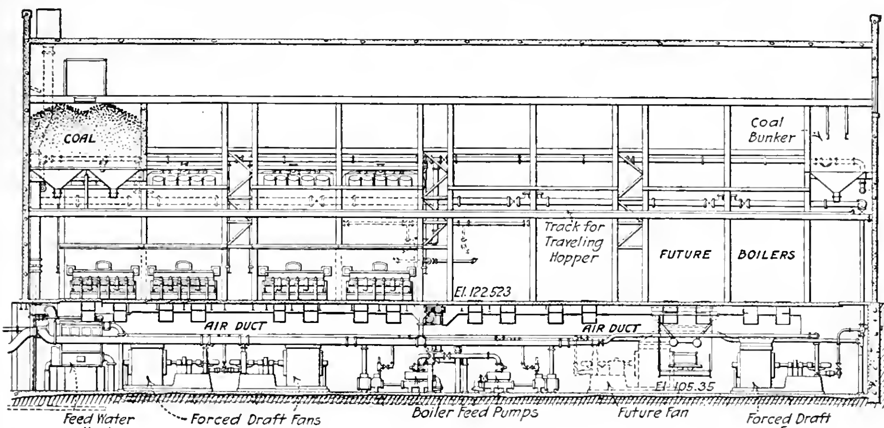

FIG. 3. SIDE ELEVATION OF THE NEW BOILER ROOM

urbine room and but little in the boiler rooms; most of he pipe lines are in the basement.

BOILER ROOMS

In the old boiler room, Fig. 5, there are 14 three-drum vater-tube boilers, each having 5200 sq.ft. of heating surace. The furnaces are fitted with mechanical stokers. The boilers are arranged two in a battery, with eight on ne side and six on the other side of the boiler room. Each furnace is supplied with induced draft by a single

boilers (Fig. 6), each having 6250 sq.ft. of heating surface. The tubes are 14 and 18 ft. in length and $3\frac{1}{4}$ in. in diameter. These boilers are of the counter-current type, the hottest water meeting the hottest gases and the coldest water meeting the coldest gases. The direct heating surface, or that in contact with the radiant heat of the furnaces, is 12 per cent. of the total heating surface, or 750 sq.ft.

The boilers are equipped with superheaters, which superheat the steam 100 deg. F. Each boiler furnace is fitted

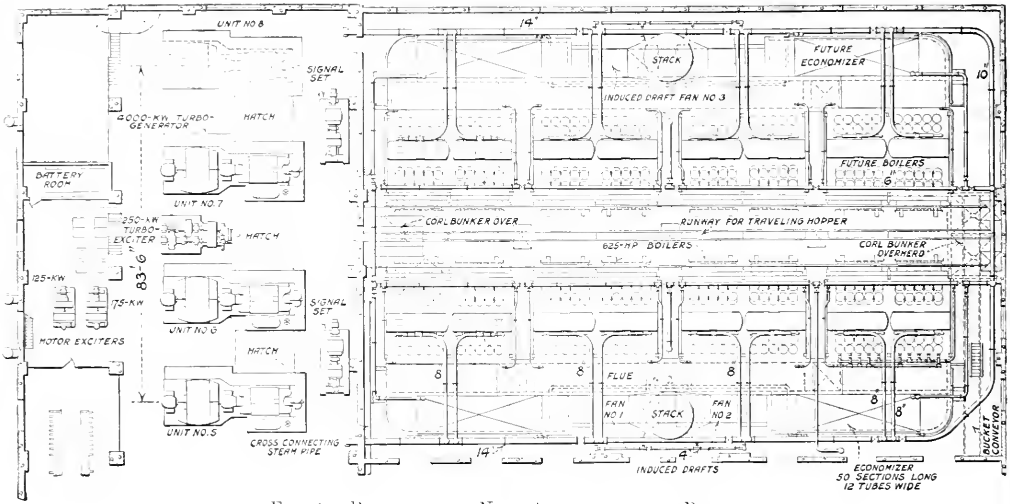

FIG. 4. PLAN OF THE NEW SECTION OF THE PLANT

with a seven-retort underfeed stoker driven by the induced-draft fan turbine. A combination forced- and induced-draft system is used. There are three double-inlet, up-blast, forced-draft, turbine-driven fans (Fig. 7) in the pump room, which is under the firing aisle of the boiler room. Each fan is 42 in. in diameter and delivers 100,000 cu.ft. per min. at 50 deg. F., against a resistance of 5 in. of water. This would require 190 hp. per fan at a fan speed of 510 r.p.m. The turbines run noncondensing at 2040 r.p.m., against a back pressure of about two pounds. Each has sufficient capacity to supply about twenty-five horsepower more than is required by the fan, for the purpose of driving stoker mechanism. Under normal operating conditions but two of the three fans are in operation, and the capacity required of them with the boilers running at 200 per cent. rating will be 95,000 cu.ft. per min. per fan. At this load the maintained resistance is figured to be only 4 in., but 5 is supplied to be on the safe side.

The speed of the fans is governed by the boiler pressure, 200 lb., 100 deg. superheat, acting on a regulating valve which controls the steam supply to the turbines. The difference in speed between the turbine and fan is due to a set of 4 to 1 reduction gears composed of a pair of double-helicoidal gears and flexible couplings, Fig. 8. As the stokers are driven by a series of chain drives, the feeding of the stokers and the speed of the fans are regulated by the steam pressure and operate in unison. The position of the fans is shown in Fig. 3. Space has been provided for a future fan outfit.

At the back of each row of boilers, and between them and the economizers, is a main smoke flue, 6 ft. 9 in. wide and 10 ft. 6 in. high. One flue connects with two economizers, which receive gases from eight boilers. On the opposite side of the boiler room the smoke flue of six boilers connects to a single economizer of the same size as the others.

The induced-draft fans, of which there are two for each row of boilers, are placed between the economizers and the $12\frac{1}{2}$-ft. diameter metal stack. The general arrangement and a plan view of the boiler room are shown in Fig. 4. One of the engine-driven fans is shown in Fig. 9. Each of the four fans is designed to handle 140,000 cu.in. of gas at 500 deg. F., against $1\frac{3}{4}$-in. suction.

FIG. 5. OLD BOILER ROOM

FIG. 6. NEW BOILER ROOM

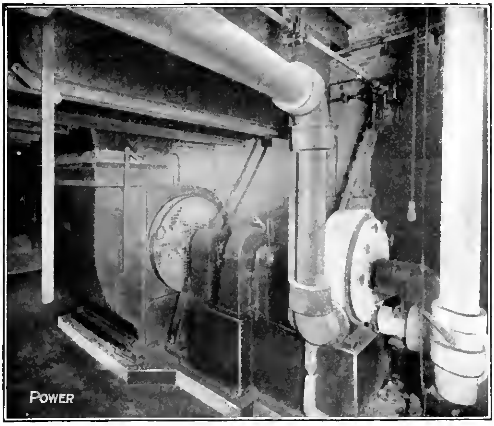

Fig. 7. Turbo-Driven Forced-Draft Fan

The normal volume of air handled is considerably less than that mentioned. The fans are on the ground floor of the boiler room. Their bearings are water-cooled.

As there are three economizers used in connection with the 14 boilers, the average is 8330 sq.ft. of boiler heating surface to one economizer. The boiler pressure being approximately 200 lb., the economizers carry about 50 lb. greater pressure. Each economizer has 624 pipes in 52 sections, each 12 pipes wide. The pipes are 10 ft. long between headers and are arranged in staggered rows. In the other boiler room there are also three economizers of 52 sections, 10 tubes in each.

The damper arrangement is such that if any battery of two boilers be cut out of service, the gases from the others will still go to the economizer. In case it is desirable either or all economizers can be cut out and the furnace gases bypassed to the stack. Although there are two fans for six boilers, on one side of each boiler room space has been reserved for another economizer and two additional boilers.

Pumps

In both the new and the old boiler plants the pump room is in the boiler-house basement. Figs. 10 and 11 show a view of each. In the old pump room there are three 12&20x12x18-in. duplex pot-valve, boiler-feed pumps which supply the turbine glands with water. In the new pump room there are two boiler-feed pumps of the same size as the others, and two 8x8x18-in. duplex pumps for supplying gland water to the turbines.

Fuel Supply

There are two sources of coal supply—by rail and by water. Barring delays, the fuel is delivered in barges to a wharf, hoisted by a clam-shell bucket and discharged into a coal crusher, from which it is loaded into two 2½-ton cable-drawn cars. These cars are hauled up the single-track runway, Fig. 12, and discharge the coal into the bins at the turbine-room end of the boiler house. At the opposite end of each boiler room is a second bin, supplied from cars which discharge into an underground hopper and crusher from which the coal is elevated to the bins by a bucket conveyor.

In case there is no available coal supply from the railroad, the bunkers can be filled by loading the 5-ton larry car used ordinarily to supply the stokers from the other coal bunkers and discharging its contents into a chute leading to a hopper above the conveyor. Thus, the supply of coal in the bin not reached by cable cars is maintained. An ingenious track arrangement permits of the cable cars passing at a turnout on the runway. This is made possible by the use of outside- and inside-flanged carwheels. A glance at Fig. 13 shows how the cars take the rails. One car has the inside-flanged wheels

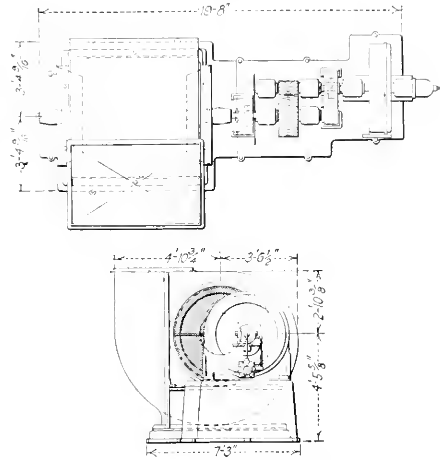

Fig. 8. Diagram of Fan Unit

and the other car outside flanges. Fig. 12 shows the cars about to pass at the turnout. This arrangement requires but a single track and reduces the construction cost of the trestle.

From the bins the coal is discharged into the larry scales, where it is weighed and then run along the track

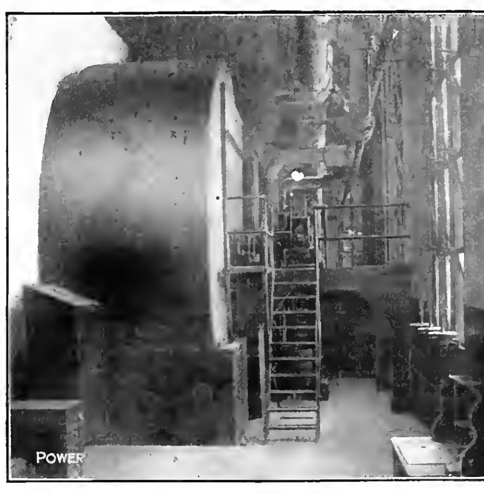

Fig. 9. Engine-Driven Induced-Draft Fan

above the stoker hoppers. Five men handle all the coal consumed in the plant. Two are at the hoisting tower, one above the coal bunkers and one man in both boiler rooms to handle the barney cars.

Ashes from each stoker fall into a brick-lined hopper under which a car is run to receive its load, which is drawn out into the yard by a small storage-battery locomotive and dumped for filling-in purposes.

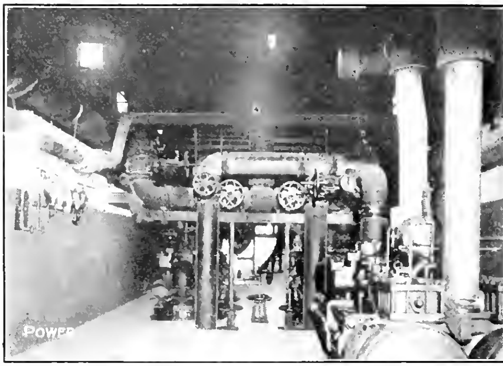

Fig. 10. New Pump Room

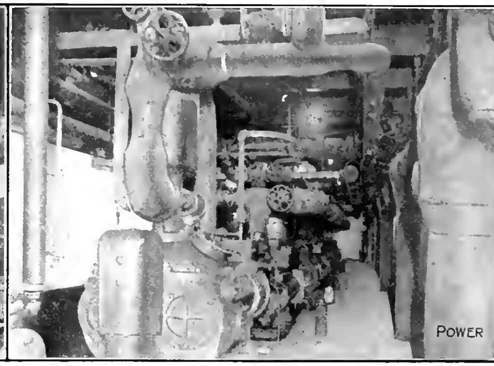

Fig. 11. Old Pump Room

Piping

An end elevation of the new boiler room is shown in Fig. 14, which with Fig. 4 presents the details. Each boiler is connected by an 8-in. branch pipe to the main 10-in. header. The header is constructed on the loop plan and so valved that any two boilers and their section of header may be cut out of service without interfering with any other units. The headers back of the two rows of boilers drop to a 15-in. cross header in the turbine-room basement. From this a 10-in. lead is run to each of the new turbines. This piping is shown in Fig. 2.

The 6-in. auxiliary header has three sources of steam supply. It is also designed on the loop plan, tapping off from each of the 15-in. vertical header pipes and also from the 10-in. end of the main steam loop in the boiler house. The auxiliary steam line supplies the condenser turbines through 3-in. pipes. The exciter turbine receives its steam supply through a 4-in. pipe connecting with that section of the 6-in. header running to the pump room and connecting the main steam line at the loop end. A study of the piping scheme shows its simplicity, although provision has been taken to insure continuity of service.

While the addition to the plant is practically a separate power plant in itself as applied to the steam end, the new boiler room is connected to the old by a 10-in. cross connection, which is connected with the 15-in. cross-feeder in the turbine basement.

The 10,000-hp. feed-water heater for each boiler plant is in the basement and is piped to the boiler feed-water pumps by a 12-in. pipe having a 7-in. branch pipe to each pump, which discharges into a 9-in. main connecting with the economizers. From the economizers the 9-in. feed line forms a loop along the front of the boiler and supplies them through 3½-in. branch lines.

All boiler blowoff pipes are in a tunnel under the main smoke flue. The blowoff main for the economizer is also in this tunnel.

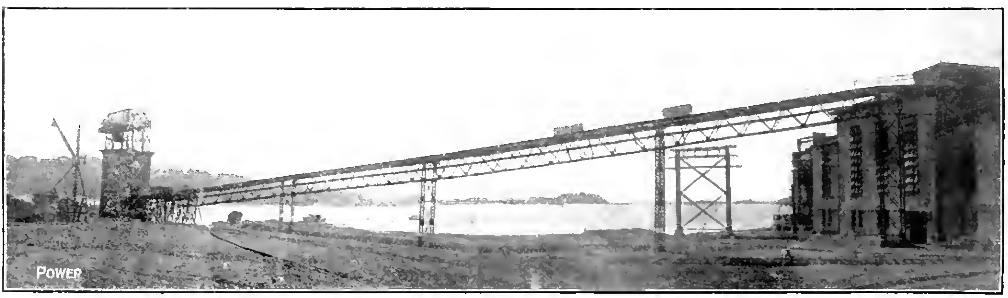

Fig. 12. Single-Track Runway Using Double-Car Service

As in most large power plants, the pipe lines are designated by colors. In the Cos Cob plant the pipe-line color scheme is as follows: White—high-pressure steam lines; red—Holly return system; yellow—auxiliary exhaust and all low-pressure drips; black—boiler-feed lines; blue—all water pipes other than feed and fire pipes; gray—fire protection; dark green—air pipes; light green—crank-case oil piping; pink—cylinder oil piping; brass, no paint—turbine oil piping.

As is now the general practice in modern power plants, all of the electrical-control apparatus is at one side of the turbine room. A gallery runs the length of the building and at one end is the chief engineer's private office, the general office and switchboard room (Fig. 15). On the same level are the remote-control oil switches (Fig. 16). Below, in suitable compartments, are the duplicate busbars. At the back of the station, a general view of which is shown in Fig. 17, is a transformer house in which are six 7200-kv.-a. auto-transformers, which raise the voltage from 11,000 to 22,000 volts, the center point of the transformers being connected to the rails.

Fig. 18 is a diagram of the present system of distribution. Line auto-transformers are arranged along the track and are similarly connected for reducing the voltage to 11,000 for the locomotives. The center terminal of the outdoor transformers is connected to the rails, one terminal to the contact wire and the other to the feeder wire. This arrangement breaks the line into short lengths. Reference to Fig. 18 shows that a train draws its current from the transformers on either side of it. If the train is midway between transformers half of the current will complete its circuit through the rails and ground in one direction, and the other half through the rails and ground in the other. When the train is nearer to one transformer than another it will receive the greater part of its current from the nearest one and the smaller part from the distant transformer. Thus the current supply balances regardless of which transformer the larger amount is taken from.

The changes from the old to the new system were considerable, because the transition had to be made without interfering with the operation of the train service, making necessary many temporary connections and the perfecting of details which would allow of a rapid and easy change-over when the final connections were made.

When it is considered that about 350 miles of track is electrified it is seen that it was important that each man along the line should know what to do and when to do it. At some points the changes consisted of merely disconnecting a few wires, and at others many changes were necessary. As the final work was done at night, team

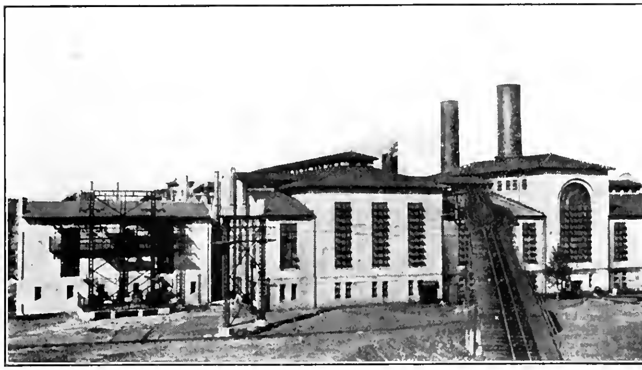

Fig. 13. Track and Turnout Arrangement for Cable-Drawn Cars

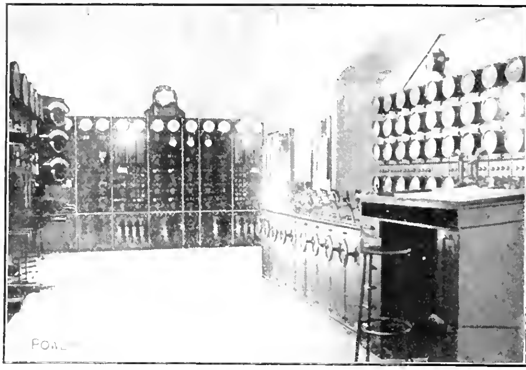

FIG. 15. CONTROL ROOM WITH SWITCH AND BENCH BOARDS

FIG. 16. AISLE BETWEEN REMOTELY CONTROLLED OIL SWITCHES

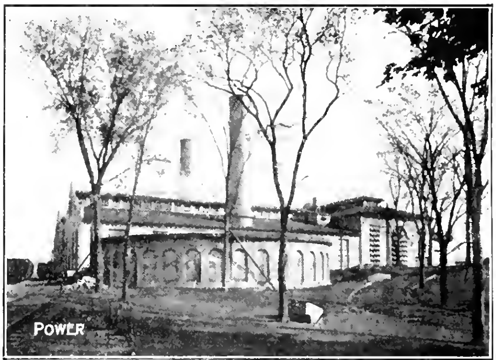

FIG. 17. GENERAL VIEW OF THE STATION

work of the highest order was imperative and a mistake would mean delay.

But four hours, from 2 to 6 a.m., were available for the final change-over. At 2 o'clock the power plant was shut down, and all concerned were notified. Within two minutes the load dispatcher received the first "ready" report. This was quickly followed by others and within 70 minutes from the start the last report was in and all work on 350 miles of track had been finished.

The power-house changes required longer, but at 3:21 a.m. the plant was ready to start up under the new system. At 4:45 a.m. every part of the system was reported ready for service and at 5:25 the first train received current by the new system. At 5:31 the operating department was advised that full normal service might be resumed.

The entire work of addition and reconstruction of both the power plant and lines as herein described was per-

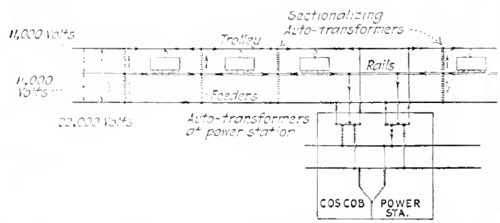

FIG. 18. DIAGRAM OF THE NEW SYSTEM OF ELECTRIFICATION

formed by the Engineering Department of the New York, New Haven & Hartford R.R., and the plans for the entire work were prepared by Westinghouse Church Kerr & Co., to whom the author is indebted for line drawings of the power-plant addition.

PRINCIPAL EQUIPMENT OF THE COS COB POWER PLANT ADDITION

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
4	Turbo-generators	Horizontal	5000-kv.-a	Main units	180 lb. steam, 100 deg. superheat, 1500 r.p.m., 1-phase, 25-cycle, 11,000 volt	Westinghouse Companies
4	Condensers	Leblanc, jet	No. 19	With 5000-kw. turbines	28-28½-in. vacuum	Westinghouse Machine Co.
4	Turbines	Single-stage		Condenser pump drive	180 lb. steam, 100 deg. superheat, 680 r.p.m.	Westinghouse Machine Co.
1	Turbine	Horizontal	125-kw	Driving exciter generator	180 lb. steam, 100 deg. superheat	De Laval Steam Turbine Co.
2	Generators	Direct-current	125-kw	Exciting main generators	750 r.p.m., 125 volts	Westinghouse Electric & Mfg. Co.
2	Motors	Induction	190-kw	Driving exciters	480 r.p.m., 440 volts	Westinghouse Electric & Mfg. Co.
2	Generators	Direct-current	125-kw	Exciting main generators	480 r.p.m., 125 volts	Westinghouse Electric & Mfg. Co.

Maintaining High Insulation Resistance

By H. M. McLellan

Where electrical machinery is subjected to fumes, as sometimes when located in gas-engine stations or near chemical plants, it is necessary that special precautions be taken to insure the insulation resistance being maintained at a high value. Deposits of carbon and copper dust, dirt, or chemicals will often be found on the windings of apparatus operated under these conditions. These are conductors and, consequently, lower the insulation resistance over the surfaces, making the current likely to creep from exposed live metal parts to the core, and so cause a burn-out.

Ordinarily, the deposit appears not to attack the insulation, and the only thing necessary to prevent trouble is to clean the machine at frequent intervals, testing its condition by readings of insulation resistance. In order that the surfaces may be readily cleaned, they should first have a good smooth finish, such as is obtained from several coats of varnish. Most machines have this finish when sent from the works, but under certain conditions it may become rough, and then it is necessary that the windings be revarnished.

The insulation resistance is most readily measured with a megger, or if this is not available, a high-resistance voltmeter may be used in the following manner:

First, read the voltage across the line; then connect the voltmeter in series with the insulation resistance (between a commutator bar and the shaft) and read the volts again.

If R is the resistance of the voltmeter, V the reading of the voltmeter across the line, and V_1 the reading in series with the insulation, then the resistance of the insulation is

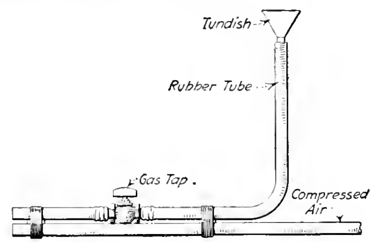
$$R_1 = \frac{R(V - V_1)}{V_1}$$

The resistance of the voltmeter is usually marked on the back of the instrument or on the carrying case; if not, it may be obtained from the makers.

When the insulation resistance of a machine shows a value of less than 250,000 ohms, this indicates that the windings are covered with dirt, and steps should be taken at once to clean them thoroughly. The best method is to thoroughly blow out the machine with compressed air. After this measure the insulation resistance. If it has reached a high value, say not less than 2 megohms, it indicates that the insulation surfaces are in good condition, but if little improvement is noted, thoroughly wipe all parts of the machine with a soft cloth and take insulation readings at frequent intervals during this operation, with a view to determining where the greatest improvement is effected. When the resistance reaches a good value, say not less than 2 megohms, the windings should be thoroughly sprayed with a good air-drying varnish. It is useless to spray the machine while covered with dirt, with the insulation resistance low; in fact, if this is done, it will be impossible to remove the dirt after it is coated with varnish, and the machine may have to be completely reinsulated.

Where compressed air is available, the best method for applying the varnish is as follows: Procure a length of ½-in. rubber tubing, say about 3 yd., and near one end fit an ordinary gas tap, as shown in the sketch, leaving about 3 in. of pipe from the tap. In the other end fit a tundish, then tie the paint tube on top of the air pipe. Varnish is poured into the tundish and will flow down the pipe, the supply being regulated by the gas tap. As it tries to pass the end of the air pipe it will be blown into a fine spray, which can be directed to the desired spot. The machine should stand for at least twelve hours after varnishing to allow for thorough drying.

In general it is desirable to give the machine more than one coat of varnish, and where the surface of the insulation is very rough it may be advisable to apply as many as four coats. These may be applied one after the other, allowing sufficient time between applications for the machine to dry, or they may be applied at convenient intervals. In the latter case, the machine must, of course, be thoroughly cleaned before each application. The point to keep in mind is that if the machine is to be easily cleaned there must be a good smooth finish on all surfaces over which the current is likely to creep, and this surface must be cleaned at frequent intervals.



Device for Applying Varnish

In dealing with direct-current apparatus, especial attention must be given to deposit forming on the under side of the armature coils between the commutator necks and the core, and on the mica between the commutator necks and the V-ring. Consequently, in cleaning such machines, these parts and the insides of the machines behind the commutator should receive particular care. A soft tape should be threaded under the armature coils, one at a time, and worked back and forth until all deposit is removed, especially from the corners where each coil leaves its slot.

Alternating-current apparatus is in general not likely to show a decrease in insulation resistance after running, as in alternating-current machines there are seldom any exposed live surfaces except collector rings, brush gear, etc., but the machines generally, and these parts especially, should be carefully cleaned at frequent intervals.

A New Canadian Periodical—"Mine, Quarry and Derrick" is the name of a new fortnightly magazine "devoted to the development of the mineral resources of Western Canada." The first issue made its appearance under date of Feb. 3, 1915, and it is promised by the publishers, Laurence & William, of Calgary, Alberta, to reappear "every second Wednesday." The staff consists of J. C. Murray, editor; W. C McGinnis, associate editor; R. W. Coulthard, contributing editor, and L. S. Kempher, manager. In the salutatory the intentions are declared to be to give real expression to the needs of the great Canadian West; to discuss the technical and other problems to be met; to correct errors and misconceptions, and, above all, to give the investing public the truth as to present conditions, all as relating to the fields of oil production, metal mining, coal mining, quarrying and the manufacture of cement and clay products.

Plate Valves for High-Speed Air Compressors

By G. J. MacFadden

SYNOPSIS—Points out the advantages of the plate valve and explains the construction and operation of several of the most widely used makes.

By the use of plate valves, a much higher piston or rotative speed is possible. Heretofore, the speed of air compressors has been limited by the air valves, as abnormal wear and breakage of valves resulted when the piston speed exceeded 500 ft. per min., caused by the excessive weight and high lift. The mechanically operated Corliss inlet valves have the disadvantage of semirotating surfaces which require positive lubrication and are liable to stick and cut. A complicated valve-gear is also employed, which requires adjustment at frequent intervals.

One of the principal advantages of plate valves is increased efficiency, due to the light weight of the valve proper and light initial tension of the valve springs, allowing the air in and out of the cylinder with small power consumption by the valves. With a light valve and low spring tension the minimum pressure is required to keep the valve open throughout that portion of the stroke in which it is operating. Another advantage is the low lift which, combined with lightness, reduces the momentum attained on opening, insuring quiet operation and little necessity of cushioning mechanism. The air is admitted to the cylinder in a constant stream and at lower temperature and higher pressure than where the ordinary chattering high-lift poppet valves are used. The valves are silent in operation up to the hignest speed, which demonstrates the absence of hammering and fluttering, and reduces wear of the valve and the valve seat. The cost of repairs with the standard makes of plate valves is small.

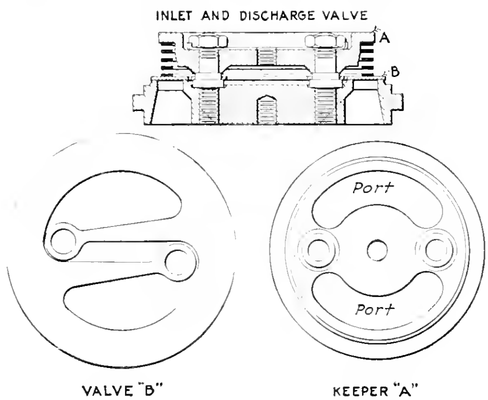


Fig. 1. The Borsig (German) Valve

The higher safe speed of compressors using plate valves means a reduced cost of installation, not only of the compressor unit, but of the building and foundation, since a compressor for a stated capacity, equipped with plate valves and operating at high speed, requires approximately two-thirds the floor space taken up by a slow-speed compressor equipped with the old-style poppet valves. In the case of motor-driven units high speeds mean the additional advantage of smaller and less expensive motors.

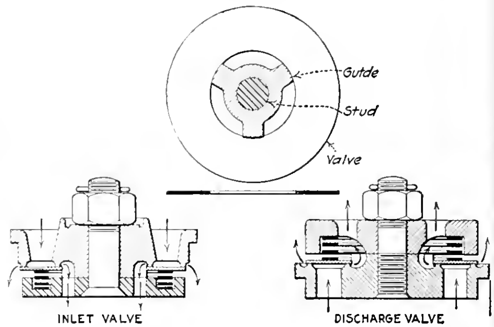

Fig. 2. Another German Valve

To sum up, the principal advantages of the use of plate valves are as follows:

1. Improved mechanical and volumetric efficiency over the old-style poppet valve.
2. Minimum wear; cost of repairs reduced to a negligible amount.
3. The valve requires no lubrication.
4. Silent operation at the highest piston speeds.

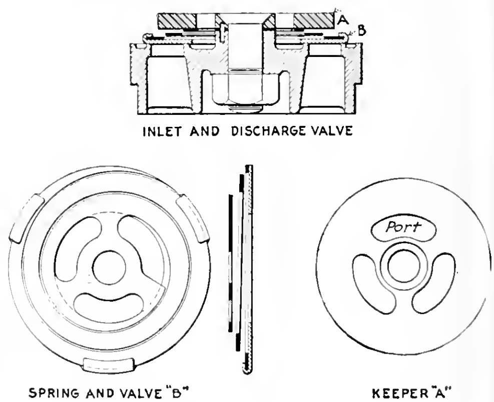

Fig. 3. Mesta Machine Co.'s Plate Valve

5. The air end is simplified, owing to the elimination of all complicated valve-operating mechanism.
6. Dependable and efficient at high speeds.
7. Floor space and cost of installation reduced on account of greater capacity of smaller units due to high speed.
8. Continuous operation under severe conditions.

Prominent American builders of large and medium-sized compressors have adopted the plate valve for use in their compressors only within the last two or three years. Conditions were ripe for the innovation, because of keen competition by foreign manufacturers, who have employed the plate valve with success for some years.

In the following description of plate valves only those of standard Continental and American construction will be discussed. They may, however, be taken as representative for the whole development along this line, since with few exceptions, they follow closely the original German design.

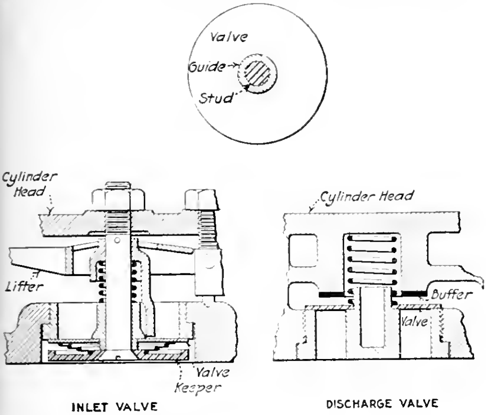

FIG. 4. VALVE USED BY THE CURTIS MANUFACTURING CO.

Fig. 1 shows a section elevation and plan view of the Borsig valve, manufactured by A. Borsig, Berlin. The valve consists essentially of a thin sheet-metal disk of light weight, and is made to form two spiral arms

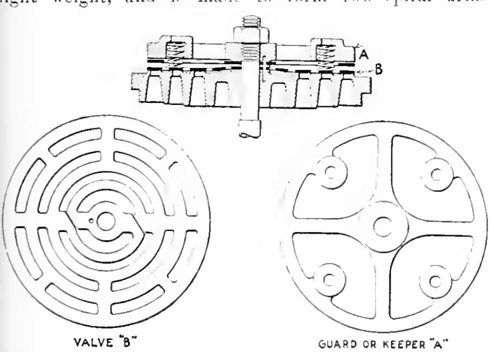

FIG. 5. THE ROGLER PLATE VALVE (INGERSOLL-RAND CO.)

secured at the center of the valve by two studs, one in each arm; a small movement of the valve arms is allowed on each stud, depending on the lift of the valve. Above the valve disk a keeper or stop is provided, in which a large helical spring is seated. This spring serves to load the valve and press it firmly on its seat. The point of support of the arms is located in the center of the valve lift so that the disk is bent upward when the valve is opened, and owing to the small mass of the valve proper, its inertia is negligible. The construction of this valve is such that it may be used for either discharge or inlet.

Fig. 2 shows a plate valve used by the *Zwichauer Maschinenfabrik Aktiengesellshaft Zwichau*, Saxony, one of the large compressor builders of Germany. The valve complete consists essentially of six pieces. The seat is a circular iron casting having either one or two ports. The keeper is a simple iron casting having ports cored through to allow the passage of air from the inner edge of the valve. The valve spring is of the helical type of rectangular section, allowing a much more compact arrangement where fully compressed than a spring of circular section. The valve keeper is provided with a recess of sufficient depth to accommodate the spring when the valve attains its greatest lift. The valve proper consists of a thin disk stamped from sheet steel, being centrally guided by projections on the valve seat. The valves are not interchangeable for inlet or discharge.

Fig. 3 shows the construction of the Mesta automatic plate valve, manufactured by the Mesta Machine Co., of Pittsburgh, Penn., under the Iversen patent. The valve

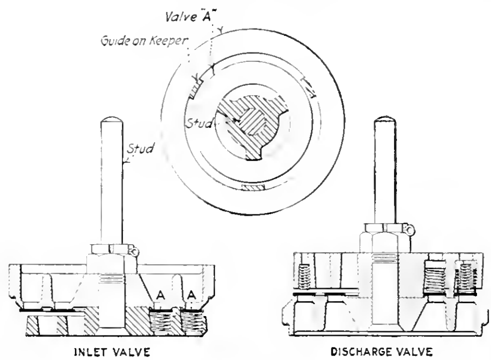

FIG. 6. THE "SIMPLATE" VALVE (CHICAGO PNEUMATIC TOOL CO.)

proper consists of a light, thin, annular steel plate, guided by a flat volute spring. The spring is permanently fastened to the valve plate by prongs or clips bent over the outside edge of the spring. The valve lifts parallel to the seat and employs no guiding surfaces or guide pins. The valve seat is a circular iron casting having one or more annular ports. The valve keeper consists of a thin plate of steel, with punched ports or recesses provided to allow the free passage of air from the inside of the valve.

Fig. 4 shows the details of the inlet and discharge valves made by the Curtis Manufacturing Co., of St. Louis, Mo. The valve proper is a thin disk stamped from sheet steel. The valve seat is of phosphor-bronze, having independent ports or cored passages for the flow of air. The inlet and discharge valves are of independent design, but are not interchangeable. The inlet-valve keeper is of steel and provided with a suitable recess to accommodate the valve spring. The valve complete is held in a pocket in the cylinder head by a flat-head stud. The discharge valve proper is screwed into a tapped hole in the air-cylinder head. The spring is held in a pocket and a seat is provided in the cylinder head to act as the valve keeper or buffer. These valves, due to their thin construction, permit the passage of air around the outside edge only, as the valve is guided on a circular projection at the center of the valve seat.

Fig. 5 shows a section of the Rogler plate valve, built by the Ingersoll-Rand Co., and which is essentially of German design. The valve proper is made of special steel, treated, tempered and ground. Narrow, integral spring arms, ground to about half the thickness of the valve proper to give them elasticity, are located at the middle portion of the valve. These arms act as a connecting means between the fixed and moving parts of the valve, holding the latter in one position and seating it always in the same place on the valve seat. The valve seat is of special material, cast with circular ports. The keeper is a special casting provided with four spring pockets to accommodate the four main valve springs which hold the valve on its seat against the slight tension of the integral valve arms. A cushion plate, fixed at the center only and having a certain amount of elasticity, is employed to cushion the valve at the point of full opening. It will be noted by referring to the cross-section that a washer is placed between the valve proper and the valve seat and between the cushion plate and the valve proper. All parts are kept from turning by a dowel pin and are clamped together by a through bolt.

Fig. 6 shows the "Simplate" valve, designed and built by the Chicago Pneumatic Tool Co. The seat is of special material cast with one or more circular ports, depending upon the size of the valve. The valve proper in the one-ported valve consists of a thin plate, or ring, stamped from sheet steel, heat treated and tempered, then ground to present a true surface on the seat. The multi-ported valves of larger size have two or three distinct and separate valve disks, operating independently of each other. These disks are similar to the one used in the one-ported valve, as described above. The valve keeper on the inlet valve is of special cast steel with suitable ports arranged to allow the flow of air from the inner valve disks. The discharge-valve keeper is of cast iron, provided with ports similar to the inlet-valve keeper. Both inlet- and discharge-valve keepers have drilled recesses for the accommodation of the valve springs. Plain, small, helical springs of light tension are employed on the inlet valve, while on the discharge valve, springs of slightly greater tension, together with buffer or cushion springs, are used. All springs are galvanized to resist the corroding action of the moisture in the air. Valve seat and keeper are held together, in the case of both inlet and discharge valves, by a centrally located stud and castle nut, as shown.

Steam Costs in 6600-Hp. Boiler Plant

By Frank G. Philo

SYNOPSIS—Interesting cost data of a boiler plant for a large manufacturing establishment.

The value of steam-cost data depends primarily on the accuracy with which the coal and steam are measured and the care with which the labor and all operating records are kept. This being the case, it will probably not be amiss to go into detail as to the methods used in obtaining the following data.

Coal Weighing and Analysis

The fuel burned is a mixture of No. 3 buckwheat with about 10 per cent. soft coal. To obtain the total weight of coal consumed as well as the proportions of the two coals mixed, the following method is used. The hard coal is weighed as received in the railroad cars, on carefully tested track scales which check within 10 lb. with standard weights. The hard coal is then dumped into a machine which mixes it thoroughly with the crushed soft coal. The mixture is carried overhead by a conveyor and dumped into cable cars of 2-ton capacity each. The weight of the mixed coal is obtained by weighing the small cars on a second set of scales at this point. From the hard-coal weights and the weight of the mixture the total weight used, as well as the percentage of each kind of coal in the mixture, is obtained. The automatic mixer is so designed that it can be adjusted to give any proportions of the two coals desired. The cost of the mixture is increased about one cent for each 1 per cent. of soft coal added. The function of the soft coal is to act as a binder for the small anthracite and to supply the necessary volatile matter which assists materially in starting a fire after cleaning periods. The soft coal also helps to burn out the fires more thoroughly before dumping.

Analyses of coal and cinders are made daily. The number of cars of coal which the sample represents, together with the road and car numbers, are entered on the laboratory sheet. The average analysis for the month is found by multiplying each analysis by the number of cars it represents and dividing the sum of these totals by the total number of cars used during the month.

The average analyses of the coal fired during the first six months of 1914 were as follows:

	Jan.	Feb.	Mar.	Apr.	May	June
Moisture	9 27	9 05	8 72	8 44	8.01	7.91
Ash (dry basis)	24 15	23 84	24 09	20 28	19.72	24.22
B.t.u (dry basis)	11,070	11,140	11,150	11,563	11,674	11,051
B.t.u (as fired)	10,043	10,132	10,178	10,587	10,739	10,177
Combustible (as fired)	68 82	69 27	69 29	72 99	73.85	69.79

Feed-Water Measurement

Feed water is measured by two venturi meters of 3000 and 4600 cu.ft. per hour capacity, respectively. The adjustments of these meters are checked weekly and once a month weight checks are run by passing water at working temperature and pressure through the meters into carefully weighed tank cars, which are run alongside the boiler house. These tank cars have a capacity of about 60,000 lb. of water. All tests are run for at least 30 min., so the personal errors in starting and stopping are small. The errors of the meters were found to be practically constant for any given rate of flow. The average error over the working range covered in practice was found and a correction applied to the daily meter readings. The average error of the meters was found to be about ¾ per cent. low.

All water blown from boilers and economizers, as well as all water discharged in emptying boilers and economizers for repairs, is subtracted from the water registered by the meters. This water amounts to from 1 to 2 per cent. of the total water passed through the meters during the month. The blow-down pipes from each boiler are provided with plug cocks and valves. The blow-down headers from each battery of boilers have gate valves. All blow-down valves and lines are inspected daily to insure against loss of water from boilers by leakage.

Records of Operation

Daily reports are made showing the weight of water evaporated, the average rating developed by the boilers, feed-water temperatures, steam pressure, economizer inlet and outlet water and flue-gas temperatures, flue-gas analyses, coal and cinder analyses and all useful information regarding the operation of the boiler house.

All materials and supplies are kept in a main storeroom and can be obtained only upon presentation of a signed requisition from the foreman in charge. All labor and materials used by other departments for repairs and maintenance of the boiler house are charged against the boiler house at the end of each month. Thus the cost of labor and material furnished by the pipe, electric, machine and carpenter shops for work done in the boiler house is always obtainable. In reporting materials used all supplies amounting to $20 or over are itemized. Time slips for all employees of the boiler house are filled out by the foremen and are sent to the time keeper's office every day.

Load Factor

The load factor of this plant is very high as the plant is run at full load 24 hr. per day, and about 26 days per month. During the shutdown periods about one-quarter of the total rated boiler capacity is in service.

LOAD ON BOILERS

	Jan.	Feb.	Mar.	Apr.	May	June
Average b.hp. per hr. (operating hr.)	7698	8070	7094	6341	6260	6151
Average b.hp. per hr. (total hr.)	7501	7781	6357	5764	5878	5626
Average load factor (operating hr.)	116 6	122 3	107 5	96 1	94.9	93.2
Average load factor (total hr.)	113.7	117.9	96.3	87.3	89.1	85 2

Total rated b.hp. of plant, 6600.

Average operating boiler horsepower = average boiler horsepower developed per hour while the plant is in operation.

Total average boiler horsepower = average boiler horsepower developed during total hours during the month.

Operating load factor = load factor based on operating boiler horsepower =

$$\frac{\textit{Operating boiler horsepower} \times 100}{6600^*}$$

Total load factor = load factor based on total average boiler horsepower =

$$\frac{\textit{Total average boiler horsepower} \times 100}{6600}$$

OPERATING COST OF EVAPORATING 1000 LB. WATER FROM AND AT 212 DEG. F., CENTS

	Jan.	Feb.	Mar.	Apr.	May	June
Coal and freight	10.64	10.38	10 76	9.62	9.82	9.67
Labor	2.60	2.56	2.81	2.89	2.99	3 12
Total	13.24	12.94	13.57	12.51	12.81	12.79
Operating cost per boiler hp.-hr., cents	0.46	0.45	0.47	0.43	0.44	0.44

*Rated capacity of plant.

OPERATING COSTS AS PER CENT. OF TOTAL OPERATING COSTS

	Jan.	Feb.	Mar.	Apr.	May	June
Coal and freight	80 4	80 2	79 3	77 0	76.7	77 2
Labor	19 6	19.8	20.7	23 0	23.3	22 8

	Jan.	Feb.	Mar.	Apr.	May	June
Tons coal used	12,331	11,145	10,450	8,392	8,865	8,136
Cost per 2000 lb. delivered	$1.66	$1.68	$1 68	$1.64	$1 67	$1 66
Lb coal per boiler hp.-hr.	4.419	4.263	4.419	4 044	4.054	4.017
B.t.u. per lb. (as received)	10,043	10,132	10,178	10,587	10,739	10,177
Efficiency (boiler, economizer and furnace)	75 5	77.6	74.4	78.3	76.9	81 1
Efficiency (boiler and furnace)	69 4	71 2	69 0	72.6	71.4	74 2

Efficiency figures are based on the total coal used during the month, including that used for starting and banking fires, etc. The total water evaporated is checked against the total coal fired. The gain in efficiency due to the economizers is figured from the rise in the feed-water temperature through the economizers.

OPERATING LABOR COSTS PER TON OF COAL FIRED, CENTS

	41 men	22 men

Total 63 men

The boiler equipment consists of fourteen 300-hp. B. & W. boilers and six 400-hp. Edgar water-tube boilers. All boilers are equipped with Green economizers. One foot of economizer surface is provided for each two feet of boiler-heating surface served. All boilers are hand-fired and are equipped with Grieve grates and forced draft produced by a 125-hp. Green fan. The grates have about 8 per cent. air space. The ratio of grate surface to heating surface is 1 to 30. The ash hoppers are of cast iron lined with brick. Ashes are dumped into small cars of one-ton capacity each and are pulled up an incline by a steel cable and dumped into the railroad cars. Coal is handled and delivered to the bunkers by the Mead-Morrison system of cable cars.

Foreign-Built Vessels Admitted to American Registry—Under the act of Congress of Aug. 18, 1914, the foreign-built vessels admitted to American registry up to Feb. 19, 1915, have numbered 129, with 468,509 gross tons, or 303,284 net tons.

The Horsepower Constant is the number of horsepower per pound of mean effective pressure developed by an engine when running at its normal speed. It will be different for different speeds. Knowing the constant, one need only multiply the mean effective pressure (obtained from an indicator diagram) by this constant to know what indicated horsepower the engine is developing. Evidently, by the definition, the horsepower constant is all of the "PLAN" formula except the P.

Testing Small Centrifugal Pumps

By M. R. Blish

SYNOPSIS—Simple directions for making capacity tests of centrifugal pumps.

Although the methods and apparatus to be described are particularly adapted to testing small pumps, they apply with limitations to pumps of large capacity.

Apparatus

The apparatus for measuring the quantity of water delivered by the pump is most important. Where available, weighing tanks will prove most satisfactory for this purpose. Usually, they are arranged side by side, and in between the two a hopper is so placed that the water may be turned from one into the other without interrupting the flow.

Each weighing tank should be of such capacity that it will accommodate as much water as will flow in at least two minutes, and have a quick-acting delivery valve of such size that the water can be let out of the tank in one-half the time required to fill it. This will then give time for closing the valve for the reception of the next charge of water and for caring for any unseen delays that may occur while the other tank is being filled. A satisfactory valve for these tanks is a large gate valve in the floor of the tank, operated by a steam or air cylinder on the outside and held to its seat by the weight of the water. This form of valve may be easily opened or closed and the controlling valves placed within easy reach of the man operating the scales. The scale beams should be so arranged that they may be read from the same platform.

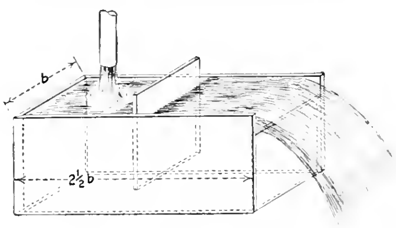

Fig. 1. Partition to Obtain Uniform Flow

Another form of apparatus used to measure the quantity of water is a single large tank fitted with a weir, as in Fig. 1. The capacity of the tank should equal about five minutes' discharge of the pump. It can be made of steel (or wood lined with sheet zinc) and the plan dimensions such that the length is two-and-a-half times the breadth. The weir is placed in the end, not along the side of the tank, and should extend the width of the tank to avoid end contractions* of the water passing over the weir. A partition running parallel with the weir and extending from the top to within 2 ft. of the bottom divides the tank into two compartments. The water should come into the tank on the side of the partition opposite the weir. This arrangement will prevent a serious "velocity of approach" of the water to the weir. If the tank is of wood, it will be necessary to provide a strip of ¼-in. or $\frac{3}{16}$-in. iron for the weir, which may be either set into the wood or screwed to the inside of the tank. The sharper the edge of the weir, the better the results that will be obtained.

*When water escapes to the atmosphere or from one vessel to another through a "drowned" (submerged) orifice, or whether it flows from an open channel or nozzle, the stream will get smaller—contract at a certain distance from the orifice; hence the term contraction.

Still another form of apparatus for measuring the delivery of the pump consists of a large tank of rectangular plan, from one end of which a wooden trough extends, as in Fig. 2. This trough is inclined at an angle not to exceed ten degrees from the horizontal, and is of such width and depth that it will carry away the overflow from the tank when inclined at the angle selected. The pitch of the trough must not be too great, for this would mean a high velocity through it, thus bringing about a large friction loss. However, it must be inclined sufficiently to carry away the pump delivery. If lined with zinc or copper sheeting, the sides of the trough will reduce the friction loss. Provision must be made for accurately measuring the depth of water in the channel or trough and a current meter for obtaining the velocity of the water in the channel is also necessary.

The water must start from the tank into the channel with almost no initial velocity; more accurate measurements are then possible. To provide for this condition a partition must be inserted across the short dimension of the tank, as described in the tank with the weir.

The most common type of drive for the small centrifugal pump is the electric motor. The connection to the pump is often by a belt long enough to allow 10 to 12 ft. from the motor-shaft center to the pump-shaft center.

The power input to the motor is measured by an ammeter and a voltmeter if using a direct-current motor, and by a wattmeter if using alternating current. In the direct-current system the voltmeter is shunted across the line at some convenient point near the motor and the ammeter is placed in series with the armature circuit. In the alternating-current system the wattmeter is placed in

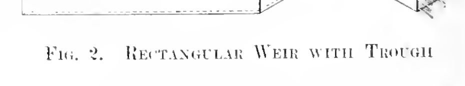

Fig. 2. Rectangular Weir with Trough

series with one of the windings. The reading must be multiplied by three if a three-phase circuit is used. In either system provision should be made to vary the speed of the motor.

If it is possible to substitute a direct-connected motor for the belt drive, better results will be obtained in that it will be possible to measure the power input to the pump more accurately. A convenient method is to insert between the motor and pump couplings a direct-reading dynamometer which records the horsepower upon a graduated scale. However, this is a rather expensive apparatus and is necessary only when great accuracy is required.

A strainer and check valve should always be placed on the lower end of the suction pipe, Fig. 3. The strainer will prevent any large pieces of foreign matter being drawn into the pump. The valve will prevent the suction

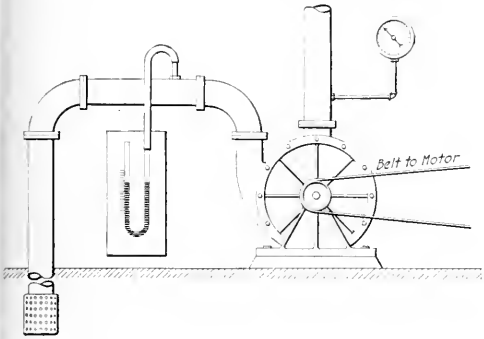

FIG. 3. U-TUBE FOR MEASURING SUCTION HEAD

head being lost, if the pump is shut down for a short time, and will also assist in starting the pump.

To measure the suction head a mercury column, consisting of a glass U-tube a little more than half full of mercury, is attached to the suction pipe as nearly as possible to the pump. A vacuum gage could be used for this purpose and attached to the same place on the suction pipe. A thermometer is needed in the well to determine the water temperature.

To measure the delivery head a pressure gage is attached to the delivery pipe near the pump. A throttle valve placed in the delivery pipe near its discharge end enables one to vary the pressure against which the pump

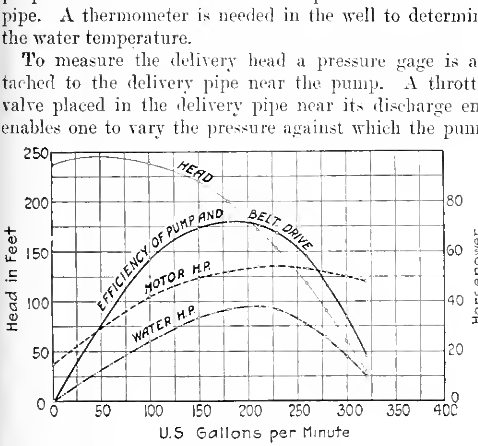

FIG. 4. HORSEPOWER-QUANTITY CURVES

works. Two speed counters are usually provided, one for taking the motor and the other for taking the pump revolutions.

An opening in the pump casing is necessary to provide for starting. This hole is fitted with a plug and should be from 1 to 1½ in. in diameter.

Having provided suitable apparatus, there are two tests that may be run—the constant speed and the variable speed.

CONSTANT-SPEED TEST

This is the most valuable test because a centrifugal pump is designed to run at a constant speed. Having filled the pump with water through the hole in the casing, open the throttle valve in the delivery pipe and start the motor. When the pump is running at its normal speed see that the throttle valve is wide open so that only the static head to the point of delivery and the friction head in the pipe exist. This will be the condition of largest capacity, smallest head.

The following readings are taken and repeated every two or three minutes for the same conditions until five are recorded, and for each new set of conditions: Voltage, amperage (if direct current is used), wattage (if alternating current is used), suction pressure, delivery pressure, speed of motor, speed of pump, and the necessary readings for determining the quantity pumped. One reading of the thermometer will usually be sufficient during the test, as the water temperature will vary slightly, if any.

The delivery throttle valve may now be closed to some extent to shut off the flow and correspondingly increase the pressure. Readings are taken at every 5-lb. increase

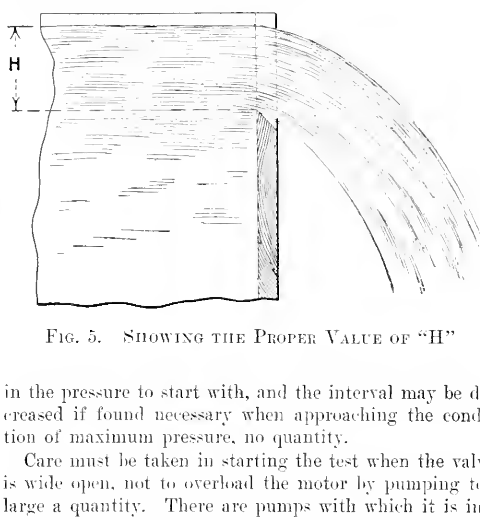

FIG. 5. SHOWING THE PROPER VALUE OF "H"

in the pressure to start with, and the interval may be decreased if found necessary when approaching the condition of maximum pressure, no quantity.

Care must be taken in starting the test when the valve is wide open, not to overload the motor by pumping too large a quantity. There are pumps with which it is impossible to overload the motor, as the motor horsepower—quantity curve—is of a form shown in Fig. 4. If a constant-speed motor is not being used, it will be necessary to slow down the motor as the quantity decreases, as the tendency will be to speed up the pump beyond its rating.

If the well from which the water is pumped is not of sufficient capacity, the level will fluctuate somewhat, provided the weighing-tank method is used. This will be noted only if the water pumped is let back into the well after being weighed.

Before finishing the test the height of the center of the pressure gage above the water level and also the height of the point of attachment of the mercury gage above this level should be recorded.

The following calculations will be necessary to convert the readings taken into terms for plotting the curves: Obtain from a table of the properties of water at different temperatures the weight of a cubic foot of water at the temperature recorded. With this figure the number of cubic feet pumped per second may be obtained from the pounds per second, if the weighing-tank method is used.

Number of Readings	Motor			Pump			Weighing Tank				Discharge Speed, Ft. per Sec.	Pressure Head, Ft.	Difference in Elevation of Gages, Ft.	Suction Head, Feet	Speed Head, Feet	Total Head, Feet	Efficiency of Motor	Horsepower of Motor
	Current Input	Voltage	R.p.M	Discharge Pressure	Suction Pressure in Hg	R.p.M.	Time, Seconds	Weight of Water, Lb.	Pounds per Second	Cubic Feet per Second								

Performance at N R.p.M.							Remarks:
Number of Readings	Total Head, Feet	Discharge		Horsepower of Motor	Water Horsepower	Water Hp.	
		Cubic Feet per Second	U. S. Gallons per Sec.			Motor Horsepower	

Fig. 6. Form for Recording Centrifugal-Pump Test Data

By the weir method of measurement the quantity may be calculated directly by the use of Francis' formula:

$$Q = 3.33\, b H^{\frac{3}{2}}$$

in which

Q = Cubic feet per second;
b = Width of weir in feet;
H = Height of water level above the weir.

Care should be taken that it is measured far enough back from the weir so that the true height is obtained, as in Fig. 5. An accurate method of obtaining height H is to measure the level of the water by means of a hook gage suspended over the center of the tank.

With the channel method of measurement the water cross-section must be determined in some manner, and this section in square feet multiplied by the velocity of the water in feet per second will give the flow or discharge in cubic feet per second.

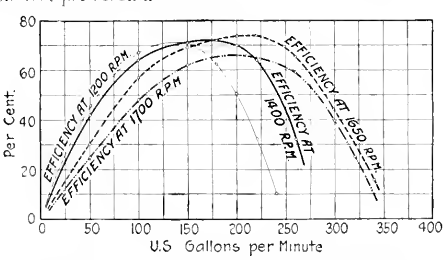

Fig. 7. Results of Speed Test on 12,000-Gal.-per-Hour Turbine Pump

The pressure head P in feet is obtained from the gage pressure in pounds per square inch by multiplying the same by the factor 2.31. The suction head in feet is obtained from the suction pressure in inches of mercury by multiplication by the ratio 17 : 15.

The total head against which the pumps are working is obtained by addition of the suction head, pressure head and the vertical distance in feet between the center of the pressure gage and the point of attachment of the mercury gage. The friction head in the delivery pipe, the suction pipe, the foot valve and strainer are accounted for by readings of the pressure and suction gages.

The horsepower output of the motor, in the case of direct current, is obtained from the product of the amperage, voltage and motor efficiency, divided by the factor 746. The motor efficiency must either have been determined beforehand by separate test or obtained from the motor manufacturers. In the case of alternating current the motor output is the watts input times the motor efficiency.

The belt loss is subtracted from the motor output to find the true power input to the pump. This loss will depend upon the condition of the belt texture, the tension put upon the belt and the amount of slip. The variation of the ratio of the motor and the pump speeds gives some indication of the loss of power in the belt.

The water-horsepower exerted by the pump is obtained as follows:

$$\textit{Water-horsepower} = \frac{62.5 \times QH}{550} = \frac{QH}{8.8}$$

where

Q = Cubic feet water per second;
H = Total head on the pump in feet.

The efficiency of the pump is then the water-horsepower divided by the horsepower input to the pump.

Fig. 6 is a form showing the readings necessary and the factors to be calculated. Fig. 7 shows the curves obtained from an actual constant-speed test on a small turbine pump of 12,000 gal. per hr. capacity. Without doubt, it will be impossible to keep the pump at exactly a constant speed, and to plot the curves for constant speed it will be necessary to correct the readings of quantity, head and horsepower by means of the following formula:

$$Q' = Q \times \frac{N'}{N}$$

$$H' = H \times \left(\frac{N'}{N}\right)^2$$

$$HP' = HP \times \left(\frac{N'}{N}\right)^3$$

where Q', H' and HP' are the quantity, head and horsepower at speed N', which is the constant speed at which the pump should run, and Q, H and HP are at the speed N, the actual speed recorded while the readings are being taken.

Variable-Speed Test

Such a test may be run when it is the desire to know at what speed the pump will give the best efficiency; in other words, for what speed the pump was designed.

The apparatus used in the former test can be used in this test. Commence at a speed somewhat below that which has been judged to be the normal speed of the pump, and with the valve wide open take readings of the power input to the motor, speed of motor, speed of pump, pressure gage, suction gage and quantity pumped. Take only one set of readings, and then increase the delivery pressure and take another set. Continue to increase the pressure, taking readings at every change until the throttle valve is entirely closed. Then open the valve, speed up the pump 50 or 100 revolutions and take the same readings as before with the same increases in pressure.

The calculations may be made by the same formula and rules as formerly, but in plotting the curves it will be necessary to plot only the efficiency curves to ascertain at what speed the pump should be run to work most economically. A set of such efficiency curves taken from a test is shown in Fig. 7. The normal speed of the pump was 1650 r.p.m., at which speed, as shown, the best efficiency was obtained.

One Thing to Remember is that if a man does not know, he cannot be cussed into knowing, especially if you have only a short time in which to give him the treatment. A better plan is to wait an opportunity, and not let it pass when it comes, to talk with the man and do your best to give him help by way of instruction and advice.—D. R. MacBain, before the Traveling Engineers' Association.

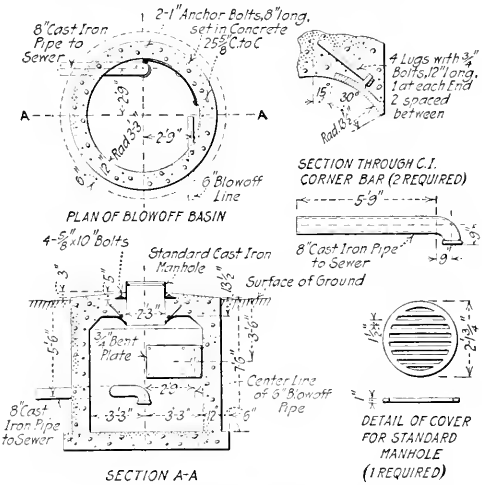
Three-Metal Bronzes—A description of the ternary metals: Copper and tin with lead, zinc, phosphorus, manganese and aluminum. Lead imparts plasticity to bronze, and diminishes hardness and temperature changes ("imparts a lower mutual freezing point"). Microscopic examination shows that the lead is distributed throughout the mass. Segregation, to which bronzes rich in lead are liable, is prevented by the addition of 1 per cent. nickel, sulphur added as galena, phosphorus, or arsenic. A small addition of zinc does not materially alter the structure of bronzes, while ductility and tensile strength are slightly increased. Bronzes containing zinc are more easily forged and cold-rolled and are less readily corroded by sea water. Phosphorus may exist entirely as solid solution (up to 1 per cent.) or as Cu_3P; it greatly increases the hardness and resistance to wear, while impairing the tensile strength, elasticity and elongation. The maximum in commercial bronzes is about 0.8 per cent. P, with about 8 per cent. Sn. The valuable properties of manganese bronze are its strength and noncorrodibility; commercial products often contain more aluminum than manganese. True aluminum bronze seldom contains more than 11 per cent. Al; it is useful in casting, though it shrinks considerably. The addition of tin increases its ductility.—"Journal of the Franklin Institute."

Concrete Blowoff Basin

By A. D. Williams

A blowoff basin or tank is one of those details of a power plant that often cause trouble. Restrictions are frequently imposed regarding the discharge of steam into sewers, and much steam is released where the blowoff pressure becomes equal to that of the atmosphere. The basin, Fig. 1, was designed for the East Fifty-third St. station of the Cleveland municipal electric-light plant and presents desirable features. It is constructed of plain 1 : 2 : 4 concrete, as it is buried in the ground. For use above ground the design must be modified and strongly reinforced concrete or steel plate used, the latter preferably.

This basin is designed to separate the steam from the hot water by whirlpool action, the blowoff pipe entering the basin tangentially, as shown in the plan section. The



Section and Details of Concrete Blowoff Tank

concrete is protected from the action of the entering stream by a ¾-in. bent plate. In action the water has a tendency to spread out on the walls of the basin, leaving the center open for the escape of the steam released. This action of the water explains the location of the cast-iron waste pipe close to the wall, where it will commence to take water to the sewer as soon as the whirling water covers it. The lip around the manhole and the curved top are designed to prevent the whirling sheet of water from spreading on the top and trying to climb out of the manhole. The curve and lip work upon the same principle as similar parts of a steam separator, and throw the water down into the tank.

To simplify the form work required in constructing the tank, the top may be chamfered as indicated by the dotted lines, at one side of section AA. In building a basin on this design the internal form is best constructed of sheet steel, galvanized or plain, held in place by a wooden skeleton built so that a man can work inside the form to place the concrete bottom of the tank. In this way any seam between the walls and the bottom can be avoided.

The basin is designed to receive the blowoff from six boilers with 10,134 sq.ft. of heating surface each. If desired, the inside diameter of the basin may be increased, but it would be inadvisable to reduce the diameter, as the blowoff water enters it at a high velocity.

Razing a Brick Chimney

An extremely hazardous method used by a wrecking company to raze a brick chimney is shown in the illustration. This chimney was 6x6 ft. inside and 125 ft. high, and belonged to an abandoned power plant. Fig. 1 shows the method used. The bricks were dug out one on side and three jack-screws placed in the opening; then those on the opposite side and also back to the center of the chimney were knocked out. The idea was to tip the stack over with the jack-screws, but too much of the brickwork had been dug out and the remaining bricks failed. The result was successive failures which let the stack down almost vertically, as shown in Fig. 2. The fountain-like upheaval of bricks in Fig. 3 would make it appear that the base was blown out from under the stack, but such was not the case.

Fig. 1. Method Employed

Fig. 2. Beginning to Collapse

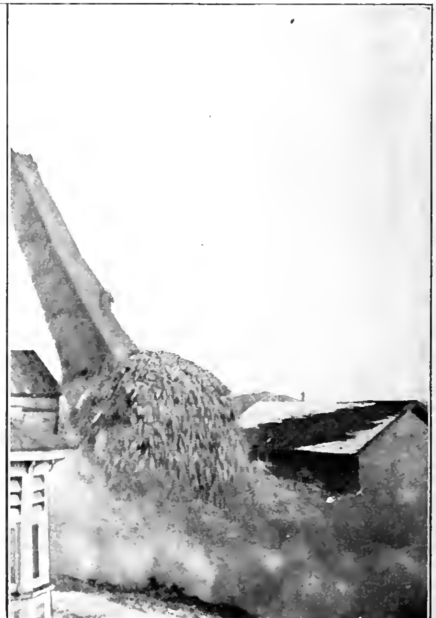


Fig. 3. Resembling an Explosion

Fortunately, no one was hurt by the premature falling of the chimney. There were two men on the scaffold when it started to collapse, but they jumped down and escaped from the danger zone. The top of the stack fell only forty feet from the base. This method is not to be favored, even when it is desired that the chimney fall within a small radius.

The whole circumstance furnishes a good illustration of the rule-of-thumb method used by many contractors, instead of making a few simple calculations. It is likely that this same process had been successfully used before on a small stack, therefore they supposed it would do for all others, but a method which proved entirely satisfactory in handling a small stack might not be at all successful for a large, heavy one. Many serious accidents have occurred in trying to adapt methods suitable enough in one case, but entirely inadequate in another. It is to be hoped that they will not experiment again.

Ocean Volume to Land Area—One per cent. of the contents of the oceans would cover all the land areas of the globe to a depth of 290 ft.—U. S. Geological Survey.

Two Causes for a Belt Not Running True upon properly built pulleys mounted upon correctly aligned shafting: The belt may not have been made straight in the first place, or the ends may not have been joined squarely. Otherwise there may have been a lack of uniformity in the texture of the hides from which the belt was made; belly leather toward one edge and flank leather toward the other, and the two stretching unequally.

Stop Acts When Rod Breaks

The value of a dependable safety stop on a steam engine was demonstrated a few days ago, when the piston rod of a 23x36-in. Wright engine parted. The engine was operating in the basement of the J. T. Perkins Co.'s factory, Kent Ave. and Hooper St., Brooklyn, N. Y.

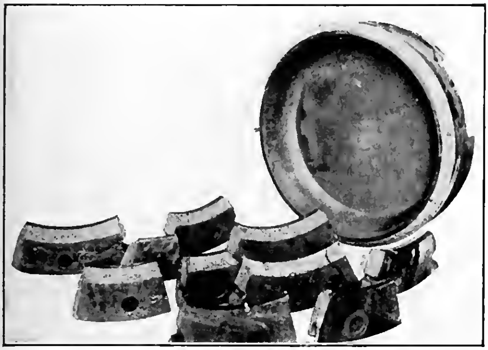

FIG. 1. CYLINDER HEAD AND PIECES OF THE FLANGE

The rod parted at the keyway in the crosshead, resulting in the knocking out of a cylinder head, breaking the flanged part into small pieces clean around the body of the head, as shown in Fig. 1.

No one was injured, and the property damage was slight. Fortunately, eight bales of camels' hair, weighing about 400 lb. each, were piled in line with the cylinder, and these received the head and piston as they were driven from the cylinder, and undoubtedly saved the lives of two operators who were working on a machine in line with the cylinder.

The engine was running at a speed of 90 r.p.m. with a boiler pressure of 125 lb. The piston rod shows on the face of the fracture that the break for the most part was old, the lighter surface at the right side of the right

FIG. 2. THE LIGHT SHADING INDICATES THE NEW FRACTURE OF THE PISTON ROD

view of Fig. 2 indicating the new fracture in the metal. The break was evidently caused by ordinary working strains, the metal appearing to be of good grade.

When the rod parted, the Wright safety stop, which is designed to operate with both high and low speeds, threw the catch blocks on the steam valves out of action, allowing the valves to remain closed and so preventing steam from entering the cylinder.

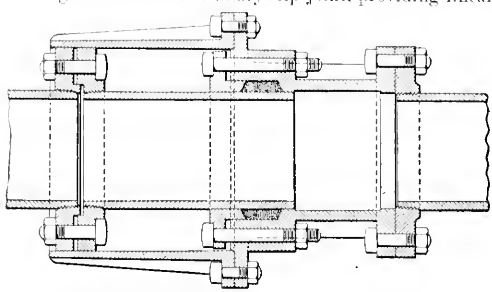
Because of the prompt action of the engine stop and the non-escape of live steam at boiler pressure into the factory, damage to the goods was prevented and the possibility of a panic and loss of life was avoided.

Ross Expansion Joint

The illustration herewith shows an expansion joint, the primary feature of which is that of guiding the pipe line so that it will be in alignment with that part of the piping which is held rigid, and thus prevent the ordinary wear and tear on packing experienced in slip-tube expansion joints. This joint automatically permits a lengthening or shortening of the pipe line to which it is applied up to a maximum of a 4-in. change of length without creating strains or distortions.

Referring to the illustration, the flanges, which are at each end of the joints, are of a size to permit of joining with the pipe-line flange on the larger end, the flange on the smaller end being bolted to a standard fitting which is anchored, or to the pipe line that is properly guided and anchored.

If it were not for the outer sleeve this device would be nothing more than an ordinary slip-joint, providing lineal



SECTION THROUGH ROSS EXPANSION JOINT

play for expansion and contraction. The slip-joint section, however, is of improved construction, as the packing space is ample and the slip tube is made of bronze, so that it will not rust in the packing.

The particular feature of this joint is the outside sleeve, which introduces an effective and rigid guide. This sleeve is cylindrical, machined on the inside and bolted to the body. The companion flanges, which travel in this guide, according to the amount of contraction or expansion of the pipe line, are machined on their peripheries to secure alignment, and wear of the packing of the slip joint and sagging of the line at the expansion joint are avoided. This prevents the tendency to leak and the joint will remain tight for long periods without adjustment of the packing.

This type of joint is made for a pressure of 200 lb. per sq.in., in all sizes up to and including 24 in. Each size will accommodate 4 in. of travel for expansion and contraction, and if a longer traverse is desired, special joints can be obtained.

This expansion joint is manufactured by the Alberger Heater Co., Chicago and Granger St., Buffalo, N. Y.

Idle Boilers should be thoroughly washed out and dried. Trays with unslaked lime should be placed inside and the boilers should be closed air tight. If the boiler is to stand ready for immediate use it should be filled with water to which burnt lime has been added, but unless the boiler is one of a battery and is kept warm, it is likely to condense atmospheric moisture from outside and corrode if filled with water.—Exchange.

Forty Years' Advance in Internal-Combustion Engines

Reference to the opposite page affords striking contrast between the internal-combustion engine of forty years ago and the present highly developed product in its special adaptations to various kinds of service. The two upper views represent the machines exhibited at the Centennial Exposition at Philadelphia in 1876, and among the rest are some that will be seen at the Panama-Pacific Exposition.

While the first attempts to produce an internal-combustion engine date back to the latter part of the eighteenth century, when gunpowder was used as the energy-producing medium, little was accomplished until 1860, when Lenoir placed on the market the first practical engine. This was horizontal, double-acting, and the cycle was patterned somewhat after the steam engine, the charge being drawn in during the first half of the stroke, ignited, and expanded during the latter half, then expelled on the return stroke. Owing to its extravagant use of gas, however, the Lenoir engine did not meet with much success.

The next engine to attract popular attention was the Otto and Langen, brought out in 1866. This was entirely different from the Lenoir and embodied the atmospheric free-piston principle. It consisted essentially of a long cylinder open at the top and containing a piston, the rod of which carried a rack. By means of a special clutch and pinion this rack was made to engage with the flywheel shaft on only part of the down stroke and that part of the up stroke during which the charge was being drawn into the cylinder. The operation was essentially as follows:

The mixture was drawn in for about one-sixth of the stroke and was then ignited by a naked flame, whereupon the rack disengaged from the pinion and the piston was projected upward: the latter part of the stroke, after the gases had expanded and cooled, being due to the inertia of the piston. On the downward stroke the rack engaged the pinion and the weight of the piston, aided by the atmospheric pressure on its upper side, performed useful work and stored energy into the flywheel. As the pressure of the gases below the piston increased above the atmosphere, they were slowly expelled from the cylinder and the speed of the piston decreased. At this point the pinion disengaged, only to engage again at the beginning of the up stroke for drawing in the next charge. The admission of the charge, ignition and exhaust were controlled by eccentrics and there were about 20 strokes per minute.

The engine was essentially limited in output and a great drawback was its irregular and extremely noisy operation. This led Otto to bring out, in 1876, a new engine operated on the four-stroke cycle (Beau de Rochas cycle) which was destined to revolutionize the gas-engine industry. It was the first gas engine to use compression and in principle formed the basis of the modern internal-combustion engine.

Just previous to this, however, in 1873, a Philadelphian by the name of Brayton brought out an oil engine in which the oil and air were mixed under considerable pressure outside the engine and passed into the cylinder through a fine-mesh wire screen, burning just beyond it, the object of the screen being to prevent backfiring into the port. The mixture was admitted for practically one-third the stroke and burned at a uniform pressure. The inlet valve then closed and the heated products of combustion forced the piston to the end of the stroke. The exhaust port opened just before the end of the stroke and on the return stroke compression was carried to the pressure in the air and fuel tanks.

Engines of this type were built in sizes of 1 to 10 hp., and were extensively used, the chief troubles being backfiring and the extinguishing of the pilot flame. Also, the addition of compressors for the oil and air made the installation somewhat cumbersome.

Without attempting to enumerate or describe the intermediate steps in the development of the gas and the oil engine, associated with the work of Dugald Clerk, Dr. Diesel and others, we will pass to a consideration of some of the present-day types. The familiarity of the reader with the principles of operation involved and their general construction makes a description unnecessary; hence, space will be devoted only to certain comparative features, some of which are included in the following tabulation:

COMPARATIVE FEATURES OF DIFFERENT TYPES

Type	Cylinders	Horsepower	Weight	Weight per Horsepower	Fuel Consumption
